ordered in terms of decreasing element and mass numbers. In this way nuclei are shifted towards iron. In the already large network of equations (18) to be solved the possible reactions of the n, p and α background particles as well as the weak interactions ((e^-,ν), (e^+,ν)) are neglected owing to assumed particle reaction and weak decay time scales much longer than the p-process duration. This makes the results independent of the composition and density of the p-process site. The results are only dependent on the abundance distribution of the input seed nuclei and the photon temperature. During the synthesis abundance is accumulating especially at the nuclei, where the photodisintegration flow is deflected to lower-Z elements by the (γ, p) or (γ,α) reactions because of a long disintegration time (waiting points). When the disintegration flow crosses the closed neutron shells at 50 and 82, the disintegration time scales become especially large because of the particularly strong binding energies. The abundances are then built up directly at the closed shell nuclei ^{92}Mo and ^{144}Sm. The abundances of the primary unstable p-nuclei eventually β decay after freeze-out to stable p-nuclei. The concept of the photodisintegration p-process was elaborated by Woosley and Howard (1978).

No single temperature exposure can produce all p-nuclei. However, with a distribution of exposures an approximate representation of the solar abundances is obtained. This is true also for the extended network including the n, p and α background reactions (figure 6) (Rayet *et al* 1990). Only the (n, γ) reactions have some influence on the yield of individual p-nuclei. In particular, it appears to be impossible to reproduce the solar abundances of the isotopes ^{92,94}Mo and ^{96,98}Ru by the photodisintegration p-process because they are too abundant and there is insufficient s- and r-process seed at $A > 96$. In the search for possible solutions of this problem, a significantly higher s-process seed abundance is suggested (Costa *et al* 2000), which would result from a higher rate of the ^{22}Ne(α,n)^{25}Mg neutron-producing reaction varied within the quoted uncertainty. In another suggestion, a different synthesis process, the rp-process on accreting neutron stars, is considered (Schatz *et al* 2001).

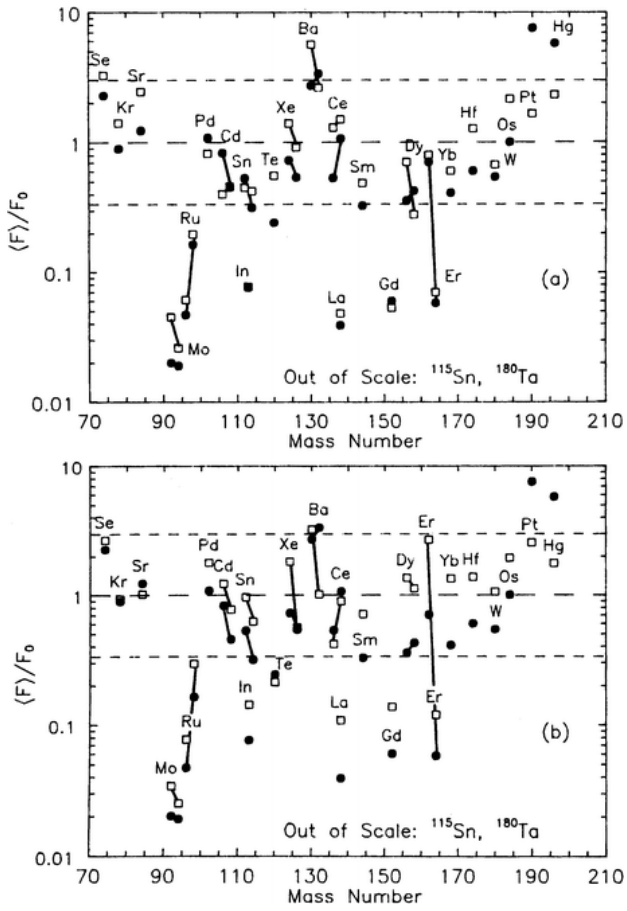

Figure 6. Relative overproduction factors for p-process nuclei. Lines connect isotopes of the same element. (*a*) Predictions for a uniform weighting of the initial temperatures: filled and open symbols correspond to different time scales and mean overproduction factors (t_{HYD}(s), F_0) = (0.446,200) and (1, 145), respectively. (*b*) Comparison of predictions for t_{HYD} = 0.446 s for uniform weighting of the initial temperatures (filled symbols) and for a best fit mix of temperatures (open symbols and F_0 = 114). (From Rayet *et al* 1990.)

Experimental and observational constraints, stellar models

The correlation found between neutron binding energy (hence photoneutron disintegration rate) and solar abundance of the p-process nuclei represents the first experimental evidence pointing to nuclear p-processing in terms of a photodisintegration process (Macklin 1970). This correlation is verified more properly between the total photodisintegration rate ($\lambda^{\gamma n} + \lambda^{\gamma p} + \lambda^{\gamma \alpha}$) of the synthesized p-nuclei and solar p-abundances at that mass number.

An important constraint on the p-process is the presence of live ^{146}Sm in the early solar system detected in meteorites and the inferred production ratio of ^{146}Sm/^{144}Sm. It appears to be a challenge to reproduce this ratio with the photodisintegration p-process.

From the success of the parametrized photodisintegration models it was astrophysically plausible to place p-processing in the oxygen/neon shell of a highly evolved massive star, exploding as a type II supernova. Such calculations were performed for the SUPERNOVA 1987A (Prantzos *et al* 1990). The supernova shock that heated up this shell provided temperature and density profiles to initiate the photodisintegration reactions on the preexisting heavy isotope s-process seed from core He burning. The results are essentially similar to the parametrized model calculations. A detailed review of the origin of the p-process nuclei was given by Lambert (1992).

Epilogue

As the understanding of nuclear processing in stars relies mainly on the analysis of the solar system heavy element composition it has to be stressed that the stellar evolution and composition of stars including stellar mixing processes and the chemical evolution of the galaxy have to play a large role in the calculations. For example the solar r-process abundances are assumed to result from contributions of ~10^8 supernova explosions.

Nuclear Properties

Nuclei consist of NEUTRONS n and PROTONS p, which belong to the family of BARYONS (a combination of three quarks (q_1, q_2, q_3)). These two combinations with the lowest masses contain only up and down QUARKS u and d. We have n = (udd) and p = (uud) with electric charge 0 and +1 and masses of 939.570 MeV/c^2 and 938.265 MeV/c^2. They are fermions, i.e. particles with intrinsic half-integer spin 1/2. The binding energy of a nucleus of mass $M(Z, N)$ with Z protons and N neutrons is given by the corresponding mass difference: $B(Z, N) = Zm_{\rm p} + Nm_{\rm n} - M(Z, N)$. The mass excess of a nucleus with a total number of nucleons $A = Z + N$ is defined with the aid of the atomic mass unit $m_{\rm u} = M(^{12}C)/12$, i.e. the average mass of nucleons inside the carbon 12 nucleus, via $M_{\rm ex}(Z, N) = M(Z, N) - Am_{\rm u}$. Here we use the notation $^A Z$ with mass number A, where Z is usually replaced by the element symbol representing that charge or proton number.

The binding energy per nucleon B/A describes how tightly bound a nucleus is. Experimental binding energies range from 0 for neutrons and protons over about 7 MeV per nucleon for ^{4}He, reaching a maximum of 8.7 MeV per nucleon for Fe and then declining to about 7.5 MeV per nucleon towards the heaviest nuclei such as Th and U. These variations of nuclear binding are responsible for the energy generation in stars during a sequence of burning stages from hydrogen burning to silicon burning, transforming in total H to Fe-group nuclei. Variations in nuclear binding are also reflected in the abundances of nuclei produced in astrophysical environments.

The, nevertheless, relatively constant binding per nucleon is related to an approximately constant density ρ_0 in the central part of the nucleus with a typically small surface diffuseness a of 0.55 fm = 5.5×10^{-14} cm. This permits one to express the nuclear mass M ($\approx Am_{\rm u}$) in terms of the mass of a constant-density sphere and explains the A dependence of the nuclear radius $R = (3/4\pi)^{1/3}(m_{\rm u}/\rho_0)^{1/3}A^{1/3} = r_0 A^{1/3}$, where $r_0 = 1.14$ fm is a constant for all nuclei if ρ_0 ($\approx$0.16 nucleons fm^{-3} = 2.7×10^{14} g cm^{-3}) does not depend on A. Such a constant density can be explained by a nucleon–nucleon interaction which drops off quickly with increasing distance and has a repulsive term for short distances. The strong repulsion ensures that the density cannot increase to infinite values, whilst the fast drop-off for large distances causes vanishing interaction with distant neighbors. Thus, only immediate neighbors are important for the interaction.

Interactions are generally explained by the exchange of (virtual) particles. The strong interaction between nucleons is due to the exchange of MESONS, particles consisting of a quark–antiquark pair ($q_1\bar{q}_2$). The lowest mass mesons—consisting of a combinations of up (u) and down (d) quarks—are π-mesons with an approximate mass of 140 MeV. If we assume that these mesons move with the speed of light c, they can at most move a distance $r_{\rm ex} = c\,\Delta t \approx 1.4$ fm when Δt is the time for which the violation of energy conservation (140 MeV) is permitted to create a particle–antiparticle pair according to the UNCERTAINTY PRINCIPLE $\Delta E\ \Delta t = \hbar$. Thus, as this concerns the lightest mesons with the largest $r_{\rm ex}$, the nuclear force has to drop off very quickly beyond that distance.

The above description is related to the dominant bulk feature of nuclear matter (either infinite in neutron stars or finite in nuclei), but it needs a substantial refinement responsible for nuclear shapes and shell structure, and the resulting effects on decay probabilities and nuclear reactions. This will be the focus of the following sections.

Mass models

The bulk part of nuclear binding is equivalent to replacing the (microscopic) many-body Schrödinger equation by independent particle models in an average potential and assuming for this average potential a simple square well potential of depth $v_0 \approx 40$ MeV. This leads to Fermi energies of degenerate nucleons (the highest populated state at temperature $T = 0$ K) of

$$E_{\rm F} = \frac{h^2}{2m}\left(\frac{3}{8\pi}\frac{N}{V}\right)^{2/3}.$$

As N/V, the nucleon density, is roughly equal for all nuclei, $E_{\rm F}$ is also a constant for all nuclei with $E_{\rm F} \approx 29$ MeV. The average energy $\bar{E}$ of a nucleon in a nucleus is $\bar{E}=\frac{3}{5}E_{\rm F}$. In order to unbind an ensemble of nucleons with average energy $\bar{E} = \frac{3}{5}E_{\rm F}$, a total energy of $N(v_0-\bar{E}) = N(v_0-\frac{3}{5}E_{\rm F})$ is needed. With v_0 and $E_{\rm F}$ being roughly constant for all nuclei, the total binding energy is just proportional to the number of nucleons. Thus, for a nucleus consisting out of A nucleons, the total binding is $B = A(v_0 - \bar{E})$. This is the dominant (volume) term of the binding energy $B_{\rm V} = a_{\rm v}A$.

This leading term has to be corrected for the errors introduced by the simplifying approximations. Nucleons which reside at the surface have fewer neighbors and are therefore less bound. This reduction in binding is proportional to the surface area of the nucleus $4\pi R^2 \propto A^{2/3}$, i.e. $B_{\rm S} = -a_{\rm s}A^{2/3}$. The electrostatic repulsion of protons is measured by the Coulomb self-energy (of a uniform charge distribution) $E_{\rm Coul} = \frac{3}{5}\,Q^2/R$ with $Q = Ze$ and $R = r_0 A^{1/3}$, leading to $B_{\rm C} = -a_{\rm c}Z^2A^{-1/3}$. The derivation of the bulk term $B_V = a_{\rm v}A$ relied on an equal density of neutrons N/V and protons Z/V. Correcting for $N \neq Z$ causes the symmetry energy correction $B_{\rm sym} = -a_{\rm sym}(N - Z)^2/A = -a_{\rm sym}(A - 2Z)^2/A$.

Neutrons and protons are both fermions with intrinsic spin 1/2. Pairs can couple to a total spin of 0 or 1. The 0 state corresponds to a lower energy level and contributes to the binding energy. The binding energies of nuclei fluctuate by approximately $B_{\rm pair} = \pm 12/A^{1/2}$ MeV around the mean defined by nuclei with an odd number of nucleons, with Z, N even-even nuclei being more and odd-odd nuclei being less bound. The total binding energy is the sum of all these terms with typical values of $a_{\rm V} = 16$ MeV, $a_{\rm S} = 18.5$ MeV, $a_{\rm C} = 0.72$ MeV and $a_{\rm sym} = 23.4$ MeV and we can express the nuclear mass via

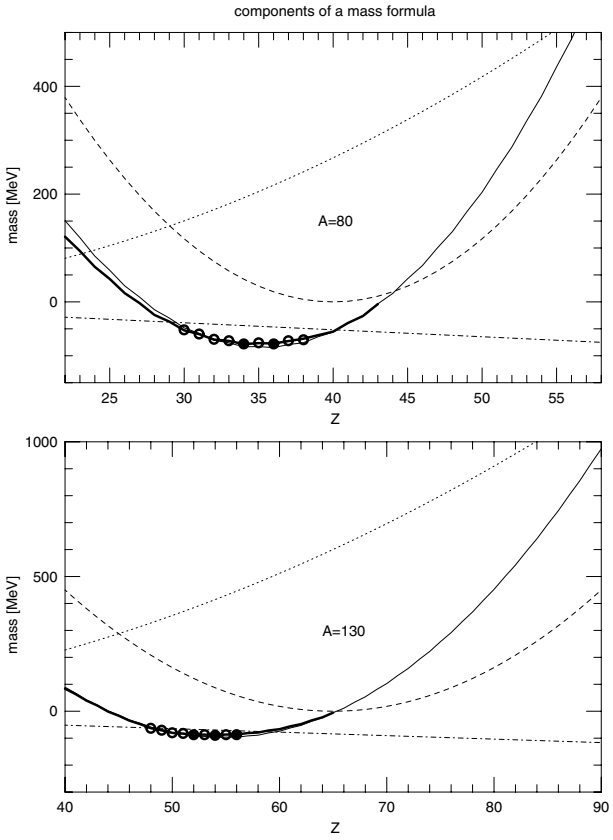

Figure 1. Several components in a liquid drop or Bethe–Weizsäcker mass formula: the dotted curves indicate the Coulomb term, the dashed curves the asymmetry term and the dash-dotted curves the Z-dependent term $Z(m_p - m_n)$. A is taken as a constant in either plot. The solid curves give the atomic mass excess. The thick solid curves result from a more elaborate modern mass model, the circles indicate experimental mass measurements, the solid circles stand for stable nuclei. The larger Coulomb term for heavier nuclei leads to a larger shift of the valley of stability from the location $Z = A/2$.

$M(Z, A) = Zm_{\rm p} + (A-Z)m_{\rm n} - B(Z, A)$, obtaining the well-known Bethe–Weizsäcker (or liquid drop) mass formula with pairing corrections (see figure 1).

In reality the single-particle levels of a nuclear potential are not as evenly distributed as for a Fermi gas in a cubic box, used for this derivation. For a realistic, spherically symmetric nuclear potential which also makes use of a 'spin–orbit' force proportional to $\vec{l}\vec{s}$, where l stands for the orbital angular momentum and s for the intrinsic spin of a nucleon, the levels are unevenly bunched in excitation energy and large spaces can be interpreted as shell closures. Mass formulas which include such shell structure add an empirical shell correction term $S(Z, A)$

$$M(Z, A) = Zm_{\rm p} + (A - Z)m_{\rm n} - a_V A + a_{\rm s}A^{2/3} + a_{\rm c}Z^2A^{-1/3} + a_{\rm sym}\frac{(A-2Z)^2}{A} + S(Z, A) - B_{\rm pair}(Z, A).$$

Shell closures (magic numbers at Z, $N = 2$, 8, 20, 28, 50, 82, 114 or 126) are very important for understanding nuclear properties. It is well known that 'magic' nuclei which are tightly bound are spherical in general, while nuclei in between closed shells try to maximize their binding via deformation, which e.g. rearranges the charge distribution and leads to smaller Coulomb repulsion. Nuclear mass models of the 'microscopic–macroscopic' type which describe the macroscopic part in terms of such a nuclear droplet and the shell corrections in a microscopic way, including also deformation effects, can quite accurately predict nuclear masses within less than 1 MeV and are at present mostly used in astrophysical applications dealing with unstable nuclei where masses are not known experimentally.

An accurate prediction of the shell corrections is essential. Figure 2 shows predicted shell corrections from the finite range droplet model (FRDM) for stable and unstable nuclei. Only unstable nuclei which do not decay by proton or neutron emission are considered. A fully microscopic many-body treatment is also possible by now within the 'shell model' for nuclei up to around Fe. Microscopic 'mean-field' theories allow the heaviest nuclei to be treated as well. The present uncertainties of the latter, due to uncertainties of nuclear forces, are still of the order of a few MeV. One of the major remaining open questions is whether shell closures (magic numbers) and the size of shell gaps change with the distance from the valley of stability.

Decay modes

A necessary condition for the decay of a nucleus is that the transition is energetically possible. This is the case when the total mass of the (final) end products of a decay or reaction is smaller than the sum of the original (initial) masses. In other words, the reaction Q value has to be positive:

$$Q = \sum_{\rm initial} M_i - \sum_{\rm final} M_i > 0.$$

The well known nuclear decay modes are α decay, $\beta^{\pm}$ decay, electron capture and fission.

(i) α decay	$(Z, A) \rightarrow (Z-2, A-4) + {}^4{\rm He}$
(ii) fission	$(Z, A) \rightarrow 2(\approx Z/2, \approx A/2)$
(iii) β^- decay	$(Z, A) \rightarrow (Z+1, A) + {\rm e}^- + \bar{\nu}_{\rm e}$
(iv) β^+ decay	$(Z, A) \rightarrow (Z-1, A) + {\rm e}^+ + \nu_{\rm e}$
(v) electron capture	$(Z, A) + {\rm e}^- \rightarrow (Z-1, A) + \nu_{\rm e}$.

Ground state fission is not fully symmetric in its end products, as indicated above. Larger energies are released if at least one of the fission products is a nucleus near a closed shell. At higher excitation energies the shell effects vanish and symmetric fission occurs. Figure 3 displays in grey scale predicted β^- decay half-lives, based on the FRDM mass model and its microscopic features of excited states in the daughter nucleus. Electron captures occur in atoms by capturing one of the electrons of the low-energy orbitals. For an ionized atom, i.e. a nucleus, electron capture can only occur as a result of continuum capture

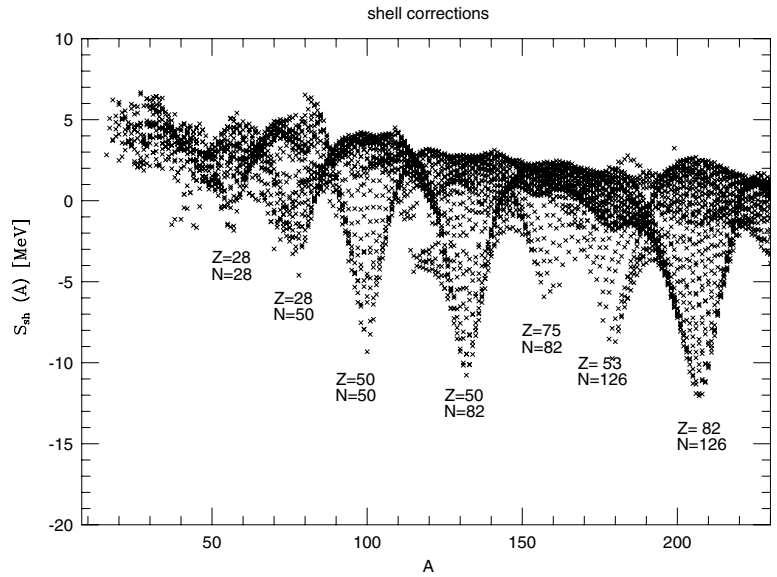

Figure 2. Shell corrections of a modern mass model. They are strongest at closed shells and can be larger than 10 MeV. The two subminima between $A = 150$ and 190 are the onset of stronger effects expected at the closed proton shells $Z = 82$ and 50, which can, however, not be realized between the proton and neutron drip-lines (see next section).

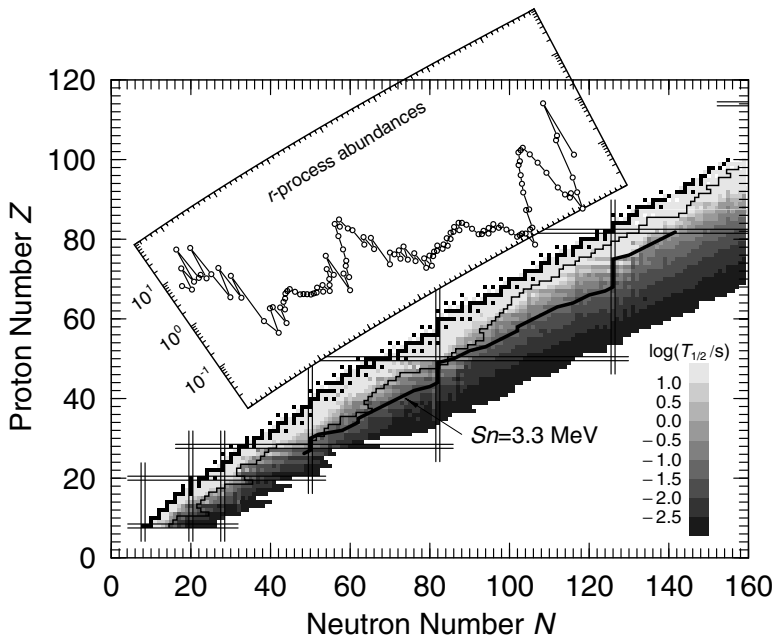

Figure 3. Some features of nuclei in the (N, Z) chart of isotopes. Stable nuclei are indicated by black filled squares. The thin solid curve represents the present limit of experimentally known nuclear masses. The magic numbers are shown as double bars. The thick solid curve is the contour line of constant $S_n = 3.3$ MeV. It relates nuclear properties to astrophysical abundances of the so-called r-process due to rapid neutron capture. It can be recognized that the abundances are proportional to the β^- decay half-lives [indicated by grey shades in $\log_{10}(\tau_{1/2})$] along S_n contour lines.

from a background electron gas. In case of a negative Q value the missing energy has to be provided by the kinetic energy of the ELECTRON.

These decay modes are only of interest between two boundaries in the nuclear chart related to the onset of (much faster) particle emission, i.e. decay of nuclei via neutron and proton emission $(Z, A) \rightarrow (Z, A-1) + \mathrm{n}$ or $(Z, A) \rightarrow (Z-1, A-1) + \mathrm{p}$. The Q values of these decays

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

are related to the neutron and proton separation energies via $Q_n = -S_n$ and $Q_p = -S_p$:

$$S_n(Z, A) = M(Z, A-1) + m_n - M(Z, A)$$

$$S_p(Z, A) = M(Z-1, A-1) + m_p - M(Z, A).$$

Nuclei with positive S_n or S_p are stable against neutron or proton emission. The connecting lines of S_p or $S_n = 0$ in the (N, Z) chart are called proton and neutron drip-lines. Figure 3 shows the predicted contour line for $S_n = 3.3$ MeV. The kinks are due to magic numbers. One of the currently open questions is whether a quenching of shell effects decreases these features towards the neutron drip-line.

Nuclear reactions

In a nuclear reaction a projectile will penetrate a target nucleus in order to form a new compound nucleus. This penetration can be described by solutions to the Schrödinger equation for a given potential via transmission coefficients T into the nucleus. Bombarding a nucleus, described by a simple box potential, i.e. $V = 0$ outside (1) and $V = -V_0$ inside (2) the nucleus, with a free neutron of energy E, momentum $\hbar k$, $k = [2\mu(E - V)]^{1/2}/\hbar$ and a reduced mass μ leads to

$$T = \frac{4k_1k_2}{|k_1 + k_2|^2}.$$

As $k_2 > k_1$, because of the large negative potential $-V_0$ inside the nucleus, $T \approx 4k_1/k_2$. Protons experience a Coulomb repulsion potential outside the nucleus, which can be larger than the projectile energy E. Expressed in the quantum mechanical WKB approximation for the Coulomb potential of a nucleus with charge Z_i and a projectile of charge Z_j, $V(x) = Z_iZ_je^2/x$, this results in

$$T = \mathrm{e}^{-2\pi\eta} \qquad \eta = \left(\frac{\mu}{2E}\right)^{1/2} \frac{Z_iZ_je^2}{\hbar}$$

where η is called the Sommerfeld parameter. This transmission coefficient decreases for larger charges and increases with increasing energy.

A quantitative measure for the probability of reactions between a target nucleus and incoming projectiles is the reaction cross section, defined as

$$\sigma = \frac{\text{number of reactions per target s}^{-1}}{\text{flux of incoming projectiles}}.$$

Because the flux of incoming particles is measured in cm^{-2} s^{-1}, σ has units cm^2. All particles passing through a circular area of that size perpendicular to the projectile trajectory will undergo a reaction. Introductory QUANTUM MECHANICS relates the cross section to the sum of transmission coefficients over all possible angular momenta l

$$\sigma = \frac{\pi}{k^2} \sum_{l=0}^{\infty} (2l + 1)T_l$$

if we neglect the fact that projectile and target have an intrinsic spin. Here l denotes the angular momentum and T_l the related transmission coefficient for incoming projectiles of momentum $\hbar k$.

This is the cross section for a successful production of the compound nucleus; however not in its ground state. With a reaction Q value, the projectile with center of mass energy E creates a nucleus at the excitation energy $Q + E$. This excited state can again (because it is not stable) decay into other states: electromagnetic transitions into lower states of the compound nucleus, i.e. γ decay, or decay via particle emission into another nucleus i.e. $i + j \rightarrow \gamma + m$ $(i(j, \gamma)m)$ or $i + j \rightarrow o + m$ $(i(j, o)m)$. In most cases of low-energy projectiles γ transitions to the ground state will dominate. In addition, s-waves ($l = 0$) dominate at low energies and the capture cross section is approximated by

$$\sigma \approx \frac{\pi}{k^2} T_{l=0}.$$

The $l = 0$ transmission coefficients are exactly the ones of the previously described one-dimensional approach, i.e. central collisions where no angular momentum is involved. From the approximate behavior of neutron and charged-particle transmission coefficients, the energy dependence (at low energies E or velocities v) for neutron and charged-particle capture reactions follows.

(i) For neutrons with $T_{n,0} \approx 4k_1/k_2 \propto E^{1/2}$,

$$\sigma = \frac{\pi}{k^2} E^{1/2} \propto \frac{1}{E^{1/2}} \propto \frac{1}{v}.$$

(ii) For charged-particle captures with $T_{c,0} = \mathrm{e}^{-2\pi\eta}$,

$$\sigma = \frac{\pi}{k^2} \mathrm{e}^{-2\pi\eta} = \frac{\hbar^2\pi}{2\mu E} \mathrm{e}^{-2\pi\eta} \propto \frac{1}{E} \mathrm{e}^{-2\pi\eta}.$$

These are key features of neutron-induced and charged-particle-induced reaction cross sections which are essential for astrophysical applications. They are, in addition, mass dependent and modulated by shell effects due to the density of available excited states.

In general, target and projectile are not spinless particles. If a reaction of the type $i(j, o)m$ takes place, the compound nucleus formation cross section has also to be multiplied by the probability of that specific outgoing channel o, $P_o = T_o / \sum_n T_n$, where n sums over all possible decay channels. In a generalized treatment the Hauser–Feshbach or statistical model formula results. With more realistic potentials than the ones discussed before, a correct inclusion of isospin conservation and mixing, an adequate treatment of γ transitions in nuclei, a level density prescription required for transitions to higher energies where individual levels are hard to resolve and with width fluctuation corrections which include correlations between incoming and outgoing channels, a quite reasonable agreement can be found with experimental cross section determinations, provided that a high density of excited states (resonances) is found in

the compound nucleus at the appropriate bombarding energy. Reactions for light nuclei, which are dominated by individual resonances, have been discussed elsewhere (see NUCLEAR REACTION RATES).

Nuclear Reactions Rates

Investigations during the last 60 yr have shown that we are connected with distance space and time not only by our imagination but also through a common cosmic heritage: the chemical ELEMENTS that make up our bodies. These elements were created by nuclear reactions in the hot interiors of remote and long-vanished stars over many billions of years. Their nuclear fuels finally spent, these giant stars met death in cataclysmic explosions, scattering far and wide the atoms of heavy elements synthesized deep within their cores. Eventually this material, as well as material lost by smaller stars during red-giant stages, collected into clouds of gas in interstellar space; these, in turn, slowly collapsed giving birth to new generations of stars, thus leading to a cyclic evolution that is still going on. In this scenario, the Sun and its complement of planets were formed nearly 5 billion years ago. Drawing on the material gathered from the debris of its stellar ancestors, the planet Earth provided the conditions that eventually made life possible. Like every object in the solar system, each living creature on Earth incorporates atoms from distant corners of our galaxy. Every molecule in our bodies contains matter that once was subjected to the tremendous temperatures and pressures at the center of a star. This is where the iron in our blood cells originated, the oxygen we breathe, the carbon and nitrogen in our tissues and the calcium in our bones. All were formed predominantly in nuclear fusion reactions of smaller atoms in the interior of stars. The present picture is that all elements from carbon to uranium have been produced entirely within stars during their fiery lifetimes and explosive deaths. A few of the lightest elements were formed before the stars even existed, during the birth of the universe itself. In addition, a few of the most reactive light elements appear to have been synthesized in intergalactic space by COSMIC RAYS. Thus, theories of nucleosynthesis have identified the most important sites of element formation and also the diverse nuclear processes involved in their production. The detailed understanding of our cosmic heritage combines astrophysics and nuclear physics and forms what is called nuclear astrophysics. There are excellent theories of NUCLEOSYNTHESIS, but theories, in all of science, are only guides to understanding. They must be constantly confronted with experimental and observational data to ensure that they evolve in a meaningful direction. In turn, nuclear reactions are at the heart of nuclear astrophysics: they influence sensitively the nucleosynthesis of the elements in the earliest stages of the universe and in all the objects formed thereafter and control the associated energy generation, neutrino luminosity and evolution of stars. A good knowledge of the rates of these reactions is essential for an understanding of this broad picture.

Nuclear astrophysical rates

In a stellar plasma the constituent nuclei have kinetic energy (see below) and move in random directions. Occasionally they collide with other nuclei, whereby they experience one of two types of processes. In one type they are scattered on each other (like billiard balls): this elastic scattering process may be written symbolically as $1 + 2 \rightarrow 1+2$ or $x+A \rightarrow x+A$ (the latter is often written as A(x,x)A). The symbol x (or 1) represents the projectile and A (or 2) the target nucleus which together constitute the entrance channel. In the elastic scattering process the same types of nuclei emerge from the collision and constitute the exit channel. In the other type of process two different nuclei emerge from the collision, $1 + 2 \rightarrow 3 + 4$ or $x + A \rightarrow y + B$ (or A(x,y)B), where y (or 3) and B (or 4) represent the emerging nuclei which together constitute here the exit channel. This type of process is called a nuclear reaction, transmuting nuclei of the entrance channel into different nuclei of the exit channel and representing thus the key to the understanding of elemental nucleosynthesis. If the nuclei in the entrance channel have nuclear masses m_1 and m_2 and those in the exit channel have nuclear masses m_3 and m_4, energy conservation together with EINSTEIN's relation $E = mc^2$ leads to the nuclear reaction Q value, defined as $Q = (m_1 + m_2 - m_3 - m_4)c^2$. If the Q value is positive, there is a net production of energy in the reaction for each event: mass is converted to kinetic energy. Clearly, such reactions are most important for the energy production in stars. The Q value can be obtained from nuclear mass tables, which are the results of decades of painstaking work. Of equal importance is the intrinsic nuclear probability that a given reaction will take place. This probability, expressed as an energy-dependent cross section $\sigma(E)$ (see below), determines how many reactions occur per unit of time and unit volume: hence, together with the Q value, $\sigma(E)$ provides important information on nuclear energy production in stars.

We know that when one is shooting at a target the probability of hitting it increases as its area increases. By analogy, one may associate with each nucleus a geometrical area, which is directly related to the probability of a projectile interacting with the nucleus. This area is referred to as the cross section for the reaction. Classically, this cross section σ is equal to the combined geometrical area of the projectile and the target nucleus; if the projectile and the target nucleus have radii R_p and R_t, respectively, the cross section may be written as $\sigma = \pi(R_p + R_t)^2$ and does not depend on energy. In reality, the nuclear reactions are governed by the laws of quantum mechanics, whereby the geometrical cross section must be replaced by the energy-dependent quantity $\sigma = \pi(\lambda/2\pi)^2 \propto E^{-1}$ (E is the energy of the nuclei), where λ represents the de Broglie wavelength reflecting the wave aspect of quantum mechanical processes. In some cases the Coulomb and centrifugal barriers related to nuclear charge and angular momentum strongly inhibit the penetration of one nucleus into another. This barrier penetration leads to a steep energy dependence of the cross section $\sigma(E)$. Other energy-dependent effects, such as resonances and their mutual interference effects, also play important roles and the energy dependence of $\sigma(E)$ can be quite complex. In addition to the effects just discussed, the cross section for

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

a particular nuclear reaction depends on the nature of the force involved (i.e. strong, electromagnetic or weak force), with strengths that vary by many orders of magnitude. It is the challenge to the experimentalist to make precise $\sigma(E)$ measurements over a wide range of energies, as our fragmented knowledge of nuclear physics prevents us from predicting $\sigma(E)$ on purely theoretical grounds.

In hot stellar matter the energies of the moving nuclei can be described by a Maxwell–Boltzmann distribution, $\Phi(E) \propto E \exp(-E/kT)$, where T is the local temperature and k the Boltzmann constant. At low energies, $E \ll kT$, the function $\Phi(E)$ increases linearly with energy E. $\Phi(E)$ reaches a maximum value at $E = kT$, and at higher energies, $E \gg kT$, $\Phi(E)$ decreases exponentially (figure 1). Folding the cross section with this energy (or velocity) distribution leads to the nuclear reaction rate per pair of nuclei:

$$\langle \sigma v \rangle = (8/\pi\mu)^{1/2}(kT)^{-3/2} \int_0^\infty \sigma(E) \exp(-E/kT)\, \mathrm{d}E \quad (1)$$

where v is the relative velocity of the pair of nuclei, E is the center-of-mass energy and $\mu = m_1 m_2/(m_1 + m_2)$ is the reduced mass of the entrance channel. Multiplication of $\langle \sigma v \rangle$ by the number densities of the interacting species in the entrance channel leads to the total reaction rate per unit of time and volume for a star of given chemical composition. In order to cover the different evolution phases of stars, i.e. from main-sequence stars ($T \approx 10^7$ K) to supernovae ($T \approx 10^9$ K), one must know the rates over a wide range of temperatures, which in turn requires the availability of $\sigma(E)$ data over a wide range of energies.

For the important class of charged-particle-induced reactions, there is a repulsive Coulomb barrier in the entrance channel of height $E_c = Z_1 Z_2 e^2/r$, where Z_1 and Z_2 are the integral nuclear charges of the interacting particles, e is the unit of electric charge and r is the nuclear interaction radius. Because of the tunneling effect through this barrier, $\sigma(E)$ drops nearly exponentially with decreasing energy (figure 2):

$$\sigma(E) = S(E) E^{-1} \exp(-2\pi\eta) \quad (2)$$

where $\eta = 2\pi Z_1 Z_2 e^2/hv$ is the Sommerfield parameter (h is the Planck constant). The function $S(E)$, defined by this equation, contains all the strictly nuclear effects, and is usually referred to as the nuclear or astrophysical S factor. If equation (2) is inserted in equation (1), one obtains

$$\langle \sigma v \rangle = (8/\pi\mu)^{1/2}(kT)^{-3/2} \times \int_0^\infty S(E) \exp(-E/kT - b/E^{1/2})\, \mathrm{d}E \quad (3)$$

with $b = E_G^{1/2} = 2(2\mu)^{1/2}\pi^2 e^2 Z_1 Z_2/h$. Since for nonresonant reactions $S(E)$ varies slowly with energy, the steep energy dependence of the integrand in equation (3) is governed primarily by the exponential term. The penetration through the Coulomb barrier gives rise to the term $\exp(-b/E^{1/2})$, which becomes very small at low energies. The other exponential term, $\exp(-E/kT)$, which vanishes at high energy, is a measure of the number of particles available in the high-energy tail of the Maxwell–Boltzmann distribution. The product of the two terms leads to a peak of the integrand near the energy E_0, which is usually much larger than kT. The peak is frequently referred to as the Gamow peak (figure 1). For a constant $S(E)$ value over the energy region of the peak, one finds $E_0 = (bkT/2)^{2/3}$; this is the effective mean energy for a given reaction at a given temperature. Approximating the peak by a Gaussian function, one finds an effective width $\Delta = 4(E_0 kT)^{1/2}/3^{1/2}$. Thus, nuclear burning takes place predominantly over the energy window $E_0 \pm \Delta/2$, the stellar thermal energy range for which information on $\sigma(E)$ must be obtained.

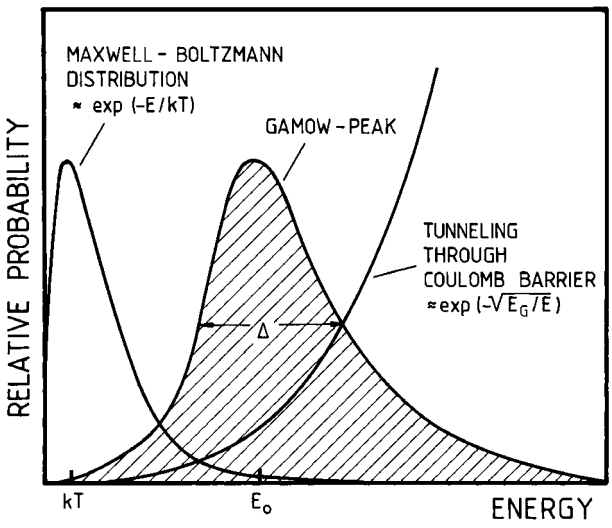

Figure 1. The dominant energy-dependent functions are shown for nuclear reactions between charged particles. While both the energy distribution function (Maxwell–Boltzmann) and the quantum mechanical tunneling function through the Coulomb barrier are small for the overlap region, the convolution of the two functions results in a peak (the Gamow peak) near the energy E_0, giving a sufficiently high probability to allow a significant number of reactions to occur. The energy of the Gamow peak is generally much larger than kT.

Because of the steep drop of $\sigma(E)$ at subcoulomb energies ($E < E_c$), it becomes increasingly difficult to measure $\sigma(E)$ as E is lowered. Although experimental techniques have improved significantly over the years, extending $\sigma(E)$ measurements to lower energies (with a low-energy limit at E_L, corresponding to a reaction yield in a detector of roughly 1 event per hour), it has not been possible to measure $\sigma(E)$ at stellar thermal energies, as $E_0/E_c \approx 1/100$ for hydrogen-burning reactions (i.e. pp chain and CNO cycles) in main-sequence stars such as our Sun. Instead, the measured energy dependence of $\sigma(E)$ at higher energies ($E > E_L$) must be extrapolated to stellar energies, using the $S(E)$ factor defined in equation (2). Such an 'extrapolation into the unknown' can lead

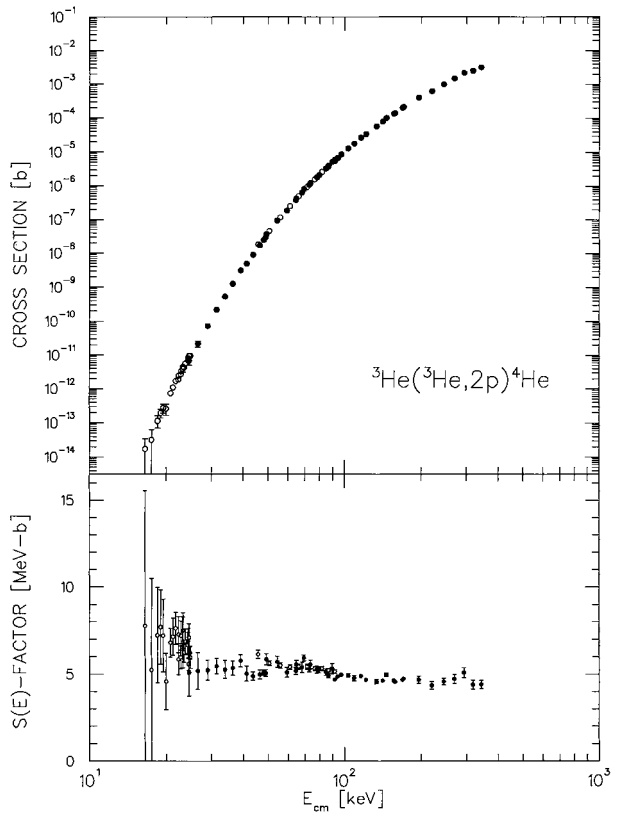

Figure 2. Energy dependence of the cross section and the astrophysical $S(E)$ factor for the ^{3}He(^{3}He, 2p)^{4}He reaction. The Gamow peak is at $E_0 = 21$ keV for solar conditions (central temperature $T = 15 \times 10^6$ K).

to considerable uncertainty. At energies lower than E_L there might be a change of reaction mechanism, or of the centrifugal barrier, or there might be a contribution of narrow or subthreshold resonances to $\sigma(E)$ at stellar energies. The danger of such extrapolations was strikingly demonstrated in the case of ^{2}H(d, γ)^{4}He, for example, where new low-energy data increased the extrapolated values by a factor 1000, mainly as a result of change in the centrifugal barrier (d- to s-waves). For another example, the observed solar neutrino fluxes in the existing neutrino detectors are not consistent with the current 'standard' picture of the microscopic processes in the Sun. A possible solution for this solar neutrino problem may be found in one or more of the areas of neutrino physics (e.g. the recent experimental evidence for neutrino oscillations at Super-Kamiokande), solar physics (models) or nuclear physics. In view of the important and fundamental conclusions regarding nonstandard physics, which may be deduced from the results of present and future solar neutrino observations, it is of utmost importance to place the predictions on a solid basis. The nuclear physics component of this problem involves the cross sections of the hydrogen-burning reactions extrapolated to the relevant solar energies. Yet another example is the reactions ^{12}C(α, γ)^{16}O, which takes places in the helium-burning phase of red-giant stars, at $E_0 \approx 0.30$ MeV. It has been found theoretically that this reaction influences sensitively not only the nucleosynthesis of the elements between C and Fe but also the evolution of stars, the dynamics of supernovae and the kind of remnant (neutron star or black hole) of a supernova explosion (see SUPERNOVA REMNANTS). At present, useful but still inadequate $\sigma(E)$ data are available only above $E_L = 1.3$ MeV. New experimental approaches are needed to reduce the uncertainties of the extrapolations.

The LUNA project

Low-energy studies to thermonuclear reactions in a laboratory at the Earth's surface are hampered predominantly by background effects of cosmic rays in the detectors, leading typically to more than 10 background events per hour in common detectors. Conventional passive or active shielding around the detectors can only partially reduce the problem of cosmic ray background. The best solution is to install an accelerator facility in a laboratory deep underground. As a pilot project, a 50 kV accelerator facility has been installed in the Laboratori Nazionali del Gran Sasso (LNGS), where the flux of cosmic-ray muons is reduced by a factor of 10^6 compared with the flux at the surface. This unique project, called LUNA (Laboratory for Underground Nuclear Astrophysics), was designed primarily for a renewed study of ^{3}He(^{3}He,2p)^{4}He at low energies, aiming to reach the solar Gamow peak at $E_0 \pm \Delta/2 = 21 \pm 5$ keV. This goal has been reached with a detected reaction yield of about 1 event per month at the lowest energy, $E = 16$ keV, with $\sigma \approx 20$ fb of 2×10^{-38} cm^2. Thus, the cross section of an important reaction of the pp chain has been directly measured for the first time at solar thermal energies (figure 2); in principle, extrapolation is no longer needed in this reaction. The work demonstrated the research potential of LUNA and that all of the experimental requirements in such low-rate, time-consuming experiments can be fulfilled. Installing larger facilities at LNGS in the near future will open the possibility of improving our knowledge of other key reactions by shifting their low-energy limit E_L significantly closer to E_0 or even to within the Gamow peak.

In the extrapolation of $\sigma(E)$ using equation (2), it is assumed that the Coulomb potential of the target nucleus and projectile is that resulting from bare nuclei. However, for nuclear reactions studied in the laboratory, the target nuclei and the projectiles are usually in the form of neutral atoms or molecules and ions, respectively. The electron clouds surrounding the interacting nuclides act as a screening potential: the projectile effectively sees a reduced Coulomb barrier. This in turn leads to a higher cross section, $\sigma_s(E)$, than would be the case for bare nuclei, $\sigma_b(E)$. There is an enhancement factor, $f_{lab}(E) = \sigma_s(E)/\sigma_b(E) \approx \exp(\pi\eta U_e/E)$, where U_e is the electron-screening potential energy (e.g. $U_e \approx Z_1 Z_2 e^2/R_a$, with R_a an atomic radius). Note that $f_{lab}(E)$ increases exponentially with decreasing energy. For ratios $E/U_e >$

1000, shielding effects are negligible, and laboratory experiments can be regarded as essentially measuring $\sigma_b(E)$. However, for $E/U_e < 100$, shielding effects become important for understanding and extrapolating low-energy data. Relatively small enhancements from electron screening at $E/U_e \approx 100$ can cause significant errors in the extrapolation of cross sections to lower energies, if the curve of the cross section is forced to follow the trend of the enhanced cross sections, without correction for the screening. Notice that, for a stellar plasma, the value $\sigma_b(E)$ must be known because the screening in the plasma will be quite different from that in the laboratory nuclear-reaction studies, i.e. $\sigma_{plasma}(E) = f_{plasma}(E)\sigma_b(E)$, and $f_{plasma}(E)$ must be explicitly included for each situation. A good understanding of electron-screening effects in the laboratory is needed to arrive at reliable $\sigma_b(E)$ data at low energies. Experimental studies of reactions involving light nuclides have shown the expected exponential enhancement of the cross section at low energies (figure 2). However, the observed enhancements were in all cases significantly larger than could be accounted for from available atomic-physics models. This situation is disturbing because, if the effects of electron screening are not understood under laboratory conditions, they are most likely to be not fully understood in a stellar plasma. A solution to the laboratory puzzle might be found in one (or all) of the following areas: the assumed energy-loss predictions from stopping-power codes at low energies, the assumed nuclear-reaction models at energies far below the Coulomb barrier, and the assumed atomic-physics models. All of these areas require additional experimental and theoretical efforts. An improved understanding of laboratory electron screening may also help eventually to improve the corresponding understanding of electron screening in stellar plasmas. It is in the nature of astrophysics that many of the processes and most of the objects one tries to understand are physically inaccessible. Thus, it is important that those aspects that can be studied in the laboratory be rather well understood. The electron-screening project addresses one such aspect.

Other rapidly developing experimental techniques

In explosive scenarios with temperatures of the order of 10^9 K (e.g. early universe, novae and supernovae), where E_0 approaches E_c, nuclear burning times can be greatly reduced, even down to seconds. If the half-life of a radioactive nuclide is longer than or of the same order as the burning time, that nuclide will be involved in the nuclear burning and thus will contribute to the composition of the final nuclear ashes. Since H and He are the most abundant species in these scenarios, the burning consists predominantly of (p,γ) and (α, γ) capture reactions involving these radioactive nuclides. If the half-life of a nuclide is longer than a day or so, it may be made into a radioactive target: e.g. ^{7}Be(p,γ)^{8}B with $T_{1/2}(^7\text{Be}) =$ 53 days. However, in a great majority of interesting cases, the half-lives are too short to make targets: e.g. ^{13}N(p,γ)^{14}O with $T_{1/2}(^{13}\text{N}) = 10$ min. In this case, a possible method is to create the radioactive nuclides in an accelerator, separate them, accelerate them in a second accelerator and allow the radioactive ion beam (RIB) to interact with an H or He target (inverted kinematics). All of this must be achieved in a time shorter than the decay lifetime of the radioactive nuclei. A growing number of laboratories have already produced RIBs of astrophysical interest or are in the stage of technical development of such beams. For the study of these capture reactions, the detection of the capture γ-rays or of the residual recoil nuclei (via their radioactive decay signals) leads in general to efficiencies far below 100%. In addition, the radioactivity of the RIB seriously hampers the detection methods. Only p(^{13}N,γ)^{14}O has been successfully studied so far via γ-ray spectroscopy, because of an unusually large cross section arising from a strong, broad resonance. For all other capture reactions studied so far, only upper limits for $\sigma(E)$ have been derived at the relevant energies $E_0 \pm \Delta/2$ owing to more typical (i.e. small) cross sections. Thus, future experiments require a significantly improved detection efficiency, with a detector that is less sensitive to background. Since the recoil nuclei are kinematically confined to a forward cone of a few degrees, a recoil mass separator (RMS) can be used to filter the recoils from the RIB and to focus all recoils onto a suitable detector for particle identification. Of course, in most RMSs one must make a choice of the charge state of the recoils; however, there is usually a charge state representing about 50% of the recoils produced and thus the capture reactions can be studied with an approximately 50% detection efficiency. Such an RMS is in preparation at Bochum, called ERNA (European Recoil Separator for Nuclear Astrophysics), for the study of ^{4}He(^{12}C,γ)^{16}O and other key reactions. Although this reaction does not involve RIBs, a similar RMS should be appropriate for work with RIBs.

It should be pointed out that the capture reactions ^{7}Be(p,γ)^{8}B and ^{13}N(p,γ)^{14}O have also been studied using the alternative method of Coulomb dissociation (Coulomb excitation into the continuum). However, there remain uncertainties about the interpretation and achievable precision of the method. It is to be hoped that these uncertainties can be resolved and that this technique will eventually prove to be useful for the indirect studies of capture reactions involving both stable and radioactive nuclides. Unique applications for this technique would be the study of capture reactions involving three particles in the entrance channel (e.g. ^{4}He(αn,γ)^{9}Be) of two radioactive nuclides in the entrance channel (e.g. a neutron plus another radioactive nucleus).

Neutron-induced reactions, mainly (n,γ), play an important role in the early universe, as well as in stars where they are involved in the nucleosynthesis of the transiron elements via the s- and r-processes. Because of the short lifetime of the neutrons ($T_{1/2} = 10$ min), they must be produced by nuclear reactions within the star (e.g. via ^{13}C(α,n)^{16}O) and are quickly thermalized through elastic scattering. Because of the absence of a Coulomb barrier

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

in the entrance channel, the most probable energy is near $E_0 = kT \approx 30$ keV for $T = 3 \times 10^8$ K. Usually $\sigma(E)$ is very large and increases with decreasing E. Thus, $\sigma(E)$ measurements of the s-process can in principle be carried out directly in the relevant stellar energy region. Since the r-process involves radioactive nuclei near the neutron-drip line, the relevant $\sigma(E)$ measurements require RIB techniques (see above).

As pointed out earlier, a few of the most reactive light elements, i.e. Li, Be and B, appear to have been synthesized in intergalactic space through spallation processes induced by high-energy cosmic rays. This possibility is currently under quantitative study using space vehicles (measurement of cosmic-ray composition and spectra) and in laboratories (measurement of high-energy spallation cross sections).

Summary

Impressive progress has been achieved in the knowledge of nuclear reaction rates. However, there remains much critical work to be done in the future to arrive at reliable data for many key reactions and processes. New techniques continue to be developed for this purpose, for nuclear reaction rates involving both stable and radioactive nuclei, and research in nuclear astrophysics will remain an exciting pursuit for many years to come.

Nucleosynthesis

Nucleosynthesis is the science related to all astrophysical processes which are responsible for the abundances of the elements and their isotopes in the universe. The astrophysical sites are the Big Bang and stellar objects, either during their stable (hydrostatic) evolution and wind ejection or during explosions like novae and supernovae, or possibly other events, where binary stellar systems are involved. The understanding of each of these environments requires in general hydro(fluid/gas)dynamics, thermodynamics and energy transport. Nuclear abundances and energy generation are determined by thermonuclear reactions.

We give a brief review of hydrostatic burning phases in stellar evolution and the specific burning features of explosive stellar events. This is followed by a discussion of the basic equations for reaction networks which govern composition changes and the required nuclear physics input for thermonuclear reactions.

The working of nucleosynthesis is presented in a survey of events which act as nucleosynthesis sources and an analysis of their role in the puzzle to explain the evolution of the elemental and isotopic composition in galaxies and especially the mixture found in the solar system (see figure 1). Different timescales due to the mass dependence of the endpoints of stellar evolution (type II supernova explosions—SNe II versus planetary nebulae) or single versus binary stellar systems (the latter being responsible for novae, type Ia supernovae—SNe Ia, or x-ray bursts) are the key to understanding galactic evolution. We also speculate on the role of (i) very massive stars not undergoing the SN II explosions but rather causing 'hypernovae' after the formation of a central black hole via core collapse, and (ii) binary neutron star or neutron star–black hole pairs.

Nuclear burning

Nuclear burning can in general be classified into two categories: (1) hydrostatic burning stages on timescales dictated by stellar energy loss and (2) explosive burning due to hydrodynamics of the specific event. Hydrostatic burning stages are characterized by temperature thresholds, permitting thermal Maxwell–Boltzmann distributions of (charged) particles (nuclei) to penetrate increasingly larger Coulomb barriers of electrostatic repulsion. We can describe the burning stages in terms of an abbreviated nomenclature for reactions with target i, projectile j, emitted particle k, and main reaction product l [$i + j \rightarrow k + l$ or $i(j,k)l$]. Projectiles are either neutrons n, protons p, α-particles (^{4}He) or nuclei, emitted particles include those listed above, photons γ or in $\beta^{\pm}$-decays positrons/electrons $e^{\pm}$ and neutrinos/antineutrinos $\upsilon/\overline{\upsilon}$. H-burning converts ^{1}H into ^{4}He via pp-chains or the CNO-cycles. Here we use the notation $^A Z$ where the mass

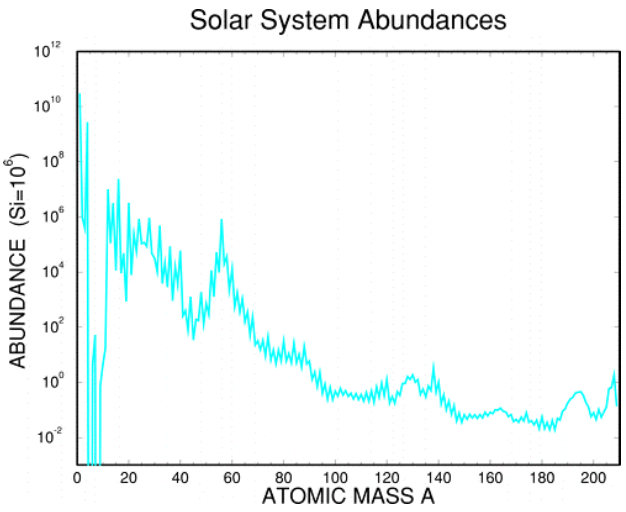

Figure 1. Abundances by number as found in the solar system from meteorite samples and solar spectra. Abundances of isotopes of different elements with the same mass number A are added. The units are arbitrarily scaled to an abundance of Si of the order 10^6.

number A is the sum of neutrons and protons $N + Z$ and Z is usually replaced by the element symbol representing that charge or proton number (see NUCLEAR PROPERTIES). The simplest pp-chain is initiated by ^{1}H(p,$e^+\upsilon$)^{2}H(p,γ)^{3}He and completed by ^{3}He(^{3}He,2p)^{4}He. The dominant CNO-cycle chain ^{12}C(p,γ)^{13}N($e^+\upsilon$)^{13}C(p,γ)^{14}N(p,γ)^{15}O($e^+\upsilon$) ^{15}N(p,α)^{12}C is controlled by the slowest reaction ^{14}N(p,γ)^{15}O. Further burning stages are characterized by their major reactions, which are in He-burning ^{4}He(2α,γ)^{12}C (triple-alpha) and ^{12}C(α,γ)^{16}O, in C-burning ^{12}C(^{12}C, α)^{20}Ne and in O-burning ^{16}O(^{16}O, α)^{28}Si. The alternative to fusion is photodisintegration which starts to play a role at sufficiently high temperatures T when $30kT \approx Q$ (the Q-value or energy release of the inverse capture reaction). This ensures the existence of photons with energies $>Q$ in the Planck distribution and leads to Ne-burning (^{20}Ne(γ,α)^{16}O, ^{20}Ne(α,γ)^{24}Mg) at $T > 1.5 \times 10^9$ K (preceding O-burning) due to a small Q-value of ≈4 MeV and Si-burning at temperatures in excess of 3×10^9 K (initiated like Ne-burning by photodisintegrations). The latter ends with nuclear reactions in a complete chemical equilibrium (nuclear statistical equilibrium, NSE) and an abundance distribution around Fe. These temperatures permit photodisintegrations with typical Q-values of 8–10 MeV as well as the penetration of Coulomb barriers in capture reaction.

In such an NSE the abundance of each nucleus Y_i, with mass number A_i, charge Z_i, and neutron number $N_i = A_I - Z_i$ is only dependent on temperature T, density ρ, and its nuclear binding energy B_i, while fulfilling mass conservation $\sum_i A_i Y_i = 1$ and charge conservation $\sum_i Z_i Y_i = Y_e$ (equal total abundances of protons and electrons). Y_e is changed by weak interactions (beta-decays and electron captures) on longer timescales. Quasi-equilibrium can

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

occur when different nuclear mass regions are locally in equilibrium with the background of free neutrons, protons and alphas but offset from their NSE values.

During core and shell He-burning specific α-induced reactions can liberate neutrons which are responsible for the slow neutron capture process (s-process). It leads to the build-up of elements up to Pb and Bi through a series of neutron captures and β^--decays, starting on existing heavy nuclei around Fe.

Many of the hydrostatic burning processes occur also under explosive conditions at higher temperatures and on shorter timescales (see figure 2), when often the β-decay half-lives are longer than the explosive timescales. This requires in general the additional knowledge of nuclear reactions for unstable nuclei. The fuels for explosive nucleosynthesis consist mainly of $N = Z$ nuclei like ^{12}C, ^{16}O, ^{20}Ne, ^{24}Mg, or ^{28}Si (the ashes of prior hydrostatic burning), resulting in heavier nuclei, again with $N \approx Z$. At high densities also substantial electron captures on nuclei $e^- + {}^AZ \rightarrow {}^A(Z-1) + \upsilon$ can occur due to energetic, degenerate electrons with high Fermi energies (equivalent to a β^+-decay which converts a proton into a neutron inside a nucleus).

Explosive Si-burning differs strongly from its hydrostatic counterpart and can be divided into three different regimes: (i) incomplete Si-burning and complete Si-burning with either (ii) a normal (high density, low entropy) or (iii) an alpha-rich (low density, high entropy) freeze-out of charged-particle reactions during cooling from NSE. At high temperatures or during a 'normal' freeze-out, the abundances are in a full NSE. An alpha-rich freeze-out is caused by the inability of the triple-alpha reaction ^{4}He(2α,γ)^{12}C, and the ^{4}He(αn,γ)^{9}Be reaction to keep light nuclei like n, p and ^{4}He, and nuclei beyond $A = 12$ in an NSE during declining temperatures, when the densities are small. This causes a large alpha abundance after freeze-out. This effect, most pronounced for SNe II, is a function of entropy.

r-process nucleosynthesis (rapid neutron capture) relates to subsets of explosive Si-burning, either with low or high entropies, experiencing a normal or alpha-rich freeze-out. The requirement of a neutron/seed ratio of 10 to 150 after charged particle freeze-out translates for a normal freeze-out into $Y_e = 0.12$–0.3. For a moderate $Y_e > 0.40$ an extremely alpha-rich freeze-out is needed.

Nuclear reaction rates and networks

In this section we want to outline the essential features of thermonuclear reaction rates and nuclear reaction networks (see also NUCLEAR REACTION RATES). The nuclear cross section for a reaction between target j and projectile k is defined by

$$\sigma = \frac{\text{number of reactions target}^{-1}\,\text{s}^{-1}}{\text{flux of incoming projectiles}} = \frac{r/n_j}{n_k v}.$$

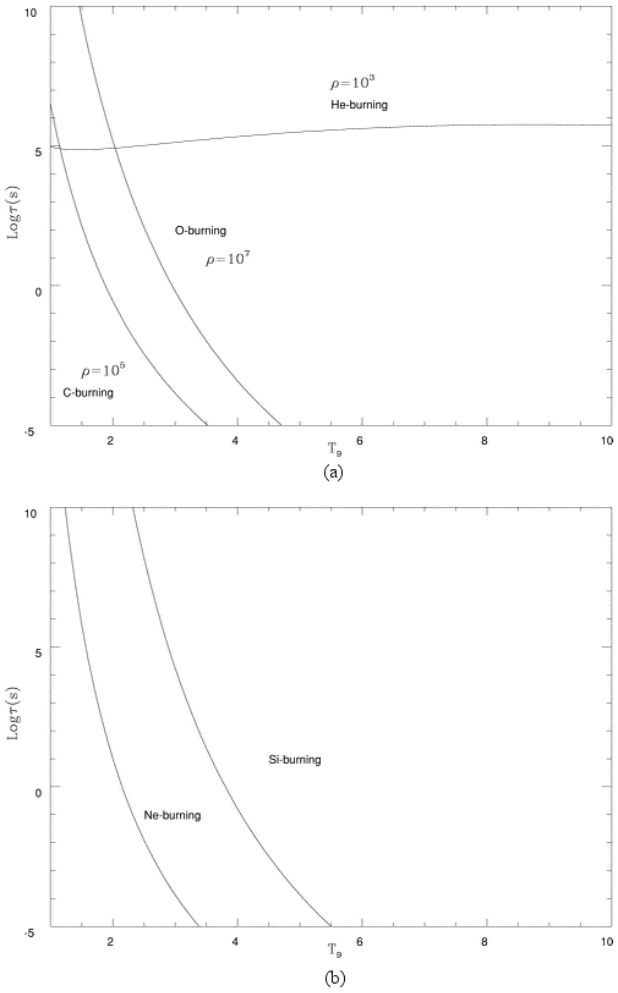

Figure 2. Burning timescales in seconds for fuel destruction of He-, C-, and O-burning (top) and Ne- and Si-burning (bottom) as a function of temperature. Density-dependent timescales are labeled with a chosen typical density (in g cm^{-3}). They scale with $1/\rho$ for C- and O-burning and $1/\rho^2$ for He-burning. Ne- and Si-burning, initiated by photodisintegrations, are not density-dependent. The almost constant He-burning timescale beyond $T_9 = T/10^9$ K = 1 permits efficient destruction on explosive timescales only for high densities.

The second equality holds for the case that the relative velocity between targets with the number density n_j and projectiles with number density n_k is constant and has the value v. Then r, the number of reactions per cm^3 and s, can be expressed as $r = \sigma v n_j n_k$. More generally, when targets and projectiles follow specific thermal momentum distributions, r is given by

$$r_{j,k} = \int \sigma(|\boldsymbol{v}_j - \boldsymbol{v}_k|)|\boldsymbol{v}_j - \boldsymbol{v}_k| \mathrm{d}n_j\, \mathrm{d}n_k.$$

The evaluation of this integral depends on the types of particles (fermions, bosons) and distributions which are involved. For nuclei j and k in an astrophysical plasma,

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

obeying a Maxwell–Boltzmann distribution, this simplifies to $r_{j,k} = <\sigma v> n_j n_k$. The thermonuclear reaction rates have the form

$$\langle \sigma v \rangle_{j,k} = \left(\frac{8}{\mu \pi}\right)^{1/2} (kT)^{-3/2} \int_0^\infty E \sigma(E) e^{-E/kT} dE.$$

Here μ and E denote the reduced mass and center of mass energy of the target–projectile system. When particle k is a photon, the relative velocity is always c and quantities in the integral are not dependent on dn_j. This simplifies to $r_j = \lambda_{j,\gamma} n_j$. $\lambda_{j,\gamma}(T)$ results from an integration over a Planck distribution for photons of temperature T.

A similar procedure is used for electron captures by nuclei. Because the electron is about 2000 times less massive than a nucleon, the velocity of the nucleus j is negligible in the center of mass system in comparison to the electron velocity ($|\boldsymbol{v}_j - \boldsymbol{v}_e| \approx |\boldsymbol{v}_e|$). The electron capture cross section has to be integrated over a Fermi distribution of electrons. The electron capture rates are a function of T and $n_e = Y_e \rho N_A$, the electron number density, where ρ denotes the matter density and N_A Avogadro's number. In a neutral, completely ionized plasma, the electron abundance is equal to the total proton abundance $Y_e = \sum_i Z_i Y_i$ and $r_j = \lambda_{j,e}(T, \rho Y_e) n_j$.

This treatment can be generalized for the capture of positrons, which are in a thermal equilibrium with photons, electrons, and nuclei. At high densities ($\rho > 10^{12}$ g cm^{-3}) the size of the neutrino scattering cross section on nuclei and electrons ensures that enough scattering events occur to thermalize a neutrino distribution. Then also the inverse process to electron capture (neutrino capture) can occur and be expressed in a similar way to photon and electron captures, integrating now over the neutrino distribution. Finally, for normal decays with half-life τ<inf>1/2</inf>, we obtain an expression with the decay rate $\lambda_j = \ln 2/\tau<inf>1/2</inf>$ independent of temperature or density.

The time derivative of the number densities of each of the species in an astrophysical plasma is governed by the different expressions for r, as discussed above for the different reaction mechanisms

$$\left(\frac{\partial n_i}{\partial t}\right)_{\rho=\text{const}} = \sum_j N_j^i r_j + \sum_{j,k} N_{j,k}^i r_{j,k} + \sum_{j,k,l} N_{j,k,l}^i r_{j,k,l}.$$

The reactions listed on the right-hand side of the equation belong to the three categories of reactions: (1) decays, photodisintegrations, electron and positron captures and neutrino induced reactions ($r_j = \lambda_j n_j$), (2) two-particle reactions ($r_{j,k} = <j,k> n_j n_k$), and (3) three-particle reactions ($r_{j,k,l} = <j,k,l> n_j n_k n_l$) like the triple-alpha process, which can be interpreted as successive captures with an intermediate unstable target. The capital Ns indicate how many nuclei of type i are destroyed (-) or produced (+) in the corresponding reaction. In order to exclude changes in the number densities $\dot{n}_i$ which are only due to expansion or contraction of the gas, the nuclear abundances $Y_i = n_i/(\rho N_A)$ were introduced. With A_i being the atomic weight, $A_i Y_i$ represents the mass fraction of this nucleus. In terms of abundances Y_i the previous equation translates into a set of differential equations

$$\dot{Y}_i = \sum_j N_j^i \lambda_j Y_j + \sum_{j,k} N_{j,k}^i \rho N_A \langle j,k \rangle Y_j Y_k + \sum_{j,k,l} N_{j,k,l}^i \rho^2 N_A^2 \langle j,k,l \rangle Y_j Y_k Y_l.$$

This reaction network has in general to be solved numerically. A simplified situation is given in the case of a nuclear statistical equilibrium (NSE) at high temperatures. Instead of solving reaction networks, which would result in the same, but much more time consuming, solution the abundances can be expressed by a chemical equilibrium for the build-up of all nuclei from neutrons and protons via the chemical potentials $\mu(Z,A) = Z\mu_p + (A - Z)\mu_n$. For the typical Boltzmann distributions this leads to

$$Y_i = (\rho N_A)^{A_i - 1} \frac{G_i}{2^{A_i}} A_i^{3/2} \left(\frac{2\pi\hbar^2}{m_u kT}\right)^{3(A_i-1)/2} e^{B_i/kT} Y_p^{Z_i} Y_n^{N_i}$$

for the abundance of nucleus Y_i, with nuclear binding energy B_i and partition function $G_i(T)$, and m_u denoting the atomic mass unit. The required solution for neutron and proton abundances Y_n and Y_p is found from mass conservation $\sum_i A_i Y_i = 1$ and charge conservation $\sum_i Z_i Y_i = Y_e$. In that case only the slow weak interaction processes, which change Y_e as a function of time, have to be followed explicitly.

The total energy generation rate per gram, due to nuclear reactions with abundance changes $\dot{Y}_i$, is expressed in terms of the mass M_i of the participating nuclei

$$\dot{\epsilon} = -\sum_i \dot{Y}_i N_A M_i c^2$$

where c is the speed of light.

As noted above, the important ingredients to nucleosynthesis calculations are decay half-lives, electron and positron capture rates, photodisintegrations, neutrino induced reaction rates, and strong interaction cross sections. Photodisintegration rates can be calculated via detailed balance from the reverse capture rates.

The early universe

The dominant contributions to the cosmic abundances of the light nuclides ^{1}H, ^{2}H, ^{3}He, ^{4}He and ^{7}Li are due to BIG BANG nucleosynthesis and thus relics of a hot and dense state of the early universe which underwent adiabatic expansion. When assuming that all microphysics is

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

understood, the final abundances of the light elements are determined by only one parameter, the entropy, expressable in terms of the baryon to photon ratio $\eta = n_B/n_\gamma$, because this initial state possesses also a weak interaction equilibrium, determining Y_e. The Big Bang entropies correspond to an extremely α-rich freeze-out (high entropies = a low density for a given temperature), where essentially no element with $A > 7$ is produced. The build-up of light elements through non-equilibrium reactions is only determined after the reaction $^1H(n,\gamma)^2H$ falls out of equilibrium close to $T_9 \approx 1$, because of a very small Q-value of 2 MeV. Uncertainties, affecting especially the primordial ^{4}He abundance, were related to the number of neutrino species and the neutron lifetime. LEP experiments at CERN proved the existence of three neutrino species in the late 1980s, and the neutron lifetime is determined by experiments with trapped ultracold neutrons. The cross sections of the relevant thermonuclear reactions linking nuclei from ^{1}H to ^{7}Li have been measured at the appropriate energies to an accuracy better than 10%. The major uncertainties are related to the determination of the primordial abundance of ^{2}H, ^{3,4}He and ^{7}Li with astronomical means. They constrain η to $2–5 \times 10^{-10}$.

Low mass stars and the s-process

STELLAR EVOLUTION is an advanced subject with many successes. Major modeling uncertainties seem to be related to the treatment of convection, the consistent inclusion of effects due to stellar rotation, and the treatment of wind losses. Reactions involving stable nuclei are in quite reasonable shape, but with a number of open questions left until now. A few are (a) pp-chain reactions in H-burning, e.g. $^3He(\alpha,\gamma)^7Be$, $^7Be(p,\gamma)^8B$, and $^7Li(p,\alpha)^4He$, which affect sub-solar and solar type stars and are directly connected to the solar neutrino emission, CNO-cycle reactions like $^{14}N(p,\gamma)^{15}O$ and $^{17,18}O(p,\alpha)^{14,15}N$, which directly relate to the surface abundances in intermediate mass stars, NeNa-cycle reactions in intermediate and massive stars, (b) the $^{12}C(\alpha,\gamma)^{16}O$ reaction in He-burning, and (c) fusion reactions of late burning stages, e.g. $^{12}C + {}^{12}C$, which are not well known at low energies.

Low and intermediate mass stars which enrich the interstellar medium via stellar winds and/or planetary nebula ejection before forming central C + O WHITE DWARFS, are contributing important amounts of He and C as well as other H- and He-burning products. Among the He-burning products one also finds about half of the heavy elements and isotopes beyond Fe and up to Pb and Bi, resulting from s-process nucleosynthesis which is due to neutron capture by pre-existing intermediate and heavy nuclei. New data (Van Eck *et al*) support this view, which hitherto had little observational support. In core and shell He-burning neutrons are provided by a side branch of He-burning reactions acting on ^{14}N, the dominant CNO nucleus after H-burning, $^{14}N(\alpha,\gamma)^{18}F(e^+\upsilon)^{18}O$ $(\alpha,\gamma)^{22}Ne(\alpha,n)^{25}Mg$. An alternative stronger neutron source during the period of He-shell flashes in low and intermediate mass stars is the reaction $^{13}C(\alpha,n)^{16}O$, which requires admixture of hydrogen and the production of ^{13}C via $^{12}C(p,\gamma)^{13}N(e^+\upsilon)^{13}C$. The s-process is characterized by neutron captures which are slow in comparison to beta-decays.

Figure 3 shows a section of the chart of nuclei and the s-process path indicated by horizontal arrows for neutron captures with reaction rates $\langle\sigma v\rangle_{n,\gamma}(A) \equiv \langle\sigma v\rangle_A$, connected by β^--decays whenever an unstable nucleus is encountered. The path can be simplified by abundances related only to mass numbers A and the abundances approach a steady flow equilibrium $\dot{Y}_A = 0$ of creation and distruction

$$\dot{Y}_A = \rho N_A \langle\sigma v\rangle_{A-1} Y_n Y_{A-1} - \rho N_A \langle\sigma v\rangle_A Y_n Y_A$$
$$= n_n \langle\sigma v\rangle_{A-1} Y_{A-1} - n_n \langle\sigma v\rangle_A Y_A .$$

This leads to $\langle\sigma v\rangle_A Y_A \approx$ const for neighboring As, with exceptions at closed neutron shells where the cross sections and reaction rates are small, i.e. the neutron capture timescales are too long to attain a steady flow equilibrium. For a large fraction of nuclei the neutron cross sections scale with $E^{-1/2}$ ($l = 0$ s-wave capture), which causes a temperature independent $\langle\sigma v\rangle$. Then the resulting abundance pattern is only dependent on the neutron exposure $\tau = \int n_n \, dt$, and in this classical analysis a very good fit to all s-only isotopes (see figure 3) can be found with a continuous (exponential) superposition of

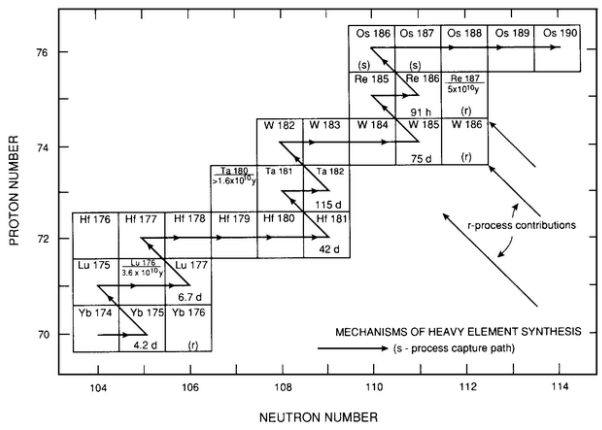

Figure 3. A typical portion of the nuclear chart for heavy elements beyond the 'Fe-group'. The s-process path, which is constrained to the 'valley' of stability, is indicated. Neutron-rich r-only isotopes formed by the r-process are identified as well as the shielded s-only isotopes, which cannot have an r-process contribution. Stable isotopes, more proton-rich than the s-process path, have typically an abundance smaller by two orders of magnitude than s- and r-isotopes. Their origin is due to the p- or γ-process (discussed later).

Dirac House, Temple Back, Bristol, BS1 6BE, UK

exposures τ. This analysis can also provide the r-process abundances (to be discussed later) by subtracting the s-process component from the total solar abundances for those nuclei which have s- and r-contributions (see figure 4). The s-process contribution has abundance peaks at stable nuclei with closed neutron shells (N = 50, 82, 126 for A = 88, 138, and 208) where small cross sections are encountered.

There exist two complications to the simple picture given above: (i) nuclei with very long β-decay half-lives (comparable to the s-process duration time) can cause branchings into two flows, and (ii) cross sections which are not s-wave dominated lead to a temperature dependent $<\sigma v>$. In that case the results are not just a function of τ but can depend on $n_n(t)$ and $T(t)$. Among the most important and difficult examples is the branching occurring at ^{85}Kr, which involves Kr, the Rb and Sr isotopes. The abundance of ^{142}Nd can only be reproduced with realistic stellar conditions due to a temperature dependent $<\sigma v>$. The s-process is recognized to occur in at least two different astrophysical sites, the weak component accounting for most of the s-nuclei below the Kr–Rb–Sr abundance peak, and the main component accounting for heavier nuclei up to Pb. The main s-process component is due to the thermally-pulsing phase of shell He- and H-burning in low mass stars ($M \leq 3M_\odot$) and primarily driven by ^{13}C(α,n)^{16}O rather than ^{22}Ne(α,n)^{25}Mg. Recent research indicates that ^{13}C(α,n)^{16}O burns in the interpulse phases at low temperatures. Core He-burning with the ^{22}Ne source contributes to the weak s-component which is a complex combination of core He-, and shell C-, and Ne-burning in massive stars.

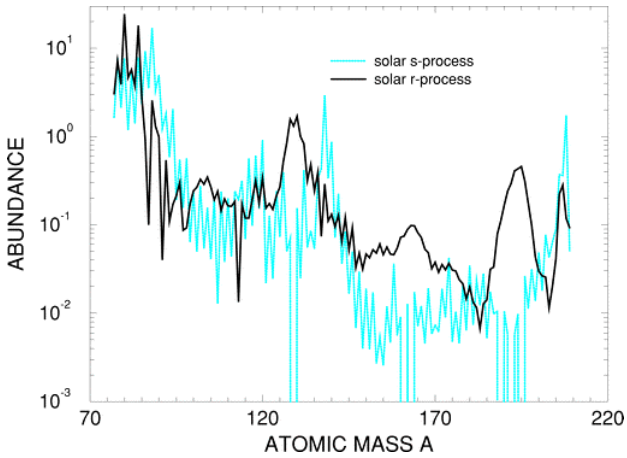

Figure 4. Decompositions of s-process and r-process abundances. Notice the opposite behavior of the two processes with respect to odd–even staggering.

Massive stars and type II supernovae

Stars with main sequence masses $M > 8M_\odot$ follow the hydrostatic burning stages beyond He-burning, develop an onion-like composition structure, and produce a collapsing core after the end of their hydrostatic evolution, which proceeds to nuclear densities (see SUPERNOVAE). The latter is due to the fact that Fe-group nuclei possess the highest binding energy per nucleon and nuclear energy generation ceases to be available. The total energy released in the collapse, 2–3 × 10^{53} erg, equals the gravitational binding energy of a neutron star. Because neutrinos are the particles with the longest mean free path, they are able to carry away that energy in the fastest fashion as seen for SN1987A in the Kamiokande, IMB and Baksan experiments. The apparently most promising mechanism for such type II supernova explosions (SNeII) is based on neutrino heating beyond the hot proto-neutron star via the dominant processes $\upsilon_e + n \rightarrow p + e^-$ and $\overline{\upsilon}_e + p \rightarrow n + e^+$ with a (hopefully) about 1% efficiency in energy deposition. The neutrino heating efficiency depends on the neutrino luminosity, which in turn is affected by neutrino opacities. The explosion via neutrino heating is delayed after core collapse for a timescale of seconds or less. The exact delay time t_{de} and other aspects of the explosion mechanism are still uncertain and depend on Fe-cores from stellar evolution and the supranuclear equation of state and maximum neutron star mass. The observational fact that many core collapse supernovae show polarized light emission is an indication of a nonspherical explosion mechanism.

Nucleosynthesis calculations

The still existing uncertainties of self-consistent models suggest making use of the fact that typical kinetic energies of 10^{51} erg are observed and light curve as well as explosive nucleosynthesis calculations can be performed by introducing a shock of appropriate energy in the pre-collapse stellar model, either by depositing thermal energy or invoking a piston. Induced calculations (lacking self-consistency) utilize the constraint of requiring ejected ^{56}Ni-masses from the innermost explosive Si-burning layers in agreement with supernova light curves, being powered by the decay chain ^{56}Ni–^{56}Co–^{56}Fe (see figure 5). However, it should be clear that, even if ^{56}Ni ejecta from a variety of progenitor masses are known, this is not a simple one parameter problem. Explosion energies can vary as a function of progenitor mass (or implicit parameters like rotation) and the delay time between core collapse and explosion can vary as well.

Figure 5 shows the radial composition of explosively processed mass zones caused by the shock wave which initiates a supernova explosion. The outer ejected layers ($M(r) > 2M_\odot$) are unprocessed by the explosion and contain results of prior H-, He-, C-, and Ne-burning in

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

stellar evolution. The interior parts of SNe II contain products of explosive Si, O, and Ne burning. In the inner ejecta, which experience incomplete and complete Si-burning, we see an alpha-rich freeze-out (^{4}He). The Y_e originates from the pre-explosive hydrostatic fuel in these layers and can change from 0.4989 to 0.494. This brings huge changes in the Fe-group composition for mass zones below $M(r) = 1.63M_\odot$, making the abundances of ^{58}Ni and ^{56}Ni comparable. All neutron-rich isotopes increase (^{57}Ni, ^{58}Ni, ^{59}Cu, ^{61}Zn, and ^{62}Zn); the even-mass isotopes (^{58}Ni and ^{62}Zn) show the strongest effect. One can also recognize the increase of ^{40}Ca, ^{44}Ti, ^{48}Cr, and ^{52}Fe with an increasing alpha-rich freeze-out, but a reduction of these $N = Z$ nuclei in the inner more neutron-rich layers.

Observational constraints

There is limited direct observational information from individual supernovae with known progenitors, leading to direct O, Ti or Fe(Ni) observations. When including also supernova remnants, there exist observations for element abundances, like C, O, Si, Cl, Ar, Co, and Ni, and isotopic abundances, like ^{56}Ni, ^{57}Ni, ^{44}Ti, and ^{26}Al, from optical, UV, and x-ray spectra, supernova lightcurves, as well as γ-ray lines following nuclear decay. They constrain the products of hydrostatic burning stages like C, O, Ne and Mg as well as the composition close to the mass cut between the central neutron star and the supernova ejecta (^{56}Co, ^{57}Co, ^{44}Ti). The latter are a measure of temperature, entropy, and Y_e and give a consistent picture for neutrino heating delay times of 0.3–0.5 s, explosion energies of the order 10^{51} erg, and a mass cut close to or outside the O-burning shell with minute permitted admixtures of deeper layers so that only matter with $Y_e \geq 0.497$–0.498 is ejected.

One has to investigate the question how the features discussed here might depend on the supernova progenitor mass and possibly other parameters. Figure 5 shows also that ^{55}Co (decaying to ^{55}Mn) and ^{52}Fe (decaying to ^{52}Cr) are products of incomplete Si-burning, while ^{59}Cu (decaying to ^{59}Co) is resulting from alpha-rich freeze-out. As these nuclei are the only (or dominant) stable isotopes of the respective element, this fact could be related to the Mn, Cr, and Co/Fe ratios observed in galactic evolution and give clues to changing mass cut positions as a function of progenitor mass.

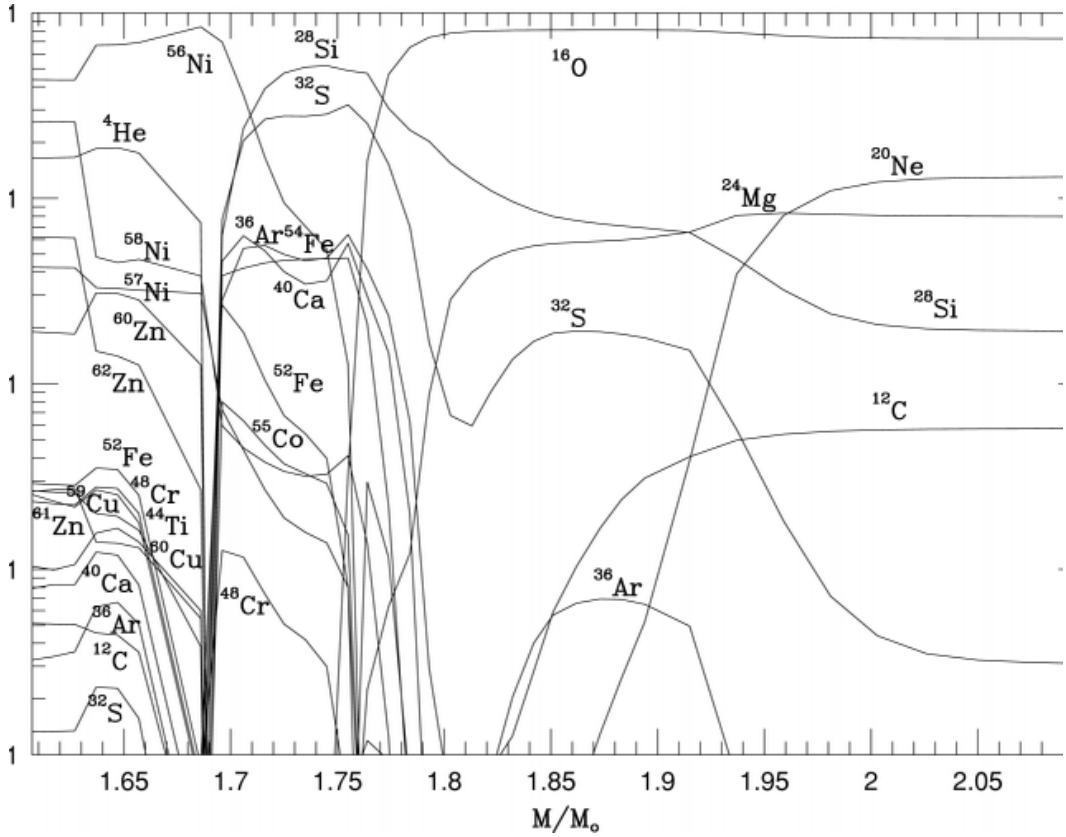

Figure 5. Isotopic composition for a core collapse supernova from a $20M_\odot$ progenitor star with a $6M_\odot$ He-core and a net explosion energy of 10^{51} erg, remaining in kinetic energy of the ejecta. The exact mass cut in $M(r)$ between neutron star and ejecta depends on the details of the delayed explosion mechanism.

Finally, the question has to be answered for which progenitor masses a large Fe-core at the end of stellar evolution leads the creation of a black hole instead of a neutron star and a supernova explosion. With SN 1998bw and SN 1997ef, which appear in optical spectra like core collapse supernovae, the transition to 'hypernovae' (failed supernovae which produce black holes and are probably powered by black hole accretion and jet ejection) is encountered. Their nucleosynthesis products have not yet been seriously analysed nor included in chemical evolution studies.

Nucleosynthesis as a witness of uncertainties

The synthesized elements form three different classes which are sensitive to different aspects of the stellar models and supernovae explosion mechanism: (1) stellar evolution treatment, (2) stellar evolution plus the explosion energy, and (3) details of the explosion mechanism which includes aspects of stellar evolution determining the size of the collapsing Fe-core.

(1) The abundances of C, O, Ne, and Mg originate from the unaltered (essentially only hydrostatically processed) C-core and from explosive Ne/C-burning. They are mainly dependent on the structure and zone sizes of the pre-explosion models and thus serve as a test for the treatment of stellar evolution. These zones and therefore the amount of ejected mass varies strongly over the progenitor mass range.

(2) The amount of mass for the elements S, Ar, and Ca, originating from explosive O- and Si-burning, is similar for all massive stars. They do not show the strong progenitor mass dependence of C, O, Ne, and Mg. Si has some contribution from hydrostatic burning and varies by a factor of 2–3. This second set (Si, S, Ar, Ca) tests the progenitor models and the explosion energy, because the amount of explosive burning depends on the structure of the model plus the energy of the shock wave which passes through it.

(3) The amount of Fe-group nuclei ejected (which includes also one of the so-called alpha elements, i.e. Ti) and their relative composition depends directly on the explosion mechanism, connected also to the size of the collapsing Fe-core. Observational checks of individual supernovae are presently still required to test the detailed working of a supernova. Three types of uncertainties are inherent in the Fe-group ejecta, related to (i) the total amount of Fe(group) nuclei ejected and the mass cut between neutron star and ejecta, mostly measured by ^{56}Ni decaying to ^{56}Fe, (ii) the total explosion energy which influences the entropy of the ejecta and with it the degree of alpha-rich freeze-out from explosive Si-burning and the abundances of radioactive ^{44}Ti as well as ^{48}Cr, the latter decaying later to ^{48}Ti and being responsible for elemental Ti, and (iii) finally the neutron richness or Y_e of the ejecta, dependent on stellar structure and the delay time between collapse and explosion. Y_e influences strongly the ratios of isotopes 57/56 in Ni(Co,Fe) and the overall elemental Ni/Fe ratio being dominated by ^{58}Ni and ^{56}Fe.

(4) r-process yields. SNe II have long been expected to be the source of r-process elements. Some recent calculations seemed to be able to reproduce the solar r-process abundances well in the high entropy neutrino driven wind, emitted from the hot proto-neutron star after the SN II explosion. However, we should keep in mind that present-day supernova models have difficulties to reproduce the entropies required for such abundance calculations. In addition, incorrect abundance features of lighter r-process nuclei are encountered. The inclusion of non-standard neutrino properties may perhaps achieve low enough Y_es, for intermediate entropies to correct for such unwanted features. However, recent observations shed also some doubts on the supernova origin. On average SNe II produce Fe to intermediate mass elements in ratios within a factor of 3 of solar. If they were also responsible for the r-process, the same limits should apply. But the observed bulk r-process/Fe ratios vary widely. In CS 22892-052 the r/Fe ratio is 30 times solar!

Type Ia supernovae

There are strong observational and theoretical indications that SNe Ia are thermonuclear explosions of accreting white dwarfs (see BINARY STARS: OVERVIEW). Theoretically, both (i) Chandrasekhar mass white dwarf models and (ii) sub-Chandrasekhar mass models have been considered. These correspond to a single white dwarf scenario, involving accretion of H or He via mass transfer from a binary companion onto the white dwarf. High rates of H-accretion cause high temperatures at the base of the accreted matter and lead to quasi-stable H-burning and subsequent He-burning in shells surrounding the white dwarf, probably related to supersoft x-ray sources. This increases the mass of the white dwarf consisting of C and O which approaches the maximum stable Chandrasekhar mass. In the case of He accretion at low rates, He detonates (supersonic burning front) at the base of the accreted layer before the system reaches the Chandrasekhar mass. A double white dwarf scenario is related to the merging of two C + O binary white dwarfs with a combined mass exceeding the Chandrasekhar limit.

Observational features of SNe Ia in early phases clearly indicate that Chandrasekhar models give a more consistent picture than the sub-Chandrasekhar models of helium detonations.

Ignition and burning front propagation

For Chandrasekhar mass models contraction and carbon ignition in the central region lead to a thermonuclear runway and a complete explosive disruption of the white dwarf. High accretion rates cause a higher central temperature and pressure, favoring lower ignition

Dirac House, Temple Back, Bristol, BS1 6BE, UK

densities. A flame front then propagates at a subsonic speed as a *deflagration wave* due to heat transport across the front. Here the most uncertain quantity is the flame speed which depends on the development of instabilities of various scales at the flame front. Multi-dimensional hydro simulations of the flame propagation have suggested that a carbon deflagration wave might propagate at a speed v_{def} as slow as a few per cent of the sound speed v_s in the central region of the white dwarf. The nucleosynthesis consequences of such slow flame speeds witness the actual burning front velocities and can thus serve as a constraint. Electron capture on free protons, intermediate mass and Fe-group nuclei affects the central electron fraction Y_e, which determines the composition of the ejecta from such explosions. The amount of electron capture depends on both v_{def} (influencing the time duration of matter at high temperatures, and with it the availability of free protons) and the central density of the white dwarf ρ_{ign} (increasing the electron chemical potential i.e. their Fermi energy).

After an initial deflagration in the central layers, the deflagration can turn into a detonation (supersonic burning front) at lower densities. The transition from a deflagration to a detonation (delayed detonation model) leads to a change in the ratios of incomplete Si-burning, complete Si-burning with normal freeze-out and with alpha-rich freeze-out, the latter being less alpha-rich than in SNe II due to the smaller entropies or higher densities. This also leaves an imprint on the Fe-group composition. Nucleosynthesis constraints can help to find the 'average' SN Ia conditions responsible for their contribution to galactic evolution, i.e. especially the Fe-group composition. SNe Ia contribute essentially no elements lighter than Al, about $\frac{1}{3}$ of the elements from Si to Ca, and the dominant (50–70%) amount of Fe group nuclei (Ti to Ni). In addition, the average Fe-group yields of SNe II differ from those of SNe Ia (e.g. in the elemental Cr/Fe, Mn/Fe ratios). The latter fact, combined with O–Ca/Fe ratios, gives the strongest constraints on the transition density ρ_{tr} from deflagrations to detonations.

Nucleosynthesis consequences

Figure 6 shows the influence of central ignition densities ρ_{ign} 1.37 (C) and 2.12×10^9 g cm^{-3} (W) at the onset of the thermonuclear runaway and slow (S) deflagration speeds of v_{def}/v_s = 0.015 (WS15, CS15), 0.03 (WS30,CS30) or 0.05 (CS50) on the resulting $Y_e(r)$ due to different amounts of electron capture. Y_e values of 0.47–0.485 lead to dominant abundances of ^{54}Fe and ^{58}Ni, values between 0.46 and 0.47 produce dominantly ^{56}Fe, values in the range of 0.45 and below are responsible for ^{58}Fe, ^{54}Cr, ^{50}Ti, ^{64}Ni, and values below 0.43–0.42 are responsible for ^{48}Ca. The intermediate Y_e-values 0.47–0.485 exist in all cases, but the masses encountered which experience these conditions depend on the Y_e-gradient determined by v_{def}. Whether the lower values with $Y_e < 0.45$ are attained depends on the central ignition density ρ_{ign}. Therefore, ^{54}Fe and ^{58}Ni are indicators of v_{def} while ^{58}Fe, ^{54}Cr, ^{50}Ti, ^{64}Ni, and ^{48}Ca are a measure of ρ_{ign}. Conclusions drawn from these results are that (i) v_{def} in the range 1.5–3% of the sound speed is preferred, and (ii) ignition densities $\rho_{ign} < 2 \times 10^9$ g cm^{-3} provide apparently a better agreement with the solar abundances of very neutron-rich species (case C rather than W). The latter interpretation is changed somewhat with improved electron capture rates on pf-shell (Fe-group) nuclei. In either case the ignition densities are in agreement with identifying supersoft x-ray sources as SN Ia progenitor systems. Their high accretion rates (close to $\dot{M} = 10^{-7} M_\odot$) would be in agreement with such ignition densities.

If a deflagration turns into a detonation, the transition density ρ_{tr} affects the total amount of ^{56}Ni, the intermediate mass elements Si–Ca, and the ratios of different explosive Si-burning regimes like alpha-rich freeze-out to incomplete Si-burning as seen in figure 7 (indicated by ^{58}Ni versus ^{54}Fe plateaux). Light curve modeling and spectra show that the typical ^{56}Ni mass should be in the range 0.5–0.7$M_\odot$, which compensates for the well known overproduction of Si–Ca/Fe in SNe II during galactic evolution with the observed Ia/II ratios in order to obtain a solar mix.

Small transition densities favor larger amounts of matter which experience incomplete Si-burning. Observations require an overproduction of Mn (and Cr) in SNe Ia. These elements are mostly made as ^{55}Co and ^{52}Fe (decaying to Mn and Cr), which are favorably

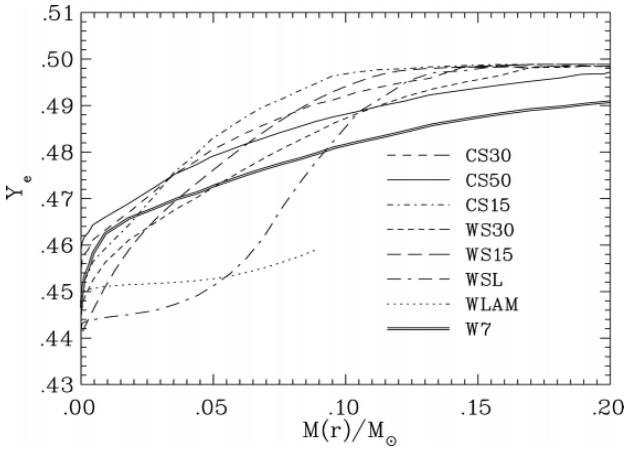

Figure 6. Y_e as a function of radial mass coordinate $M(r)$ after freeze-out of nuclear reactions measures the electron captures on free protons and nuclei. Small burning front velocities lead to steep Y_e-gradients which flatten with increasing velocities (see the series of models CS15, CS30, and CS50 or WS15, WS30, and W7). Lower central ignition densities shift the curves up (C versus W), but the gradient is the same for the same propagation speed. Only when the Y_e from electron captures is smaller than for stable Fe-group nuclei, will subsequent β^--decays reverse this effect (WSL and WLAM).

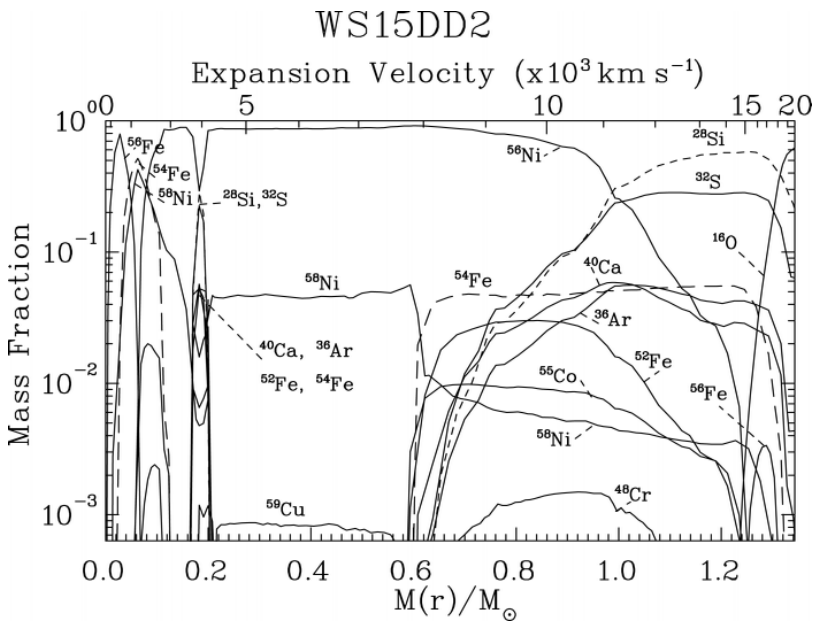

Figure 7. Composition of model WS15DD2 as a function of the expansion velocity and $M(r)$ for a delayed detonation model with a deflagration/detonation transition density of 2.2×10^7 g cm^{-3}. We see intermediate mass elements (Si–Ca) in the outer layers (at higher expansion velocities after the explosion), ^{56}Ni from explosive Si-burning dominating from about 0.2 to 1$M_\odot$, with features of incomplete Si-burning (^{54}Fe-plateau) and an alpha-rich freeze-out (^{58}Ni-plateau). The very central regions experience substantial electron capture and show more neutron rich nuclei (see figure 6).

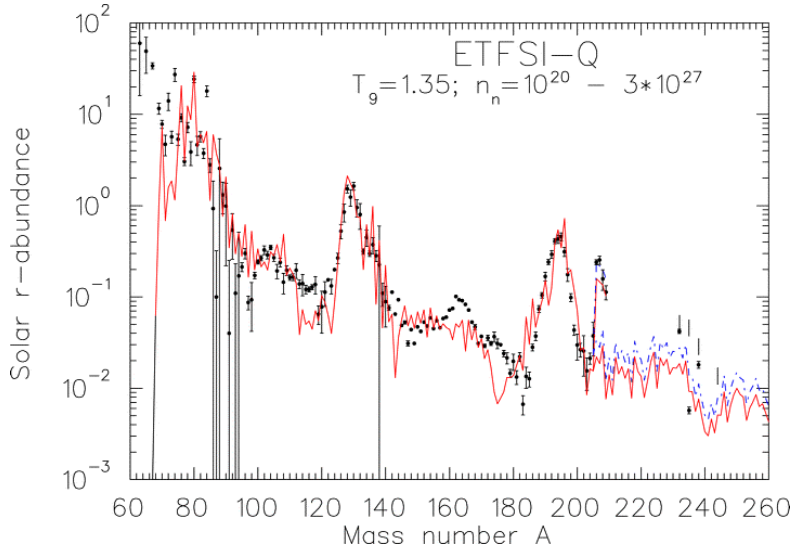

Figure 8. Comparison of theoretical abundances prior to and after β- and α-decay with solar r-process abundances (small filled circles). For $A > 206$ two superpositions are shown, obtained from fitting either the three r-process peaks or the global mass region $A = 125$–209 with r-process calculations obtained from 17 equidistant $S_n(n_n,T)$ components between 1 and 4 MeV. Both calculations make use of the ETFSI-Q mass model which assumes a quenching of shell effects far from stability.

produced in incomplete Si-burning. Combining all requirements on transition densities from total ^{56}Ni-yields, Si/Fe and Ia/II ratios, as well as specific elements favored in incomplete Si-burning, argues for a transition density close to 2×10^7 g cm^{-3}.

The r-process

The site-independent classical analysis based on neutron number densities n_n, temperatures T, and duration times τ assumed constant values of n_n and T and a fast drop of these quantities at $t = \tau$. The combination of n_n and T is

related to an r-process path in the nuclear chart along nuclei with a neutron separation energy $S_n(n_n,T)$ or neutron capture Q-value (see figure 3 in the article on NUCLEAR PROPERTIES). A continuous superposition of components with neutron separation energies in the range 4–1 MeV on timescales of 1–2.5 s, provides a good overall fit (see figure 8). For the heavier elements beyond A = 130 this reduces to about S_n = 3–1 MeV. The beta-decay properties along contour lines of constant S_n towards heavy nuclei are responsible for the resulting abundance pattern. These are predominantly very unstable nuclei not accessible in laboratory experiments to date. A recent detailed analysis of the A = 206–209 abundance contributions to Pb and Bi isotopes from α-decay chains of heavier nuclei also allows the prediction of abundances of nuclei as heavy as Th with reasonable accuracy. The results of this study are shown in figure 8.

A different question is related to the actual astrophysical realization of such conditions. Stellar spectra of low metallicity stars, stemming from the very early phases of galactic evolution, are all consistent with a solar r-abundance pattern for elements heavier than Ba, and the relative abundances among heavy elements do not apparently show any time evolution. This suggests that all contributing events produce the same relative r-process abundances for the heavy masses, although a single astrophysical site will still have varying conditions in different ejected mass zones, leading to a superposition of individual components. The physical conditions must vary smoothly, as expected from a single astrophysical site. (This is opposite to the s-process, where the solar abundances are only an average of many sites with different features.)

Some meteoritic abundances and very recent observations of low metallicity stars indicate that at least two r-process sources have to contribute to the solar r-process abundances. The observed non-solar r-process pattern for e.g. Ag, I, and Pd demonstrates the need for a second r-process component in the nuclear mass range $A \approx 80$–120 in addition to the main process which provides a solar r-process pattern for $A > 130$. It is not clear, yet, which of the two processes is related to SNe II and which one is related to possible other sources.

To identify possible stellar sites, the basic requirement is a surplus of 10 to 150 neutrons per seed nucleus (in the Fe-peak or somewhat beyond) which have to be available to form all heavier r-process nuclei by neutron capture. For a composition of Fe-group nuclei and free neutrons that translates into a Y_e = 0.12–0.3. Such a high neutron excess is only possible for high densities in neutron stars under beta equilibrium ($e^- + p \rightarrow n + \upsilon$, $n \rightarrow p + e^- + \overline{\upsilon}$), based on high electron Fermi energies which are comparable to the neutron–proton mass difference. Neutron star mergers from binary neutron star systems eject such matter and are a possible (low entropy) site. Recent calculations show that on average about $10^{-2}M_\odot$ of neutron-rich matter can be ejected and preliminary calculations with assumptions on Y_e predict a solar-type r-process pattern for nuclei beyond A = 130. The smaller masses are depleted due to a long duration r-process with a large neutron supply in such neutron-rich matter, which also leads to fission cycling. This seems (accidentally?) to be in accordance with the main observed r-process component. Given the frequency ($\approx 10^{-5}$ y^{-1} per galaxy) and amount of ejected matter, this component alone could be responsible for the heavy solar r-process pattern and also explain the large scatter of r/Fe elements found in low metallicity stars. Neutron star–black hole mergers have not been analysed yet with the same accuracy, but bear similar options.

Another option is an extremely alpha-rich (i.e. high entropy) freeze-out in complete Si-burning with moderate $Y_e > 0.40$, related to SNe II. Given the galactic occurrence frequency, SNe II would need to eject $\sim 10^{-5}M_\odot$ per event. Explaining the r-process by ejecta of SNe II faces two difficulties: (i) whether the required entropies can really be attained in supernova explosions has still to be verified, (ii) the mass region 80–110 cannot be reproduced adequately. It has to be seen whether the inclusion of non-standard neutrino properties can cure both difficulties. It is also possible that none of this very high entropy matter escapes the neutron star surface and that outer mass zones in explosive He-burning introduce a 'fast' s-process, also dubbed an n-process, which just supplies the lower mass region ($A < 120$), missing or underproduced in some of the low metallicity stars, with the strongest r-process pollution. We should keep in mind that the question whether we understand fully all astrophysical sites leading to an r-process is not a settled one.

Conclusions

After an introduction into hydrostatic and explosive burning, the working of nucleosynthesis in general and its mathematical description, this overview concentrated on astrophysical sites or nucleosynthesis processes in the big bang, low and intermediate mass stars, type II and type Ia supernovae and analysed the options and sites of r-process nucleosynthesis. These are the major contributions to galactic chemical evolution.

Nucleosynthesis calculations have a right on their own to predict abundance patterns for many stellar events, but they can also serve as a tool to test the correctness of model descriptions, either in comparison to direct observations or indirect information from galactic evolution. We tried to show especially for SNe Ia and II how specific isotopic abundances can test ignition densities, burning front speeds, deflagration/detonation transitions or explosion energies (entropies), temperatures and delay times between collapse and explosion.

There exist other nucleosynthesis sites not mentioned here, e.g. (i) the p or γ process (explosive neon burning in possibly both types of supernovae, producing proton-rich stable nuclei via photodisintegration from pre-existing heavy nuclei), or events in binary systems like (ii) novae (small hydrogen accretion rates onto a white dwarf and explosive ejection of the accreted layer), and (iii) x-ray bursts (hydrogen accretion onto a neutron star and explosive processing of the accreted layer). With the possible exception of ^{15}N, ^{26}Al and other proton-rich nuclei lighter than S (in novae) or possibly some of the hard-to-make p-process nuclei in the range of Sr and Mo (in x-ray bursts), neither novae nor x-ray bursts are primary nucleosynthesis sites. This is due to the small or negligible amounts of ejected mass. The energy in x-ray bursts might not be at all sufficient to overcome the gravitational potential. But in all of these cases there exists very interesting nuclear physics on the proton-rich side of stability (rp-process), which is important to understand these explosive astrophysical events.

Nuffield Radio Astronomy Laboratories

The Nuffield Radio Astronomy Laboratories are a part of the University of Manchester's Department of Physics and Astronomy. They are located at Jodrell Bank in Cheshire, UK.

In 1945, while it still functioned as the university's botanical station, the site was used by Bernard Lovell to observe cosmic rays. The radio echoes he detected were soon found to come from meteors burning up in the atmosphere.

Under the initiative of Lovell and engineer Charles Husband, the world's largest fully steerable telescope was completed in 1957. One of its first tasks was to use radar to track Sputnik 1, the world's first artificial satellite, and its rocket's upper stage. It was then in great demand for sending and receiving telemetry from US and Soviet satellites, particularly lunar and planetary missions.

Through a donation by Lord Nuffield and the Nuffield Foundation, the debts outstanding on the telescope's construction were cleared. The Jodrell Bank Experimental Station then became Nuffield Radio Astronomy Laboratories. On the telescope's thirtieth anniversary in 1987, the 76 m Mark I telescope was renamed the Lovell Radio Telescope.

Small portable telescopes were later linked to the Mark I telescope by microwave radio links to create a radio interferometer. These instruments played a major role in the discovery of quasars in the early 1960s.

The parabolic 38 × 25 m MKII telescope, completed in 1964, was built to a similar design to the Goonhilly 1 telescope which received the first TV signals relayed by the Telstar satellite across the Atlantic. It was the first telescope of any type in the world to be controlled by a digital computer, the Ferranti Argus 100.

In 1976, work began on the building of a 134 km array of telescopes linked by microwave radio links to Jodrell Bank. Three new 25 m telescopes were built to add to the MKII, MKIII and Defford telescopes already operated by Jodrell Bank. These were located at Knockin, near Oswestry, Pickmere, north of Northwich, and Darnhall, south of Winsford.

In the early 1990s the array, now called MERLIN, was extended to include a new 32 m telescope at Cambridge. It can be linked to other observatories around the world for VLBI studies.

Current research at Jodrell Bank includes studies of stars, pulsars, galaxies, quasars, gravitational lenses, cosmic microwave background and SETI.

Numerical Simulation of Stellar Convection: Comparison with Mixing-length Theory

The energy released by nuclear fusion in the STELLAR INTERIOR is carried to the surface by two different transport mechanisms, *radiation* and *convection*. In the presence of a temperature gradient, there is always a net radiative energy flux since more photons travel from hot to cool regions than in the other direction. If the temperature gradient exceeds a certain threshold, convection sets in. The resulting large-scale circulation of hot rising and cool sinking gas constitutes a very efficient mode of energy transport, usually dominating over radiation.

While an elaborate theory of RADIATIVE TRANSFER is well established, a rigorous theory of stellar convection is lacking due to the complexity of the underlying hydrodynamical problem. So far, stellar structure models still rely on a phenomenological approximation, the so called *mixing-length theory* (MLT). However, radiation hydrodynamics simulations based on first principles can now provide physically consistent *ab initio* models of stellar convection which can serve to check the validity of MLT.

Stellar convection

Convection is a universal feature: essentially all types of stars have either a convective core, a convective envelope, or both. Low-mass stars are fully convective, giants may accommodate several distinct convective shells. In the case of the Sun, the energy transport in the inner parts is entirely due to radiation (radiative layers), while in the outer 28.7% (in radius) it is primarily due to large-scale convective currents. At the surface, the solar granulation is the visible imprint of gas flows in the outermost layers of the convection zone (see SOLAR INTERIOR: CONVECTION ZONE).

The role of stellar convection is far-reaching: convective energy transport determines the internal temperature structure of a star and its radius (which decreases with increasing convective efficiency), and hence controls the star's global properties. Convective regions are chemically completely mixed, and overshooting convective flows lead to partial mixing of the adjacent radiative layers. 'Overshoot' and similar mixing processes which are not confined to the convectively unstable layers are thought to be responsible for the existence of carbon stars, carbon-rich white dwarfs, and for the destruction of lithium in solar-type stars. Convective motions and concomitant temperature inhomogeneities exert a direct influence on stellar spectra, causing small but practically relevant changes in wavelength position, shape and strength of spectral lines. Stochastic convective motions can excite stellar oscillations (like the five-minute oscillations in the Sun) and are a source of acoustic energy, contributing to the heating of stellar chromospheres. In combination with DIFFERENTIAL ROTATION, convection is a necessary precondition for the operation of the magnetic dynamo mechanism, and hence for STELLAR ACTIVITY.

Schwarzschild criterion

A region in a star is convectively unstable if a gas element which is displaced from its equilibrium position is further accelerated due to buoyancy forces. In 1906, K Schwarzschild discovered that this situation occurs whenever the temperature stratification is superadiabatic, i.e. $\mathrm{d}\ln T/\mathrm{d}\ln P > (\mathrm{d}\ln T/\mathrm{d}\ln P)_{\mathrm{ad}}$, where T and P denote temperature and gas pressure, respectively (*Schwarzschild criterion*). For stellar applications (inviscid fluids), this is the necessary and sufficient condition for convective instability of a chemically homogeneous layer. In terms of the specific entropy, s, the criterion can be rewritten as $\mathrm{d}s/\mathrm{d}z < 0$, implying convective instability wherever entropy of the gas decreases with height, z.

In the envelope of stars, convective instability is favored by large radiative opacities (steep radiative temperature gradient) and large specific heats (small adiabatic temperature gradient). This situation is found particularly in regions where an abundant element (hydrogen or helium) is partially ionized. Convective instability also occurs in the core of main-sequence stars more massive than $\approx$1.3 times the Sun, where the strong temperature dependence of nuclear fusion rates leads to very steep temperature gradients.

For a given stellar structure, the Schwarzschild criterion can be used to determine the location of convective regions. However, it does not give any information about the properties of the corresponding convection zone, like flow velocities and convective energy flux. Moreover, since convection changes the thermal structure, the boundaries of the unstable region depend on the convective efficiency. In addition to the Schwarzschild criterion, a theory of convection is required to compute the structure of stellar convection zones in a self-consistent way.

Mixing-length theory

As a 'first approximation', the mixing-length theory was developed mainly by Biermann (1932), Cowling (1935), Vitense (1953), and Böhm-Vitense (1958). The underlying picture is that of turbulent elements ('bubbles') moving relative to a mean background stratification. In an unstable region, elements accelerated upwards gain an excess of thermal energy, while downward moving elements cool relative to their surroundings. After traveling some characteristic distance, ℓ, the 'bubbles' are assumed to dissolve completely. The mixing length, ℓ, determines the mean flow velocity, the typical amplitude of horizontal temperature fluctuations and the resulting convective energy flux.

This simplistic formalism is unsatisfactory in several respects. First of all, the mixing length, ℓ, which is usually expressed as $\ell = \alpha H_{\mathrm{p}}$ (where the local pressure scale height, H_{p}, measures the distance over which the gas pressure changes by a factor e^{-1}), is a *free parameter*. The *mixing-length parameter* α is *a priori* unknown and must be determined empirically; its value may depend on stellar type. Moreover, MLT is a local theory: convection

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

is restricted to the unstable region as defined by the Schwarzschild criterion, and the transport properties of convection are assumed to depend only on local thermodynamic variables and their local gradient. But actually convection is non-local: the velocity of a gas element at some point, for example, is determined by the acceleration it has experienced before along its path, not by local conditions. Obviously, MLT is not based on sound physical principles, and some of the basic assumptions are not even valid in real stars. Still, almost all current stellar evolution models rely on this phenomenological 'theory'. The same holds for modeling convective STELLAR ATMOSPHERES.

Numerical simulations

The differential equations governing the physics of stellar convection are well known but difficult to solve: these are the conservation equations of hydrodynamics, coupled with the equations of radiative transfer. While their highly nonlinear and non-local character precludes an adequate analytical treatment, the numerical integration of the system of partial differential equations has now become feasible. This approach constitutes an increasingly powerful method to study in detail the time-dependent properties of a radiating, partially ionized fluid under stellar conditions.

Using modern supercomputers, it is possible today to perform three-dimensional numerical simulations of stellar convection with realistic background physics (equation of state, radiative opacities). Although such simulations are usually confined to a small section near the surface, even two-dimensional convection models require substantial amounts of computer time, particularly for solving the multidimensional, non-local radiative transfer problem in several wavelength bands, taking into account the influence of spectral lines. In order to yield meaningful information, the simulated time sequence must be long enough to ensure relaxation towards a statistical steady state which is independent of initial conditions. Also, the horizontal size of the computational domain must be large enough to accommodate at least two 'convection cells'.

Just like 'classical' stellar atmospheres, the hydrodynamical models are characterized by the average total energy flux per unit area and time F (related to the *effective temperature* of the stellar atmosphere $T_{\rm eff}$ via $F = \sigma T_{\rm eff}^4$, σ being the Stefan–Boltzmann constant), *surface gravity* g, and *chemical composition*. But in contrast to the mixing-length models, there is no longer any free parameter to adjust the efficiency of the convective energy transport. Similarly, spatial and temporal scales are not imposed on the simulations, but rather develop naturally as a consequence of the underlying equations.

MLT versus hydrodynamics

Time-dependent numerical simulations of stellar convection can be used for a qualitative comparison with the basic picture and assumptions underlying the mixing-length theory, and for a quantitative comparison of the average transport properties.

While the granules ('bubbles') seen at the solar surface have a typical size (dominant contribution to area coverage) of ≈1 000 km, the 'bubbles' considered in mixing-length models have a size of the order of $\alpha H_{\rm p}$, which is about five times smaller. Clearly, the MLT concept of single-sized 'bubbles' must not be taken too literally. On the other hand, the numerical convection models are capable of reproducing the size distribution of solar granules and other statistical properties rather well. As these models teach us, the typical granule size is determined by a complex interplay of nonlinear dynamics and radiative energy exchange.

According to the simulations, the dynamics of convection is dominated by *fast, cool, narrow downdrafts* (sometimes also called 'plumes' or 'jets'), embedded in much more extended, slowly ascending, warm material (granules). This pronounced up/down asymmetry is a general feature of the numerical models (2D as well as 3D), and is seen for all types of stars investigated so far. Obviously, this result is in stark contrast to the picture of MLT: instead of 'bubbles' traveling for about one pressure scale height before dissolving, we actually have deep-reaching 'jets' surviving over many $H_{\rm p}$, possibly extending all the way to the base of even deep convective

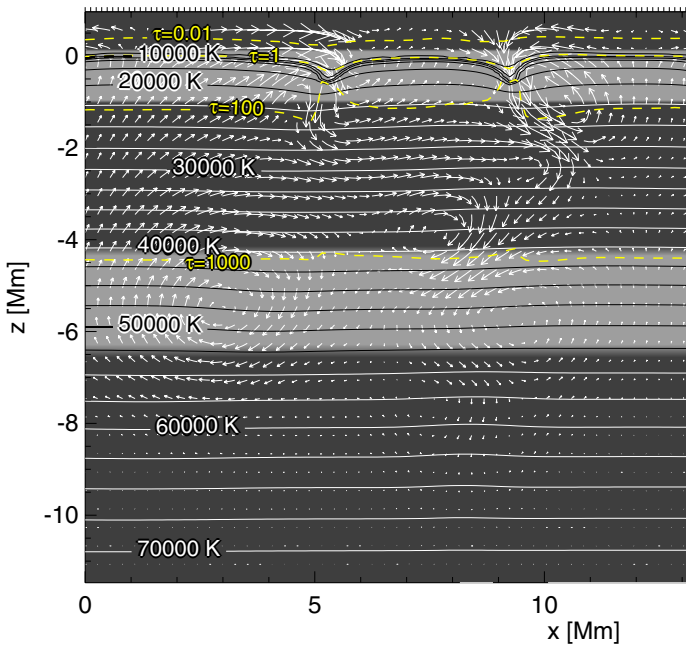

Figure 1. Snapshot from a 2D simulation of convection in an A-type star ($T_{\rm eff} = 80$ two separate convection zones. The unstable regions ($d\bar{s}/dz < 0$, $\bar{s}$ being the horiz gray. The velocity field is represented by pseudo streamlines, indicating the displa velocity 15.4 km s^{-1} at this moment); the thermal structure is outlined by tempera levels of constant optical depth ($\tau = 0.01, 1, 100, 1000$). Geometrical height $z = 0$ c non-local, multidimensional radiative energy exchange and partial ionization. The zone; lateral boundaries are periodic. The 'dents' seen at the 'surface' ($z = 0$) are t intergranular lanes. (From Freytag *et al* (1996)).

envelopes. The downward 'jets' originate and are accelerated in the stellar surface layers, which are highly unstable (steep temperature gradient, density inversion) as a consequence of efficient radiative cooling. Since their temperature deficit relative to the surroundings is determined by the efficiency of surface cooling, convection is an extremely non-local process. The properties of the surface determine the dynamics and structure of the whole convection zone. Certainly, the inherently 'linear' approach enforcing symmetry between up and down, as well as the assumption of locality, are the major problems with MLT.

A variety of observations (e.g. the fact that the granulation is still visible at the solar limb, corresponding to optical depths $\tau < 0.3$), and numerical simulations indicate that convective flows are not limited to the Schwarzschild-unstable regions, but rather must penetrate into the adjacent stable layers by some amount. Though not inherent in MLT, the problem of 'overshoot' was first recognized, considered and discussed in the original work by Vitense (1953). There is no simple rule to predict the amount of 'overshoot', since it depends on the nature of the particular convective boundary under consideration.

The role of 'overshoot' is illustrated in figure 1. In this A-type main sequence star there are two distinct convection zones: the one at the surface is driven by the combined first ionization of hydrogen and helium, the deeper one is related to the second ionization of helium. Although the Schwarzschild-unstable regions are separated by a stable radiative layer extending over more than two pressure scale heights, they are effectively connected by vigorous convective currents; the stable buffer layer is completely mixed, in contrast to MLT predictions.

It is a physical property of overshoot that the pressure field that serves to drive the motions in the unstable regions extends far into the stable layers and accelerates the fluid there, even though the thermal stratification is convectively stable. The hydrodynamical simulations demonstrate that the velocity field due to overshooting declines exponentially with distance from the Schwarzschild boundary. In the example of figure 1, the velocity scale height below the He II convection zone is $H_v \approx 0.3 H_p$. 'Overshoot' above the surface convection zone is the explanation for 'microturbulence' and the asymmetry of spectral lines; it cools the upper photosphere slightly below radiative equilibrium temperatures.

In order to achieve agreement between observed and computed stars (isochrone fitting), stellar evolution models have to include some amount of 'overshoot', which is usually implemented by introducing another parameter, d_{over}, specifying the distance (in terms of H_p) by which convection penetrates into the stable layers. This empirical approach ignores the hydrodynamical results indicating that 'overshoot' is characterized by an exponential velocity field causing (partial) diffusive mixing.

A quantitative comparison of mixing-length models and averaged results from numerical simulations has been performed for various stellar types, including the Sun, A-type main sequence stars and DA WHITE DWARFS. The result is similar in all cases: no single choice of α can produce a detailed match of the structure of the hydrodynamical models in the framework of MLT. Adjusting α can only serve to fit particular properties, like maximum convective flux or maximum convective velocity, but it is impossible to reproduce the depth dependence of these quantities correctly. This point is illustrated in figure 2: while $\alpha = 1.5$ gives the correct maximum enthalpy flux, $F_{h,max}$, MLT fails to match the flux profile $F_h(z)$ even roughly. A much larger α would be required to reproduce the correct depth of the convection zone ($F_h > 0$). This result resolves an apparent inconsistency which arises when modeling ZZ CETI STARS (a class of non-radially pulsating white dwarfs) with MLT. The observed spectrum (atmospheric structure) is best described adopting a moderate value of $\alpha \approx 1.5$, but at the same time a large convective efficiency ($\alpha > 2.5$) is required for driving the observed pulsations of these stars. Note that the simulations show a distinct region of negative (downward) F_h—due to 'penetration' into the stable layers—and a significant negative kinetic energy flux. Both these features are missing in MLT.

While it seems hopeless to successfully model the structure of the superadiabatic surface layers within the framework of MLT, it is possible to calibrate MLT through

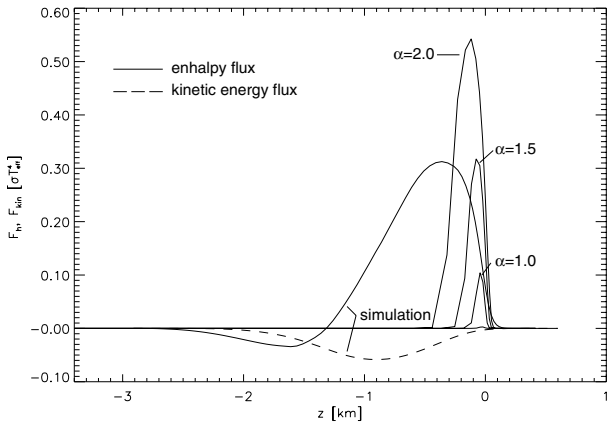

Figure 2. Comparison of the enthalpy flux, $F_{\rm h}$, predicted by MLT for different α and a 2D hydrodynamical simulation for the outer layers of a DA white dwarf ($T_{\rm eff} = 12\,200$ K, $\log g = 8.0$ [cgs units]). The flux of kinetic energy, which is ignored in MLT, is negative (downward) according to the simulation. (Adapted from Freytag *et al* (1996)).

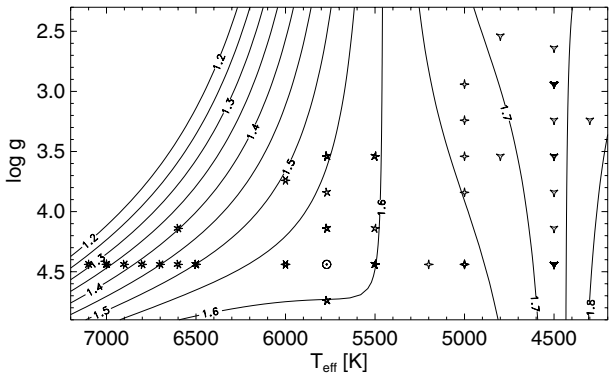

Figure 3. Calibration of the mixing-length theory for stellar evolution calculations based on 2D hydrodynamical simulations of surface convection. Symbols indicate that at least one simulation has been performed for the corresponding stellar parameters. For each simulation, an effective mixing-length parameter α has been determined from a differential comparison with MLT models. Contour lines, labeled with the respective value of α, visualize the derived variation of α as a function of $T_{\rm eff}$ and $\log g$ (From Ludwig *et al* (1999)).

hydrodynamical simulations for application to STELLAR EVOLUTION. The key quantity here is the entropy jump, Δs^*, from the surface to the interior, which can be 'measured' from the simulations. MLT can then be calibrated by adjusting α to produce the given Δs^*. This procedure gives the correct adiabat and depth of the convective envelope, as verified for the Sun by comparison with helioseismic measurements.

For a sample of 'solar-type' stars, the result of this calibration is shown in figure 3. It is the first theoretical prediction of how the mixing-length parameter α depends on stellar type. According to this calibration (which needs to be verified by 3D hydrodynamics), the variation of α over the investigated region of the HERTZSPRUNG–RUSSELL DIAGRAM is only moderate (from 1.8 to 1.2 for spectral type K to F). Certainly, this is one of the reasons for the surprising success of MLT over the past 40 years.

There have been many attempts to improve MLT. A recent example is the CGM model (Canuto, Goldman and Mazzitelli 1996), which accounts for the full spectrum of eddy sizes in a turbulent flow and adopts a mixing-length of the form $\ell = z + \zeta H_{\rm p}^{\rm top}$, where z is the distance to the (nearest) Schwarzschild boundary and ζ is a free parameter related to 'overshoot'. In comparison with MLT, CGM makes efficient convection more efficient and inefficient convection less efficient, implying that the variation of ζ across the Hertzsprung–Russell diagram is even smaller than that of α. Further claims that CGM is superior to MLT need to be verified. It is highly doubtful, however, that convection can be properly described in terms of classical turbulence, since the basic assumptions typically made in these models are found to be violated in the hydrodynamical simulations: in a stratified medium, large-scale motion is strongly anisotropic while small-scale turbulence is confined to the downdrafts and contributes little to the energy transport, which is dominated by scales exceeding the local pressure scale height by an order of magnitude.

Further details can be found in the article on SOLAR INTERIOR: CONVECTION THEORY.

Nutation

Short-period oscillations in the long-term motion of the pole of rotation of a rotating body that is being acted on by external perturbing forces. In the case of the Earth, the gravitational attractions of the Sun and Moon on its equatorial bulge causes the direction of its axis, and hence the positions of the celestial poles, to revolve slowly around the pole of the ecliptic (the points on the celestial sphere 90° away from the ecliptic), this phenomenon being called precession. Because the orbital plane of the Moon is inclined to the plane of the ecliptic by an angle of about 5°, and revolves round the Earth in a period of 18.6 years, an additional small oscillation in the position of the celestial poles is superimposed on the general precessional motion. The effect of this additional motion is to cause the Earth's poles (and hence the celestial poles) to tilt, or 'nod', periodically toward and away from the poles of the ecliptic, the term 'nutation' deriving from this 'nodding' motion. The magnitude of this nutational motion is about 9 arcsec, and its period of oscillation is 18.6 years. Nutation also gives rise to a corresponding periodic variation in the obliquity of the ecliptic.

See also: celestial poles, ecliptic, node, obliquity of the ecliptic, precession.

OB Associations

The term OB association is used to describe a large collection of gas and young stars (O-type and B-type) located primarily in the disk of SPIRAL GALAXIES. There is a great variance of size and star number among these associations, from ten stars or fewer at the lower end up to tens of thousands of stars. The latter case is sometimes referred to as an OB superassociation (NGC 206 in the ANDROMEDA GALAXY, for example).

OB associations are among the least dense of the STAR CLUSTERS. Most OB associations lack the structure and central compactness present in the more easily discernible GLOBULAR CLUSTERS. In some cases, the overpopulation of O-type and B-type stars is the only factor that allows the association to be distinguished from the remaining stars in its vicinity. Because of this lack of structure, OB associations fall within the category of open clusters.

There is a considerable difficulty in studying a complete sample of OB associations in our own galaxy. This difficulty arises from the fact that OB associations, as well as the other types of open clusters, are highly concentrated toward the GALACTIC PLANE. This means that the more distant OB associations in our galaxy will most likely be obscured by dust. As a result, studying the distribution of OB associations in other nearby galaxies allows us to learn more about the probable distribution of such associations in the Milky Way.

One of the most important roles for OB associations in the field of astronomy is to act as tracers for both current and recent massive STAR FORMATION. In other words, regions where OB associations are found are interpreted as areas where massive stars are currently being formed or have just recently been formed. If knowledge can be gained regarding the environments in which OB associations tend to be found, then that knowledge should directly lead toward what environments trigger massive star formation.

Determining the most accurate description for the dimension and content of any OB association requires knowledge about the spectral type of each potential member star. For our own galaxy, as well as other nearby galaxies, this is at least within the realm of possibility. It should be noted that nearby galaxies with small inclination angles are preferred, since this minimizes complications due to projection effects. For galaxies that are more distant, only signatures from the associations as a whole can be detected. This can be done from the actual stars themselves (ultraviolet light) or from the gas surrounding the stars as it becomes excited (Hα emission). It should be noted that while all OB associations will have an overdensity of O-type and B-type stars by definition, some may be of sufficient age that they will not have a detectable amount of gas remaining around them.

Current research is being done to locate OB associations both in the Milky Way and in other nearby galaxies. Information from both catalogs, such as HIPPARCOS AND TYCHO CATALOGUES, and observations, including some from the HUBBLE SPACE TELESCOPE, is being used in these projects. This research is very important to the understanding of the distribution of OB associations and the environments in which massive stars are most likely to form.

Oberon

A mid-sized satellite of Uranus, discovered by William Herschel in 1787. Its diameter is 1520 km and it orbits at a distance of 191 000 km. The images of Oberon obtained by Voyager 2 were not clear, but were enough to show an extensively cratered surface, some craters surrounded by bright ejecta or rays, and some with dark floors, possibly a result of the eruption of water ice mixed with organic material. The largest crater is the 206 km diameter Hamlet. An 11 km mountain peak, possibly the central peak of an impact basin, was visible on the limb. The preponderance of craters suggest that this is an ancient surface, largely undisturbed by geological activity, save for the 500 km muted fault feature Mommur Chasma. One hemisphere is rather redder than the other, perhaps as a result of dust accumulated from the two small outer retrograde satellites of Uranus. Like most of Uranus's satellites, Oberon has captured rotation, so the dust would be swept up by the leading hemisphere.

Oberth, Hermann (1894–1989)

German space travel visionary, born in Sibiu, Hungary. His book *Die Rakete zu den Planetenrämen* (*The Rocket into Interplanetary Space*), established his reputation in 1923, and he became president of the German Society for Space Travel. In the Second World War he worked on rockets at Peenemünde, and went with WERNHER VON BRAUN to the US Army Ballistic Missile Agency in Huntsville, Alabama to develop rockets in the American space program.

Objective Lens

The principal lens of a refracting telescope, which collects light from a distant object and forms an image of the object at its focus, or focal plane. The objective lens, or objective, is also known as the object glass (OG) because, in a telescope, it is the lens nearest to the object that is being imaged.

The simplest form of objective is a single biconvex lens in which the curvature of each face corresponds to part of a sphere, the radius of which is called the radius of curvature. A ray of light passing through the center of the lens, perpendicular to its surface, passes through undeviated. Rays entering other parts of the lens meet its surface at an angle to the perpendicular and are refracted (deflected) so as to converge together and form an image. A simple objective lens of this kind suffers from a number of optical defects, or aberrations, notably spherical aberration (an inability to bring rays that enter different parts of the lens to the same focal point) and chromatic aberration (an inability to bring all wavelengths, or colors, to a focus at the same point). Chromatic aberration arises because different wavelengths of light are refracted by differing amounts, shorter wavelengths (e.g. blue) being refracted more than longer wavelengths (e.g. red). Consequently, blue light is brought to a focus closer to the lens than red light and the focal points for the various different colors lie at different points along the optical axis (the line that passes perpendicularly through the center of the lens). The range of focal points for light of different wavelengths is called the longitudinal chromatic aberration, or secondary spectrum.

Both of these aberrations are considerably reduced by the achromatic lens, a compound lens consisting of two components, each made of different kinds of glass with different optical properties. The combination of two lenses is called an achromatic doublet. An achromatic doublet normally consists of a converging (biconvex) lens, usually made of crown glass, and a diverging lens (usually plano-concave: concave on the front surface and flat on the back), usually made of flint glass. The radii of curvature are chosen so that the positive spherical aberration introduced by one component is to some extent cancelled by the negative spherical aberration induced by the other. The different dispersive powers (ability to refract different wavelengths by differing amounts) of the two types of glass are used to minimize the spread of focal positions. An achromatic doublet is normally figured (shaped) to bring two particular wavelengths, for example 400 nm (indigo) and 600 nm (orange), to the same focal point. The spread in focal positions for the other wavelengths are usually reduced by a factor of 10–20 compared to the spread that would be produced by a single lens. The addition of a third lens further reduces the spread of focal positions. A three-element objective lens is called an apochromat.

As the residual chromatic aberration decreases with increasing focal ratio, achromatic doublets usually have focal lengths that are at least ten times their apertures (focal ratio f:10 or more). Objective lenses with large focal ratios have small fields of view. Where a wider field of view and shorter focal ratio is required, an apochromat is normally used.

Oblateness

The degree of flattening of an oblate spheroid, the solid body obtained by rotating an ellipse about its minor axis. The shape of the Earth is approximately an oblate spheroid, for the equatorial diameter is slightly greater than the polar diameter. Jupiter and Saturn are considerably more oblate than the Earth. If a hypothetical planet had a polar radius of 10 000 km and an equatorial radius of 20 000 km, the oblateness (or flattening) would be:

$$\frac{20\,000 - 10\,000}{20\,000} = 0.5.$$

By measuring the degree of flattening at the poles of a planet as compared with the speed of rotation, it is possible to infer the density distribution inside the planet. If two planets had the same mass and bulk density, the planet with most of its mass concentrated close to the center would be more flattened by rotation. For example, from the relatively small oblateness of Uranus combined with the planet's relatively rapid rotation, it would appear that its constituents, ice and gas, are well mixed and a rocky core is small or non-existent.

Obliquity of the Ecliptic

The angle between the planes of the ecliptic and the equator. On the celestial sphere, the angle at which the ecliptic intersects the celestial equator. The current (year 2000) value of the obliquity of ecliptic, which is denoted by the symbol ε, is $23^\circ\ 26'\ 21''$. Its value varies by $\pm 9''$ over a period of 18.6 years as a consequence of a phenomenon called nutation. Over a much longer period (about 40 000 years) the perturbing influence of the planets causes its value to vary between $21^\circ\ 55'$ and $28^\circ\ 18'$; currently ε is decreasing at an average rate of about $0.5''$ per year.

Observatoire de Besançon

Founded in 1878 to provide an astronomically derived time reference service for the region's watch-making industry, the Observatory today continues its research and service activities in the field of time and frequency metrology and has also developed active research groups in the fields of stellar and galactic evolution and the chemical physics of astrophysical media. A galactic stellar population simulation model and a database of double and multiple stars may be consulted via the Observatory's web site. Occupying an attractive park and buildings, the Observatory's instruments include a meridian telescope (2.37 m focus, 19 cm diameter) dating from the 1880s, an astrograph (two 3.5 m and one 3 m focal length instruments) commissioned in 1956 and a modern time and frequency laboratory equipped with three cesium atomic clocks. The staff is made up of 16 university lecturers and other researchers, 11 engineers and technical personnel and 6 support staff, plus a variable number of students up to PhD level. The Observatory is a part of the Université de Franche-Comté and is recognized by the Centre National de Recherche Scientifique (CNRS/INSU) and the Bureau National de Metrologie (BNM).

Observatoire de la Côte d'Azur

This French public institute was founded in 1988, with the mission to collect and interpret astronomical data. In 1881 Raphael Bischoffsheim founded and equipped its oldest component, Nice Observatory. The dome of its great refractor, 76 cm, was built by Eiffel. The second component, the CERGA, founded in 1974 for positional astronomy, is located near Grasse.

Observatoire de Lyon

The Observatoire de Lyon is a laboratory of Université Claude Bernard Lyon1, under the authority of the INSTITUT NATIONAL DES SCIENCES DE L'UNIVERS. It constitutes the Centre de Recherche astrophysique de Lyon together with the astrophysics group of the École Normale Supérieure de Lyon.

It operates a 1 m Ritchey–Chrétien telescope, which is now mainly used by students and the general public. Formerly installed on the summit of Gornergrat in Switzerland, the instrument was returned to Lyon in 1983 for trials of various instruments—including photometers, an infrared camera and the OASIS spectrograph—that were developed at the observatory.

Observatoire de Marseille

The Marseille Observatory was founded by the Jesuits in 1702 and taken over by the State in 1763. A century later it was transferred to its present site on the Longchamp Plateau in Marseille, southern France.

The observatory, which is part of the University of Provence, belongs to the Provence Astronomical Federation. It owns an 80 cm telescope, made in 1867 by Léon Foucault, which was the first large telescope with a silvered mirror ever built. It was used for observations until 1960 and designated an historical monument in 1993.

The observatory is funded by a number of sources including the Ministry of Higher Education and Research, CNRS, the Gassendi Institute and regional authorities. It also carries out research and contracts for industry, and participates in international projects such as the CANADA–FRANCE–HAWAII TELESCOPE and the EUROPEAN SOUTHERN OBSERVATORY.

Scientific research covers all areas of astronomy, from optical to radio and infrared observations.

Observatoire de Paris

The Observatoire de Paris is the largest French institution dedicated to astronomy. Created in 1667 by Louis XIV to define the 'Méridien de Paris' and then devoted to metrology, celestial mechanics and positional astrometry, it further developed many branches of astrophysicis and is now established on three sites: the initial Paris Observatory, the Meudon Observatory (south-west suburb of Paris) appended in 1926, and the radioastronomy facility of Nançay (central France), appended in 1953. Research activities cover many fields from theoretical to observational astronomy, experimental physics and chemistry, instrument development for international ground-based observatories and space experiments for astronomy and planetology missions. Services related to its research activities are provided to the astronomical community (time and frequency metrology, solar monitoring, International Earth Rotation Service, etc). The observatory also has an educational mission and provides an astrophysical research degree and PhD course, courses in astronomy for high school teachers, visits and exhibitions for the public.

The Observatoire de Paris is a governmental institution. Its sources of support are, for the most part, contracts with the Ministère de l'Education Nationale, de la Recherche et de la Technologie (MENRT), the Centre National de la Recherche Scientifique (CNRS), the Centre National d'Etudes Spatiales (CNES), the European Community, or with European scientific agencies such as the EUROPEAN SOUTHERN OBSERVATORY (ESO) or the EUROPEAN SPACE AGENCY (ESA).

The Observatoire de Paris comprises ten research groups. Its staff is of about 800 people, of whom 640 are on permanent jobs (230 scientists) and 160 are students and research fellows on long-term contracts.

Observatoire de Section de Meudon, Paris

The Meudon Observatory in France was founded on an old royal estate in 1876. It was built with public funds and placed at disposal of astronomer Jules Janssen, in order to allow him to develop his research on solar spectra far from urban pollution.

Several instruments were installed by 1893: an 83 cm refractor placed under the dome over the castle; a 1 m reflector, which was restored in 1969; and various spectroheliographs and siderostats. Later additions included an equatorial table, a 60 cm telescope, and a solar tower, which was used for spectroscopic studies of the Sun.

It merged with the Paris Observatory in 1926. The section is now devoted to theoretical astrophysics, with departments devoted to studies of stars, the interstellar medium, galaxies and cosmology.

Observatoire de Strasbourg

The Strasbourg Astronomical Observatory, located in Strasbourg, France, is a research unit of Université Louis Pasteur and CNRS. It hosts teaching and research activities, the services of the Strasbourg Astronomical Data Center (CDS), and public outreach activities, with its Planetarium.

Founded in 1881, the Strasbourg Observatory currently carries out research in the following fields: stellar populations and galactic evolution, galactic dynamics, high-energy astrophysics, data and information management. It is active in the development and exploitation of space missions such as Hipparcos or XMM.

The Data Center is used by professional astronomers worldwide for its databases and services related to astronomical objects outside the solar system.

Observatoire des Sciences de l'Univers de Bordeaux

Ground-based observations (meridian circle, radiotelescope, magnetic resonance spectrometer, radiometer, specrophotometer) are one of the main features of 'Observatoire des Sciences de l'Univers de Bordeaux, laboratoire d'astrodynamique, d'astrophysique et d'aéronomie', which is located in its original place of foundation, in 1878, at Floirac, in the suburbs of Bordeaux.

Dedicated to research, teaching and science for the general public, the Observatory is run by the Centre National de la Recherche Scientifique (CNRS), and the Teaching and Research Ministry. There are about thirty scientists and students, and six research groups: astrodynamics: (astrometry/Hipparcos, galactic dynamics, dynamic of the solar system, nucleus of galaxies); radio-astronomy (interstellar medium, galaxies and quasars, star formation, space missions (First, Rosetta)); radio-aeronomy (ground based microwave radiometry, space radiometry (UARS, Odin), ozone international network); atmosphere of planets (photochemistry of giant planets, primitive atmospheres, atmosphere of Mars (Mars-Express probe), and Saturn (Huygens probe)); Exobiology (prebiotic atmosphere of the Earth, extra-terrestrial molecules and matter); and exoplanets.

Observatoire des Sciences de l'Univers de Grenoble

Young stars and their environment, their formation and evolution, plasmas in active galactic nuclei, together with adaptive optics and optical interferometry research and development, are the main activities of the Laboratoire d'Astrophysique. Created in 1979 on the campus, later forming the Observatoire with geophysical laboratories, it has a permanent staff of around 50. It is a joint facility of CNRS and the Joseph Fourier University.

Observatoire Royal de Belgique

This observatory was founded in 1826 and installed in the present site in 1891. It is organized into four departments, concerned with public services and scientific activities in: time; Earth rotation; space geodesy; seismology; Earth tides; gravimetry; astrometry and dynamics of objects in and outside the solar system, astrophysics of Galactic and extra-Galactic objects; stellar atmospheres; and solar physics (structure and dynamics of the solar atmosphere, solar activity). The library contains about 120 000 books. A large Planetarium, receiving about 30 000 visitors each year, is managed by the Royal Observatory. The budget is supported by the Ministry on Science Policy (60%) and by special projects initiated by the Royal Observatory (40%).

The staff is composed of 32 permanent researchers and 50 technicians, who collaborate in public services and scientific researches, administration and maintenance. Also there are, on average, 10 to 15 researchers on contract (PhD students, post-doctoral positions. . .).

Observatories and their Location

As astronomy and astronomical instruments have evolved over the centuries, so too have observatories.

Up to the seventeenth century, observatories were usually privately owned. Rulers, wealthy land-owners and members of the aristocracy sponsored both the instruments and the astronomers who operated them. The first observatories were built where the sponsors had land that was available. For example, Castle of the Heavens. TYCHO BRAHE was sponsored by King Frederick II of Denmark, who built him a castle called Uraniborg (*Star-city*) on the island of Hveen (now Ven).

In their second phase of development, observatories were a mixture of private facilities, perhaps owned and operated by a wealthy amateur, and public organizations, owned and funded by universities (too many to mention), cities and regional governments (for example, Florence, Palermo, ...), churches or other religious foundations (for example, the ARMAGH OBSERVATORY, founded by the Archbishop of Ireland), and scientific societies (for example, the Portuguese Royal Academy of Sciences).

In recent times, the costs of big telescopes being so large, major observatories have been funded by government agencies (the Russian Academy of Sciences, the French Institut National des Sciences de l'Univers, the National Research Council of Canada, ...), or by associations of public bodies (such as AURA, the ASSOCIATION OF UNIVERSITIES FOR RESEARCH IN ASTRONOMY, operator of the KITT PEAK NATIONAL OBSERVATORY and the CERRO TOLOLO INTERAMERICAN OBSERVATORY for American university astronomers). Private finance is still a factor, however, as in the W M KECK OBSERVATORY (capital finance from the Keck private foundation and running costs through the California Institute of Technology and the grants that it obtains) and the SETI INSTITUTE (privately financed).

The major observatories of the current generation and the future are and will be financed and operated by international consortia. Sometimes this is obvious in their names (like the ANGLO-AUSTRALIAN OBSERVATORY, the CANADA–FRANCE–HAWAII TELESCOPE, and the EUROPEAN SOUTHERN OBSERVATORY), sometimes not (like the ISAAC NEWTON GROUP OF TELESCOPES on La Palma, the GEMINI OBSERVATORY, or the ATACAMA LARGE MILLIMETER ARRAY, ALMA).

The transition to state-operated observatories began in the seventeenth century. In Britain, King Charles II approved the foundation of the ROYAL OBSERVATORY AT GREENWICH in 1675 in order to produce a new star catalog that would assist British seafarers. Since the Royal Navy paid for it, the observatory was located on a hill overlooking the busy wharves along the River Thames and within an easy carriage drive of the royal palace and Admiralty buildings in London. Because of its location in a royal park, the observatory's architect, SIR CHRISTOPHER WREN, acknowledged that he designed it 'a little for pompe'.

Although the importance of dark skies was generally recognized, astronomers had to accept poor weather as a price for accessibility in the days when transportation was not as easy as now. Thus, two optical telescopes that held the title of 'world's largest' prior to the twentieth century were built in locations that today would be considered completely inappropriate for world-class observatories. In 1789, funded personally by King George III, William Herschel (see HERSCHEL FAMILY) placed his 40 ft (focal length), 48 in (aperture) reflector in Slough, a low-lying rural area near Windsor next to the River Thames. Lord ROSSE himself financed his 72 in 'Leviathan of Parsonstown', which was built in 1845 in the grounds of his home, Birr Castle in Ireland, a site surrounded by numerous peat bogs.

As time went by, urban expansion, increasing air pollution from smoke and light pollution meant that observatories located near cities were increasingly at a disadvantage. Thus, the VATICAN OBSERVATORY, which was formally founded by Pope Leo XIII in 1891, was originally located in the Vatican gardens behind St. Peter's Basilica. As light pollution increased, it was moved out of Rome to the Papal summer residence at Castel Gandolfo. By the 1970s, light pollution from the nearby city had become so bad that it was decided to relocate the observatory to Arizona.

A similar process occurred in the case of the Royal Observatory at Greenwich. In the 1950s, the observatory's main telescopes were removed from the growing, smog-ridden metropolis of London to the Sussex countryside at Herstmonceux. This site, whether or not it was among the best possible sites in the UK, suffered from the damp English climate with its frequent cloud cover and poor seeing conditions, and the population growth of the south coast area increased sky background. As a result, the main instrument, the 2.5 m (98 in) Isaac Newton Telescope, was relocated to La Palma in the Canary Islands in 1990.

Much the same happened with the Paris Observatory (OBSERVATOIRE DE PARIS) that was commissioned by King Louis XIV in 1667. Although accessible from the King's main place of residence it was originally built so far from the center of Paris that it never grew, as planned, into the cultural center of the then Royal Academy of Sciences. It is now surrounded by the city. The observatory established a new campus south of the city, at Meudon, for observing facilities, but French astronomers' attention has shifted since to more remote telescopes in ESO and on Hawaii. As one further example, the national operation of the Helsinki Observatory in Finland was also moved from its hill-top site, in land originally outside the city, first to Turku and then to Tuorla in the countryside. Finnish astronomers' attention is now focused on the NORDIC OPTICAL TELESCOPE on La Palma and towards ESO.

Radio observatories have likewise been established, first in fields near to universities and research institutes, and then in radio-quiet zones, like GREEN BANK, West Virginia.

Nevertheless, the vast majority of observatories remain located with accessibility in mind, near the sponsoring body; if a telescope is intended for use by students or by the public, then accessibility is the over-riding concern. This means that most observatories for general use are in or near cities.

Mountain sites and city lights

In a famous passage in *Opticks* (1730), ISAAC NEWTON wrote that telescopes 'cannot be so formed as to take away that confusion of rays which arises from the tremors of the atmosphere. The only remedy is a most serene and quiet air, such as may perhaps be found on the tops of the highest mountains above the grosser clouds'. Modern technology has, in recent times, proved Newton wrong in the first statement but his second statement was proved correct in 1856. The Astronomer Royal for Scotland, CHARLES PIAZZI SMYTH, mounted an expedition to the mountain of El Teide on the island of Tenerife in the Canary Islands. Re-erecting the 18 cm telescope with which he had made calibrating observations in Edinburgh, approximately at sea level, he found that he could see stars that were four magnitudes fainter through the more transparent mountain air at altitudes of 2700–3200 meters. He could also distinguish closer double stars, because the seeing was better.

The first large observatory built on a mountain summit according to Newton's conjecture and Smyth's experiments was LICK OBSERVATORY, opened on Mount Hamilton in northern California in 1888 at an altitude of 1280 meters. There one of the world's largest refracting telescopes was built (the 36 in refractor), funded by a wealthy private donor, James Lick.

Over the following decades, many leading mountain observatories sprang up in the dry, clear air of the American west. In California, the world's largest (at the time) reflecting telescopes were installed. The 100 in Hooker Reflector was built in 1917 at MOUNT WILSON OBSERVATORY near Pasadena and the 200 in Hale Reflector in 1948 at Mount PALOMAR OBSERVATORY near San Diego. An almost permanent temperature inversion below the mountain tops more or less guaranteed low atmospheric turbulence and a cloudless sky. Even with the increase in urban sky glow as a result of the development of California since those times, these sites remain competitive in terms of 'SEEING' and image quality (table 1). Mount Wilson, for example, is the host site of CHARA, an optical interferometer, to which, since it works with bright stars, artificial sky glow matters little.

Table 1. Loss of effective aperture and value due to urban sky glow. In the table that follows, *X* is the sky glow level. A value of 1.0 designates the natural sky background, without any human contribution; a value of 1.2 means a 20% increase above the natural sky background due to a man-made skyglow; 2.0 is double the natural background, and so on.

X	Equivalent aperture in meters	Equivalent aperture in inches	Per cent of original value
For a 4 m aperture telescope			
1.00	4.00	157	100
1.10	3.81	150	88
1.20	3.65	144	78
1.25	3.58	141	74
1.50	3.27	129	58
2.00	2.83	111	39
3.00	2.31	91	23
5.00	1.79	70	11

(Copyright the International Dark Sky Association, December 1996.)

Desirable physical characteristics for an observatory

All observatories need road access for the installation, maintenance and operation of the telescopes and instrumentation, and a level-enough site to build on, with appropriate foundation material. Power from transmission lines is desirable, but can be supplied by local generators, which in any case are needed as back-up if power fails over the sometimes long and vulnerable lines. Telecommunication facilities are necessary, and in these days of high-speed data links optical fiber connectivity or telecommunication satellite bandwidth is becoming the norm. In the installation of such facilities, care has to be taken not to degrade the electromagnetic environment of the observatory—small currents can be induced through pickup in the detector electronics and amplified, with interference to the observations (see also TELESCOPE ENGINEERING).

For an optical-infrared observatory, chosen for lack of cloud, water run-off from buildings is not likely to suffice for the operation of the facility, or for use by the staff, and must be pumped from artesian supplies or brought in. Remoteness from population sources minimizes artificial sky background, industrial smoke or dust generation, and background radio noise from electrical machinery, so it is not likely there will be abundant water, since water would probably have already attracted settlements.

Prime requirements for an optical observatory are good atmospheric transparency and seeing characteristics. For an infrared or millimeter wave observatory, transparency is linked to (lack of) water vapor content in the air, measured by precipitable water vapor, and carbon dioxide absorption.

There will undoubtedly be a winter–summer cycle in all these weather-related characteristics, but the less seasonal the variation, the more all-sky access there will be. If winters are severe, ice or snow may also affect building costs and access. To establish the weather characteristics of candidate sites for a major telescope, a period of site testing is necessary, and has to be at least a year long to establish the annual cycle. Moreover, since there are year to year differences across a region or even a hemisphere, similar testing should be carried out at a reference site whose long-term characteristics are known, to establish the differences between the new site and the established one.

As Newton conjectured, high altitude sites have the advantage of being above the inversion layer, which restricts aerosol content to the Earth's surface layer. The inversion layer can be between 2 km and 10 km in altitude, depending on ground or sea heating.

Local effects on seeing are minimized if the mountain presents a streamlined contour to the prevailing wind, so that air heated by the ground layer does not mix with colder, higher air. The thickness of the skin of air above the land surface in which there is local heating and turbulence drives the decision about the height at which the telescope is placed above the ground on a pillar, and is a cost-driver through the building costs. The prize of locating the telescope above the ground layer is that the seeing created by the air above this skin could be as small as 0.3 arcsec.

Merle Walker (1983) identified a group of good observatory sites on mountain tops to the east (this is usually the down-wind direction) of cold oceanic currents, which stabilize air flow, reduce the scale height of convection and therefore keep the inversion layer low (at say 2 km). California, the Canary Islands, and Chile all fit this pattern; Walker also identified Namibia in southern Africa as a relatively under-exploited astronomically desirable country.

Today, the vast majority of the world's largest, most powerful, optical-infrared telescopes are to be found in a handful of high-altitude sites. There are concentrations of such sites in the western half of the continental United States, in the fiftieth state, Hawaii, in the arid Andean mountains of Chile, and in the Canary Islands. The local environmental factors outlined above are the driving force behind these concentrations. As remote observation and telescope control become increasingly common, while the jet plane makes travel quick and easy, accessibility for the astronomers who use these instruments and the engineering staff who build and maintain them drops down the list of priorities.

Large regions of the world are downgraded as possible observational sites through their geographical location. Much of eastern North America, continental Europe, southeast Asia and the tropical regions of Africa and South America suffer not only from proximity to man-made pollution but from higher humidity, a higher percentage of cloudy days and poorer atmospheric transparency caused by water droplets, dust, smoke or other aerosols. Nevertheless, for the reasons already stated, most observatories, except the very largest, are located in these regions, near to the population.

Of course, there are penalties associated with mountain top locations. Their geographical remoteness inevitably means that road and air links are probably limited or non-existent and these may have to be provided before construction can begin. Part of the costs of operating the observatory will consist of access maintenance. Access to the PIC DU MIDI OBSERVATORY in the French Pyrenees is by cable car. The IRAM millimeter-wave observatory at Plateau du Bure near Grenoble is also accessed by cable car, whose collapse in 1999 caused loss of life and suspension of operations.

Once the site has been selected, its rocky, sloping surface then has to be flattened and prepared for the foundations for the observatory building and its subsidiary facilities. Apart from the difficulty of building in remote conditions, staff and visiting astronomers have to survive low temperatures, strong winds, occasional blizzards and altitude sickness caused by the thin air. Acclimatization is important for visitors unfamiliar with the oxygen deprivation. On Mauna Kea, where the telescopes are at 4200 m, a 'halfway house' has been set up at 3800 m. Here a visitor may acclimatize before heading for the summit, an astronomer may sleep during the daytime after his or her night-time observations, and engineering staff may think about problems encountered at the summit but unsolved in an oxygen-poor, headache-inducing atmosphere.

Earth tremors pose a threat to any facilities located nearby. One notable example was the earthquake which struck the BIG BEAR SOLAR OBSERVATORY in June 1992. The tremor, which measured 6.6 on the Richter scale, occurred only 9 km from the observatory. The causeway which links the observatory with the lake shore suffered from subsidence and fractures, while the support pedestal for the telescopes and the tracking machinery were also damaged. The observatory was out of action for more than four months while repairs were undertaken. Telescopes on the volcanoes of Mauna Kea and La Palma are protected against earthquakes of a size that is thought possible there, with spring-loaded pivots pulling gears apart in the case of tremors that could damage the main bearings.

Observatories in Australia and La Palma have been uncomfortably close to bush fires, which threaten buildings, and drift ash onto delicate optical surfaces.

Astronomical observatories are also affected by air pollution, vibrations and thermal pollution. For example, studies by the US NAVAL OBSERVATORY in Washington, DC have shown that thermal turbulence and refractive index asymmetries over the site created by large heated buildings nearby are compromising the astrometric value of the site. Even aircraft lights and contrails can cause problems for observatories located beneath flight paths. Civilian air traffic has been re-routed away from La Palma and use of the take-off and approach path to Nice airport, which passes over the Observatoire de Calern, is not permitted at night for this reason.

Environmental and ecological considerations may also play a part in influencing location. Many observatories are located in remote regions that are noted for their scenic beauty and rare fauna and flora. Some, such as Australia's Siding Spring Observatory, are built close to a national park.

Conflicts may sometimes arise with local residents or environmental groups. When the University of Arizona and its international partners selected Mount Graham as the site for a series of world class instruments, including the LARGE BINOCULAR TELESCOPE, the 3200 m mountain seemed

Dirac House, Temple Back, Bristol, BS1 6BE, UK

an ideal location, not only for its excellent 'seeing' but also because it already had a two-lane access road maintained for summer residences and rural industries such as logging. After a lengthy environmental impact assessment, permission to go ahead with the first stage of construction was duly granted by the US Fish and Wildlife Service. Unfortunately, the astronomers then became embroiled in a series of costly legal arguments centered around the fact that Mount Graham is a 'sky island', an isolated pocket of rare fauna and flora. Environmentalists argued that the unique ecosystem, which included an endangered subspecies of the red squirrel, would be irrevocably damaged by the new observatory, even though the initial area of construction was limited to 3.5 hectares (8.6 acres). Even after two bills of Congress were passed in order to allow the Large Binocular Telescope to go ahead, further appeals and protest meetings caused the project to be badly delayed and its costs to escalate dramatically.

Environmental issues and the religious concerns of the Hawaiian native people to whom the mountains are sacred areas are factors that limit the development of Mauna Kea and Haleakala in Hawaii.

Socio-economic conditions

Economic development and political stability also play a significant part in influencing decisions about where to locate modern astronomical observatories. The governments of developed countries, sometimes assisted by private funds, seek to maintain astronomical facilities at the cutting edge of cosmological research by placing them in the most advantageous locations. These can be anywhere in the world where the environmental requirements are met.

The underdeveloped infrastructure that is likely at an observatory location means that development of an observatory has to be undertaken from scratch, entailing a much longer, more expensive process of preparation and construction. The intangible asset of confidence is engendered by an economically solvent, politically stable and astronomically supportive regime in the host country, providing a basis for investment of large sums by the external partners. The establishment of a major astronomical center can help to improve economic conditions in the host country, by providing jobs, by improving levels of education and technical training, and by providing an aspirational example for future development. As a 'site fee' the host nation usually receives a proportion of the observatory's observing time, providing guaranteed access for its scientists to world class observational facilities at relatively little cost.

The southern hemisphere

The latitude of an observatory is important, with low latitudes generally favored. The natural sky glow decreases away from the polar regions (but this is a disadvantage if geomagnetic phenomena are the subject of investigation), the nights are of more uniform length near the equator, and a larger fraction of the sky passes above the horizon. The southern hemisphere sky contains unique astronomical phenomena, such as the galactic center and the Magellanic Clouds. Such objects are available for longer periods when they pass overhead, and for this reason, for multiwavelength studies driven by satellite telescopes that orbit the earth and see both hemispheres equally, and to provide a complete picture of the Galaxy and the universe, astronomers have required southern observatories. The need to improve coverage of the southern hemisphere skies was one of the driving forces behind new observatories in the twentieth century. In the early years of the twentieth century, the main observational centers south of the equator were the Radcliffe Observatory at Pretoria and Mount Stromlo near Canberra. The 1.9 m (74 in) reflectors that were built in Pretoria and in Canberra remained the largest telescopes in the southern hemisphere for 20 years.

As light pollution from the nearby conurbation of Australia's capital city increased, the Australian National University (ANU), which became responsible for Mount Stromlo Observatory, established a new facility at Siding Spring (MOUNT STROMLO AND SIDING SPRING OBSERVATORIES) near the town of Coonabarabran in New South Wales. In addition to its good local infrastructure and easy access, its observing conditions were among the best that could be found in Australia. The UK government joined Australia to add to the ANU facilities at Siding Spring, including the UK Schmidt telescope and the 3.9 m Anglo-Australian Telescope, in the 1970s.

Today, the Siding Spring site is at a disadvantage when compared with other newer southern locations. First, it is only 1000 m (3200 ft) above sea level. As a result, atmospheric turbulence is significant, while observations on cloud-free nights are only possible for about 60% of the year. Light pollution is also beginning to encroach from conurbations far to the south. At a time when funding for astronomical facilities is increasingly tight, these factors may militate against further development or even continued support for such middle-range facilities in the future.

This experience compares and contrasts with the fortunes of South Africa. During the early 1970s, the British Science Research Council joined with its South African counterpart, the Council for Scientific and Industrial Research, to set up a modern observatory in the semi-desert region of the Karoo, near Sutherland, northeast of Cape Town. The Radcliffe Telescope was relocated from Pretoria and several smaller telescopes were added—new and relocated from the Cape Observatory. Despite its relatively low altitude (1760 m), this site has now been selected by an international consortium for a new 9 m class instrument (SALT, the SOUTHERN AFRICAN LARGE TELESCOPE). South Africa looks to enjoy an astronomical revival in the next decade, once more operating the largest telescope in the southern hemisphere, in competition with the VLT, whose individual telescopes will be slightly smaller but which together lay joint or greater claim to that title.

Island sites

Because mountain tops are favored for large astronomical telescopes, and building on the development work carried out by the INSTITUTO DE ASTROFISICA DE CANARIAS, the UK prospected La Palma in the Canary Islands for its 'northern hemisphere observatory'. The La Palma site became available in 1979 after Britain and Spain, to which the Canary Islands belong, signed an agreement to establish the OBSERVATORIO DEL ROQUE DE LOS MUCHACHOS on the rocky volcanic island. Site protection was guaranteed in Spanish law. British astronomers selected the site for the relocation of the Isaac Newton Telescope, then western Europe's largest optical telescope, after examining other promising locations in Tenerife, Madeira and Italy. The 4.2 m William Herschel Telescope followed in 1989, funded by the UK in partnership with The Netherlands.

The summit of La Palma is 2500 m above sea level and is home to half a dozen major astronomical instruments that are owned and operated by various European countries. La Palma is the site for the Gran Telescopio de Canarias, virtually a clone of the Keck telescope and the nucleus of the 'European northern observatory'.

However, despite its advantages, La Palma has been overtaken by Hawaii as the prime choice for today's 8–10 m class telescopes in the northern hemisphere. Indeed, the huge extinct volcano of Mauna Kea in Hawaii lays claim to be the best observatory site in the world. At an altitude of 4200 m it is also by far the highest of the major observatory sites.

This extreme altitude is important because it opens the way to observations at optical, infrared and sub-millimeter wavelengths. The observatory lies above some 90% of the atmospheric water vapor, and almost all of the remainder is removed from the air as frost or snow, while the trade winds which blow across the Pacific are forced around the mountain, leaving the summit in a pocket of exceptionally stable air. Since the island is far from any large land mass, the air is also free of dust. It is unaffected by light pollution, and there are strong zoning laws controlling lights in the coastal towns.

On the other hand, as its name (Mauna Kea means 'White Mountain') suggests, weather conditions on the summit can sometimes be severe, with heavy snowfall and 150 km h^{-1} winds which can last for days. Oxygen levels are 60% those at sea level, and oxygen deprivation affects visitors' ability to breathe, move around and make rapid decisions, as well as the cooling capacity of fans, the stability of computer disk drives and the power of diesel engines. Remote control facilities and remote diagnostic capability are emphasized for the Mauna Kea telescopes. The 10 m Keck telescopes on Mauna Kea are operated from a base at the foot of the volcano at Waimea, the James Clerk Maxwell Telescope likewise.

Sub-millimeter and radioastronomy

In contrast with optical observations, radioastronomy has a relatively short history. However, it follows a similar pattern. From the earliest experiments, radio interference from terrestrial sources has been an obstacle to studies of the universe.

One of the earliest examples of this dilemma came in December 1945, when BERNARD LOVELL borrowed three trailers of radio equipment from the British army for cosmic ray studies. In order to avoid electrical interference on the main campus, Lovell moved his equipment to the rural setting of the University of Manchester's botany department at Jodrell Bank. In 1957 this became the site of the world-famous 76 m fully steerable antenna, later known as the Lovell Telescope, and is now the home of the NUFFIELD RADIO ASTRONOMY LABORATORIES, and the center of the MERLIN interferometer complex distributed across the UK.

Unfortunately, facilities such as Jodrell Bank are now immersed in an electromagnetic jungle composed of signals from innumerable sources, including everything from TV transmitters to electric motors and CD players. Inevitably, modern radioastronomy observatories, such as the Goldstone and OWENS VALLEY RADIO OBSERVATORIES in California, and the Australia Telescope are built in radio-quiet areas, far from large population centers and often shielded by hills.

Sometimes, the sites are able to benefit from local legislation that prevents interference. For example, the new Green Bank Telescope, the largest fully steerable dish in the world, lies in a 150 km wide National Radio Quiet Zone in West Virginia. This means that the observatory director is consulted over the installation of any new radio transmitters within this zone or any significant modification to existing transmitters. The radio telescopes of the MULLARD RADIO ASTRONOMY OBSERVATORY in Cambridge were protected from radio noise from car-ignition systems on the nearby motorway by sinking the road and erecting a metallic fence that acts as an electromagnetic shield.

Today, interferometry is a vital technique for radioastronomers, and a number of multi-telescope systems have been created. These occupy large areas, so remote desert sites where flat land is cheap and plentiful are ideal. The largest of these observatories is the VERY LARGE ARRAY in New Mexico, where 27 separate dishes are spread in a Y-shape along three arms, each of which is 21 km long.

While sheltered valleys are popular sites, local topography can sometimes be utilized in unusual ways. The most famous example of this is the ARECIBO OBSERVATORY, the largest radio telescope in the world, which lies within a natural rock basin in the limestone hills of Puerto Rico. Since the antenna is not intended to be steerable, the giant depression provided an ideal site for the construction of the 305 m diameter dish. China has plans to construct a similar dish, FAST, the Five-hundred meter Aperture Spherical Telescope, in a region of southern China with many hemispherical karst depressions in which the telescope could be mounted. This project might be helped to fruition if a radio-quiet zone could be implemented in the area.

Physical factors are relatively insignificant for long-wavelength radio observations. At sea level, observations at wavelengths of 2 cm or more are possible without serious interference, but at shorter wavelengths, it is necessary to observe from high-altitude sites where absorption by atmospheric water vapor is minimized. In particular, sub-millimeter observations benefit greatly from such high-altitude locations. Not surprisingly, the world's largest sub-millimeter telescope, the JAMES CLERK MAXWELL TELESCOPE, is located on the summit of Mauna Kea.

The VLT at Paranal—a case study

The European Southern Observatory's Very Large Telescope (VLT) site at Cerro Paranal in Chile, located 2650 m above sea level, exemplifies many of the advantages and problems involved in the construction and operation of a modern mountain-top observatory. Its physical advantages are fairly obvious. Its altitude and its low rainfall (a storm every decade) result in up to 350 clear nights a year, unusually stable air which allows a spatial resolution of 0.45 arcsec for 15% of the viewing time and low water vapor concentrations which increase atmospheric transparency at infrared wavelengths.

On the other hand, these advantages were bought by major investments of time and money. Seven years of extensive site testing were undertaken before preparation work at Paranal began in 1991. Once a road was built from a nearby highway to the summit, some 350 000 cubic meters of rock and soil were removed from the site, flattening the mountain to create the 20 000 square meter platform on which the four 8.2 m telescopes and the interferometric complex would be built.

Before construction began, political factors had to be resolved between the European Southern Observatory (ESO) and the government of Chile. Following the signature of a treaty between ESO and the Chilean government in 1963, 15 world-class telescopes had been located at Cerro La Silla in the arid mountains of the Atacama Desert. However, when ESO requested permission to build the VLT at Cerro Paranal, in 1991, the government of Chile asked for modification of the original Convention.

A protracted period of negotiations ensued, concerning ownership of the Paranal site, labor relations, guaranteed observing time on the ESO telescopes for Chilean astronomers, and the rules governing the installation of additional telescopes in the future. These difficult discussions, spread over several years, inevitably delayed completion of the Paranal site, increased costs, and prompted ESO management to pursue studies of other first-class astronomical sites elsewhere in the world. The difficult issues were eventually resolved, the VLT is now in operation at Paranal and it is likely that the Atacama Large Millimeter Array will be built nearby.

Prior to construction of the main accommodation and office complex at Paranal, which began in 1999, ESO staff and visitors were housed in containers at a 'Base Camp', while the workers and engineers of the contracting firms were housed in similar quarters along the mountain road.

Since the nearest town, Antofagasta, is 120 km away, and Paranal lies in the middle of the Atacama Desert, everything from food and water to telescope spare parts, is brought in by road. Several diesel generators are used to maintain a stable electricity supply for the sensitive astronomical instruments and to ensure a minimal level of comfort for staff and visitors. A hotel and observatory maintenance facilities, including the advanced aluminizing plant for the giant VLT mirrors, are situated at the foot of the mountain.

In order to squeeze as much performance as possible out of such substantial investments, every effort is made to reduce the impact of the physical environment on the observational efficiency. At Paranal, for example, the laboratories, control building and most of the office/accommodation block are buried underground, in order to minimize disturbances to the wind flow around the mountain summit.

Future sites

Three major threats to future research have been recognized by the astronomical community:

- Growing levels of radio pollution, interference at radio frequencies from telecommunications satellites and their ever-increasing demand for new wavebands cloud the future of radio astronomy.
- Space debris is a growing threat to scientific satellites and also interferes with ground-based observations as satellites or space junk leave streaks across sky images.
- Observatories around the world are also in danger from the proliferation of outdoor lighting, increased urbanization, and projects to launch highly luminous objects into space for various purposes such as Earth illumination or artistic, celebratory and advertising goals (see table 1).

The only undeveloped site on Earth known to rival Mauna Kea for infrared and sub-millimeter observations, and for freedom from radio noise and urban sky glow is Antarctica. Stratospheric air is pulled down onto the South Pole by convection upwards at latitudes closer to the equator and the cold, dry and stable conditions on the high-level Antarctic Plateau allow small telescopes at the South Pole to outperform much larger telescopes at temperate sites. Difficult access and the extreme climate have discouraged construction and observations, but there are astronomical observational facilities at the American CENTER FOR ASTROPHYSICAL RESEARCH IN ANTARCTICA (CARA), so far all quite modest in size and capability.

As even near-Earth space becomes polluted with space debris, some astronomers have begun to look towards future observatories on the far side of the Moon. Problems with cloud cover, atmospheric turbulence and absorption of incoming radiation by water vapor are non-existent on the airless Moon. The absence of an

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

atmosphere means that every type of radiation can stream down to the surface without being filtered by a blanket of air. Optical and infrared interferometry would also be much easier in the lunar environment. Whereas terrestrial optical and infrared telescopes can only operate at night, lunar telescopes would be able to operate around the clock. With the Moon's slow rotation, it would be possible to observe faint objects non-stop during the two-week-long nights. And in a one-sixth gravity environment, much larger, lighter mirrors or reflector dishes could be installed without being deformed.

The difficulties in establishing a telescope on the Moon are not only the obvious ones of doing anything in space, but also the dusty environment (bad news for mechanical and optical devices). A study by the EUROPEAN SPACE AGENCY concluded that the theoretical advantages of an optical-infrared or millemeter wave observatory on the Moon were outweighed by the disadvantages. Free-flying observatories like the Hubble Space Telescope (HST), the Next Generation Space Telescope (NGST) and the Far Infra Red Space Telescope (FIRST) were the way to go.

The lunar far side would, however, be particularly favorable for radio astronomy. Shielded by the body of the Moon from terrestrial signals, the telescopes would have a clear view of the radio universe. Lunar craters would make ideal sites for giant Arecibo-style radio antennae. There would even be the opportunity to explore an entirely new region of the electromagnetic spectrum. Very-low-frequency radio waves (below about 15 MHz), which are absorbed or scattered by the Earth's atmosphere, would be readily accessible to telescopes on the Moon. Moreover, since the body of the Moon screens radio telescopes from artificial signals engendered on the Earth, this might be the place from which artificial signals from other civilizations can be identified most readily. To protect the operational electromagnetic environment of the Moon for these purposes, astronomers have already established norms for radio communication between lunar colonies.

Observatories: History

An astronomical OBSERVATORY is a building, installation or institution dedicated to the systematic and regular observation of celestial objects for the purpose of understanding their physical nature, or for purposes of time reckoning and keeping the calendar. At a *bona fide* observatory such work constitutes a main activity, not just an incidental one. While the ancient Egyptians, Babylonians, Chinese, Greeks and Mayans made many observations of scientific and historical interest, their efforts were not carried out at observatories *per se*. In this article we shall concentrate on installations that were intended to be *bona fide* research centers.

Observatories in Islam

There was a strong motivation in medieval Islam to preserve the knowledge of the Greeks and if possible to add to it. In a large city the presence of a hospital, a university and a public library was considered sensible and desirable. Within this context, in which knowledge and piety were highly encouraged and intertwined, the tradition of observatory building began during the reign of al-Ma'mūn, the seventh Abbasid caliph (AD 813–833). He organized a scientific academy in Baghdad called the House of Wisdom, which included a library and observatory. This was the most significant scientific endeavor since the establishment of the Alexandrian Museum in the 3rd century BC. A second observatory was built on the plains of Tadmor in Syria. al-Ma'mūn's astronomers measured the obliquity of the ecliptic (obtaining a value of $23^\circ 33'$), concluded that the precession of the equinoxes amounted to 54 arcsec yr^{-1}, determined that the Earth was 6500 miles in diameter and produced tables of motion of the planets based on PTOLEMY's work, but updated on the basis of new observations. Astronomical work continued in Baghdad under the ninth Abassid caliph, but then ceased (see also ISLAMIC ASTRONOMY).

A second scientific academy, the Hall of Wisdom, was established in Cairo in 1005. It lasted until 1171. An observatory was begun there in 1120 and nearly completed, but was ordered destroyed by the caliph in 1125 after the death of the vizier in charge of the observatory and its instruments. Apparently, serious conflicts had arisen between this vizier and the caliph, and it did not help that the superstitious populace presumed that trying to understand the motions of the planets was akin to delving into magic.

The Istanbul Observatory, completed in 1577, met a similar fate. Political back-stabbing and superstitions regarding astronomy led to that observatory's destruction by 1580.

The two most successful and extensive Islamic observatories were those at Maragha (in Azerbaijan, in modern-day Iran) and at Samarkand, in modern-day Uzbekistan. The Maragha Observatory was built under the direction of NASIR AL-DIN AL-TUSI (1201–1274). It was situated on the flattened top of a hill, covering 400 m by 150 m. Completed in 1264, it was active at least until 1304, perhaps until 1316. It was the first observatory whose activity did not greatly diminish after the death of its founder. While the motivation for the construction of the observatory was *astrological*, the prediction of future celestial events needed to be carried out on the basis of exact physical measurements. A significant number of instruments were built, among them equinoctial and solsticial armillary spheres, and a mural quadrant of radius 4.3 m. The observatory's library at one time contained 400 000 volumes. The principal accomplishment at Maragha was the compilation of the Ilkhanic Tables, which were tables of motion of the Moon, Sun and planets. These identified some of the major shortcomings of Ptolemaic astronomy.

The most important astronomer of the 15th century was ULUGH BEG (1394–1449). For most of Ulugh Beg's life his father was the ruler of Transoxiana, a region situated between the River Oxus (Amur Darya) and the River Jaxartes (Syr Darya). This provided the son with the opportunity to indulge his passion for astronomy. As a young man Ulugh Beg visited the remains of the Maragha Observatory, and he endeavored to build an even greater institution in Samarkand. As many as 70 astronomers were active there between 1408 and 1437. The largest instrument constructed was a sextant of radius 40 m, a fixed instrument mounted on the north–south meridian which could achieve a resolution of several arc seconds, a value not to be exceeded until the invention of the telescope and the micrometer in the 17th century. This sextant was primarily used for observations of the Sun.

On the basis of new observations, Ulugh Beg and his fellow astronomers compiled a catalog of the brightest 1000 stars visible at the latitude of Samarkand. No one since Ptolemy (ca 150 AD) or perhaps as far back as Hipparchus had made such extensive stellar observations. Ulugh Beg's catalog was most likely based on observations with a zodiacal armillary sphere graduated to 15 arcmin, with interpolation to two-tenths of a mark, or 3 arcmin. The typical positional accuracy in the catalog is ± 16 arcmin.

China and India

At the very end of the 17th century one Louis Lecomte published his *Memoirs and Observations of a Journey through China*. He noted in some detail the vigilant activity carried out by astronomers at the Imperial Observatory in Beijing: 'Five mathematicians spend every night on the tower in watching what passes overhead; one is gazing towards the zenith, another to the east, a third to the west, the fourth turns his eyes southwards, and a fifth northwards, that nothing of what happens in the four corners of the world may escape their diligent observation'. Such activity had been going on for three millennia. As a result, the Chinese had accumulated records pertaining to many hundreds of lunar and solar eclipses, observations of novae, supernovae, comets, meteor showers, aurorae,

Dirac House, Temple Back, Bristol, BS1 6BE, UK

naked-eye sunspots and even a possible observation of Jupiter's moon Ganymede in 364 BC, nearly two millennia before the invention of the telescope (see also CHINESE ASTRONOMY IN HISTORY). The first clock drive was built by the Chinese in AD 132; it was powered by a constant pressure-head of water in a clepsydra, or water clock. The Chinese astronomer Yü Xi independently discovered the precession of the equinoxes in AD 320, finding a value of about 72 arcsec yr^{-1}, twice the value found by Hipparchus. Sunspot records in the Chinese annals demonstrate the 11 yr solar cycle.

Just as spices were transported along the caravan routes, so too was astronomical knowledge. Astronomers from Persia arrived in China in AD 719. The astronomical ties between the mid-East and far East became quite extensive during the Yüan Dynasty (1271–1368). In 1267, only 8 yr after the founding of the Maragha observatory, blueprints for seven instruments were sent to China. Actual models may have followed.

In 1270 the astronomer Guo Shoujing (1231–1316) built the first equatorially mounted instrument. After the Beijing Observatory was re-equipped in 1276–1279 under his direction, it was equal in stature to the Maragha Observatory. The Chinese also operated an observatory at Nanjing.

The Chinese did not appreciate or understand the Greek geometrical models of planetary motions or the Arabic use of geometry, particularly spherical trigonometry and stereographic projection. However, 300 yr before Tycho Brahe became convinced that right ascension and declination were the 'coordinates of the future', the Chinese were fully committed to their use. Just as the influence of the Emperor radiated in all directions, so the hour circles radiated from the pole, 'like the spars of an umbrella'. The Chinese laid out a system of 28 lunar mansions (*xiu*), which were defined by the points at which these hour circles intersected the celestial equator.

One of the most important events in the history of Chinese science was the arrival of the Jesuits in 1600, towards the end of the Ming Dynasty. They had a very specific motivation. By demonstrating the superiority of Western science, they hoped to convince the Chinese of the superiority of Western religion. Western science clearly won out over the traditional Chinese and Muslim methods of predicting the solar eclipses of 15 December 1610 and 21 June 1629. In November 1629 a new calendar bureau was established under the direction of the Chinese Christian convert Xu Guangqi, who supervised the work of 50 astronomers, many of whom converted to Christianity. However, in 1664, at the start of the Qing Dynasty, politics led to the dismissal of the Jesuits and most of the Chinese converts from the calendar bureau. Some of these astronomers were later beheaded.

The Jesuits regained favor in Chinese astronomy in 1669. From 1673 to 1676 the Beijing Observatory was re-equipped with a new set of Tychonic instruments, which are still in place today. However, the astronomical activities in China were hindered by several factors, notably the limited interest of the Chinese in questions other than calendrical revision, the Jesuits' observance of the Church's prohibition of the discussion of heliocentrism, which was in effect until 1757, and their attraction for the hybrid geo-heliocentric model of Tycho Brahe.

In India the most significant observatory construction was carried out under the direction of Jai Singh (1686-1743), a Hindu prince in the court of a Muslim Mogul emperor. Large instruments of masonry were constructed at Delhi, Jaipur, Ujjain, Benares, and Mathura. The largest instrument was a sundial 27 meters tall. Jai Singh wished to follow in the footsteps of Ulugh Beg, minimizing observational errors by using the largest instruments possible. His star catalog was an update of Ulugh Beg's star catalog, but apparently with no new observations: $4^\circ 8'$ were simply added to Ulugh Beg's ecliptic longitudes to account for precession over 288 years (see also INDIAN ASTRONOMY).

Early European observatories

Astronomical observations were carried out in Moslem Spain at Cordova in the 10th century, at Toledo in the 11th, and at Castille in the 13th century under the patronage of the Christian King ALFONSO X. The Toledan astronomical tables were translated into Latin in the 12th century. The Alfonsine Tables, the first state-sponsored astronomical ephemerides published for general use, were reprinted as late as 1641.

The first European observatory worthy of the name was built by Bernard Walther (1430–1504), a wealthy private citizen of Nuremberg, who was at the same time the pupil and patron of REGIOMONTANUS (1436–1476). Together they found that the positions of the planets differed to a significant degree from the predictions of the Alfonsine Tables. They printed astronomical treatises on a printing press set up in Walther's house. One such treatise by Regiomontanus laid out the 'method of lunar distances' for determining longitude at sea. A significant innovation at Walther's observatory was determination of the times of observations by mechanical clocks instead of by astrolabes or armillary spheres. Observations with Walther's instruments exhibited an improved accuracy, to ± 10 arcmin.

Wilhelm IV (1532–1592), the Landgrave of Hesse-Cassel, began systematic observations in 1561. In 1567 his father, the Landgrave of Hesse, died, and the landgraviate was divided up amongst the four sons. Wilhelm was compelled to take over the administration of his province and had to lay aside his astronomical endeavors. In 1575, however, he was visited by Tycho Brahe and was inspired to resume observing.

Wilhelm constructed a number of metal instruments, among them an azimuthal quadrant of radius 0.4 m, a torquetrum, a sextant of radius 1.3 m, a quadrant of radius 1.5 m, and armillary spheres. He demonstrated the superiority of metal instruments over wooden ones. Wilhelm's most significant innovation was the rotating dome; he observed from one built in a tower of his castle.

His star catalog of about 400 stars, although far short of the intended number of stars he had hoped to measure, was one of the first assembled in Europe.

The most significant observatory prior to the invention of the telescope was that of TYCHO BRAHE (1546–1601). It was situated on the 2000 acre island of Hven, in the Danish sound between Copenhagen and Elsinore. There Tycho built Uraniborg, the 'castle of the heavens'. It sat in the middle of a square 300 feet on a side and enclosed by a wall 22 feet high. The castle itself had two main levels and was taller than a seven-story building. In addition to the observing rooms and verandahs on the upper level, it contained a dozen or so bedrooms, a dining room, library, chemical laboratory and even a jail in the basement. Begun in 1576, it was completed in 1580. Over the north portal was an inscription, carved in stone: *nec fasces nec opes sola artis sceptra perennant* ('neither wealth nor power, but knowledge alone endures'). Uraniborg was the first scientific research institute in Renaissance Europe, and Tycho was the first full-time scientist.

At Uraniborg Tycho and his assistants used a dozen instruments. The one that produced the most accurate stellar positions was a mural quadrant of radius 2 m, which was located in the southwest room on the ground floor. A mural quadrant is attached to a wall, fixed on the celestial meridian. Its fine construction and the use of transversals allowed the determination of declinations with a resolution of 10 arcsec.

An auxiliary observatory, Stjerneborg, was built in 1584 a short distance to the south of the main building. There were five new instruments, the largest of which was an equatorial armillary made of iron, which was 2.9 m in diameter and could be used to measure declinations with a resolution of 15 arcsec. Each of these five instruments was situated in a subterranean crypt. Three were sheltered by folding roofs, while two had revolving domes.

From observations at Hven Tycho discovered four inequalities in the Moon's motion, two in longitude (the 'variation' and the annual equation with a period of one solar year) and two in latitude. His observations of Mars were used later by Kepler to discover the elliptical nature of planetary orbits. From observations of 1588–1591, Tycho produced a catalog of 777 stars with an improvement in positional accuracy of an order of magnitude. More than one of Tycho's instruments produced positional accuracies for his nine principal reference stars of ± 0.6 arcmin. The average uncertainty of the (other) brighter stars in Tycho's catalog is 1.9 arcmin in ecliptic longitude and 1.2 arcmin in ecliptic latitude. For the fainter stars the uncertainties amount to 2.8 and 2.6 arcmin, respectively.

Tycho was able to afford such a magnificent observatory because his annual income from various fiefdoms was the equivalent of 1% of the Danish government's income, and this continued for a period of nearly 30 yr. It was not just money, of course, that led to the improvement in instrumentation. More than one of Tycho's metal instruments required the workmanship of five or six people over a period of 3 yr.

Tycho's fortunes, both literally and figuratively, began to decline in 1588 after the death of Tycho's patron, the Danish king Frederick II. Tycho left Hven in 1597 and his observatory fell into disuse.

JOHANNES HEVELIUS (1611–1687), the son of a prosperous brewer of Danzig (Gdansk), built what was for a short time the world's leading observatory. He copied a number of Tycho's instruments, building many quadrants and sextants of wood or copper. For observing the Moon and planets he constructed refractors up to 150 feet in focal length, in which the objective was mounted on a tall mast. However, for stellar positions he preferred the unaided eye, as he explicitly stated in his *Machina coelestis* (1673). This precipitated a controversy with Robert Hooke, who was a strong advocate of telescopic sights. EDMOND HALLEY was compelled to visit Danzig in 1679 to try to resolve the controversy. For 2 months Halley observed with a telescope fitted with sights while Hevelius used naked-eye instruments. Their observations were of equal accuracy, slightly less than 1 arcmin. The *Selenographia* (1647) of Hevelius had been a milestone in lunar mapping, while his posthumous star catalog (1690) contains the positions of 1564 stars.

The rise of national observatories

First era: 1576–1725

We may distinguish three eras in the construction of national observatories. Tycho's island observatory was, in effect, a national observatory, but the Paris Observatory (established 1667) was the prototype of the national observatories that followed. Astronomers in Paris, along with those at the Greenwich Observatory (1675), Berlin (1701), and St Petersburg (1725), were dedicated to practical matters of national importance: improving navigation (especially the determination of longitude at sea), geodesy, calendar reform, producing accurate stellar coordinates and the determination of ephemerides of the Sun, Moon and planets.

The Paris and Greenwich observatories stand out as institutional models on which many subsequent observatories were based. The Paris Observatory reflected the splendor of the court of Louis XIV, and many significant astronomers were associated with it. Jean Dominique Cassini (1625–1712), his son, grandson and great-grandson, all of whom were unofficial directors at Paris, formed a most notable astronomical dynasty (see CASSINI DYNASTY). The first Cassini discovered four moons of Saturn and the division of the ring system named after him. Paris astronomers used extremely long focal length refractors (up to 136 feet), mounted on tall masts, to observe the planets and Moon. Ole Römer demonstrated the finite nature of the speed of light from observations of Jupiter's Galilean satellites. Paris astronomers carried out the first geodetic surveys, covering the full arc of meridian of France by 1700, and were later involved in expeditions to Peru and Lapland.

From the outset both Paris and Greenwich were mandated to aid navigation, and the production of nautical

almanacs was a way of doing this. The French *Connoissance de Temps* first appeared in 1679, and the *Nautical Almanac* in 1767. In 1795 production of the *Connoissance* became the responsibility of the newly created Bureau des Longitudes, which supervised the work of the Paris Observatory. In Britain the Board of Longitude supervised the work of the Greenwich Observatory from 1714 to 1828. By then, with the existence of accurate star positions, ephemerides and the invention of the marine chronometer, the problem of determining one's geographical position at sea was essentially solved.

The buildings, staff size and funding level of the Greenwich Observatory were, until the 20th century, modest compared with those of Paris. Several of the Astronomers Royal, such as Flamsteed, Halley, Bradley, Maskelyne and especially GEORGE BIDDELL AIRY (1801–1892), were among the most important astronomers of their day. Airy organized the observatory as an astronomical factory with himself as factory director and sought to carry out the observatory's mission (data acquisition, reduction and publication of results) as accurately and efficiently as possible.

Second era: 1820–1918

The second era of national observatory building was characterized by offshoots from previous national observatories (such as Royal Observatory Cape, South Africa, 1820), by newer observatories of younger nations (United States Naval Observatory, 1839) and later the rise of astrophysical observatories (Potsdam, Prussia, 1874). Other national observatories of the second era include Pulkovo (Russia, 1839) (figure 1), the Chilean National Observatory (1852), the Argentine National Observatory (1870), the Smithsonian Astrophysical Observatory (USA, 1891) and Canada's Dominion Observatory (1903) and Dominion Astrophysical Observatory (1918).

Of 19th century observatories, Pulkovo deserves special mention. Tycho had been given *carte blanche* by his sovereign to build the finest observatory in the world, and WILHELM STRUVE (1793–1864) was amply funded likewise by Tsar Nicholas I. Struve ordered an Ertel transit instrument (for the determination of absolute right ascensions), an Ertel vertical circle (for the determination of absolute declinations), a Repsold meridian circle (for the determination of differential stellar coordinates) and prime vertical transit (for the determination of aberration and nutation), a Merz & Mahler heliometer (for the determination of angular sizes or angular separations) and the 15 in Merz & Mahler refractor (for the discovery and measurement of double stars). This refractor was the largest telescope in the world at that time; a twin was built for Harvard College Observatory in 1847.

The instruments listed above testify to the maturation of positional astronomy as a field of endeavor. Not only did Pulkovo astronomers measure some of the first stellar parallaxes and discover many double stars, they also produced the most accurate values for the constants of precession, aberration and nutation—values not superseded until 1964.

It is important to note that progress in astronomy depended very greatly on progress in instrument making and optics. Thomas Tompion, George Graham, John Bird, Jesse Ramsden, Joseph Fraunhofer, Edward Troughton, Carl Zeiss, Alvan Clark, Alvan Graham Clark, Howard Grubb and George Ritchey are some of the men who made significant contributions to instrument making during this era.

Third era: 1956–present

The present era of national observatory building is characterized by national or international consortia, large budgets and the investigation of celestial objects at all electromagnetic wavelengths. From ground-based observatories we may investigate optical, infrared, radio, and submillimeter waves. Because of absorption by water vapor in the Earth's atmosphere of certain infrared and submillimeter waves, we must make some observations from balloons and aircraft. Ultraviolet, x-ray and gamma-ray astronomy *must* be carried out from satellites.

Significant national observatories of the third era include the National Radio Astronomy Observatory (USA, 1956), Kitt Peak National Observatory (USA, 1957), National Radio Astronomy Observatory (Australia, 1959), Cerro-Tololo Inter-American Observatory (Chile, 1963) (figure 2), European Southern Observatory (Chile, 1964), Anglo-Australian Observatory (Australia, 1967), the Kuiper Airborne Observatory (USA, 1975–1995) and the Space Telescope Science Institute (1981).

Private observatories

Not all significant astronomical work is carried out at observatories funded by federal governments, universities and research foundations. In the late 18th century and throughout the 19th religious orders (notably the Jesuits) and various (usually wealthy) individuals established their own private observatories.

The most accomplished private astronomer of all time was the German–English astronomer William Herschel (1738–1822) (see HERSCHEL FAMILY). He pioneered the production of larger and larger *reflecting* telescopes (up to 48 in in diameter), whose light-gathering power enabled him to establish the field of galactic astronomy. His discovery of the planet Uranus in 1781 won him a royal pension that enabled him to give up his profession of music, and he moved to the neighborhood of Windsor Castle where his only obligation was to demonstrate the heavens to the royal family when requested to do so. He carried out deeper and deeper surveys of the northern sky, discovered hundreds of double stars and many hundreds of nebulae, and laid the groundwork for studies of the evolution of stars and stellar systems.

Herschel's son John followed in his father's footsteps and took an 18 in, 20 foot focal length reflector to South Africa where from 1834 to 1838 he conducted a southern sky survey that completed his father's work. The nebulae discovered by the Herschels were to form the basis of Dreyer's *New General Catalogue* (1888).

Following Herschel's discovery of Uranus, the German astronomer JOHANN HIERONYMUS SCHRÖTER (1745–1816) quit his post in Hanover and moved to the small town of Lilienthal to devote himself to observational astronomy. He built what was then the largest observatory on the European continent, and was assisted by Karl Ludwig Harding (who discovered the third asteroid Juno in 1804) and Friedrich Wilhelm Bessel. Schröter made detailed drawings of features on the lunar surface and believed he detected changes in the structure of some of those features. He inspired many observers to dedicate themselves to planetary studies.

William Parsons, the THIRD EARL OF ROSSE (1800–1867), in 1839 constructed at Parsonstown in central Ireland a reflector with a mirror 3 feet in diameter, and he followed this in 1845 with a monster with a mirror 6 feet in diameter. The 'Leviathan of Parsonstown' faced in a southerly direction, slung between masonry walls. Within weeks of completion it revealed the spiral nature of certain nebulae.

In 1856 WILLIAM HUGGINS (1824–1910) established a private observatory at Tulse Hill, near London, where he observed the spectra of stars and other celestial objects. Huggins was the first to prove that some nebulae are composed entirely of glowing gas. After his marriage in 1875 to Margaret Lindsay Murray, husband and wife formed a productive scientific partnership.

In 1868, simultaneously with the Frenchman Jules Janssen, the English amateur NORMAN LOCKYER (1836–1920) used a spectroscope attached to a refractor to observe solar prominences outside of a total solar eclipse. He was subsequently appointed head of the Solar Physics Observatory at South Kensington. When he retired in 1911 he established his own observatory at Salcombe Regis.

The American HENRY DRAPER (1837–1882) was a pioneer of astrophotography. His widow funded significant spectroscopic research carried out by astronomers at the Harvard College Observatory.

Figure 2. Cerro Tololo Inter-American Observatory illuminated by moonlight. The largest dome houses the 4 m reflector. (Photo by Kevin Krisciunas.)

Figure 3. Lick Observatory, ca 1936. The large white dome houses the 36 in refractor, still the second largest in the world.

GEORGE ELLERY HALE (1868–1938), the son of a wealthy Chicago industrialist, invented the spectroheliograph while an undergraduate at the Massachusetts Institute of Technology. He established a private solar observatory in his parents' backyard in Kenwood, then a suburb of Chicago; this later became part of the University of Chicago. Hale became the greatest observatory entrepreneur of all time, setting up the Yerkes Observatory (1897) and the Mt Wilson Observatory (1904). He was the driving force behind the establishment of Palomar Observatory (1948).

Today, as a result of advances in electronics and imaging devices, many amateurs obtain significant hard data for professional research projects. Photoelectric and CCD photometry by amateurs has been very important for variable star research and has even led to the discovery of a new class of pulsating stars. Astrometry from CCD imagery routinely provides data on recently discovered asteroids, which allows the calculation of their orbits.

Until very recently the most successful discoverer of supernovae in other galaxies was the Australian amateur Robert Evans.

Mountaintop observatories and the modern era

As a result of his optical researches, Isaac Newton realized that the Earth's atmosphere acts as a lens of sorts and that one could achieve much better astronomical image clarity by siting one's telescope on 'some lofty mountain' (see OBSERVATORIES AND THEIR LOCATION).

In 1741 the French astronomer François de Plantade carried out the first high-altitude astronomical observations near Pic du Midi in the French Pyrenees. Unfortunately, he died at the foot of the Pic, although the cause of his death is not known.

The next small step leading to improved observing was taken with the establishment in 1783 of Dunsink Observatory, an institute of Trinity College, Dublin. The observatory was intentionally sited some 8 km outside the city. It also had the first fully functional rotating hemispherical dome, and the primary telescope was mounted on a pier which was structurally (and therefore vibrationally) isolated from the walls of the building.

In 1856 the Scottish astronomer Charles Piazzi Smyth spent nearly 4 months at Tenerife in the Canary Islands and demonstrated that mountaintop observing was both desirable (for image clarity) and viable (for humans).

The first mountaintop observatory intended to be permanent was Lick Observatory (figure 3), which was completed in 1888. Situated at the 1280 m summit of Mt Hamilton, near San Jose, California, it boasted a 36 in refractor by Alvan Clark, then the world's largest. After the subsequent spectacular success of the Mt Wilson Observatory and the Palomar Observatory, it became clear that the best seeing was obtained at mountaintop sites within 50 miles of the ocean. Because of the proximity of the ocean, one gets a smooth, laminar flow of air over the coastal mountains when the prevailing wind conditions are in effect. This has been borne out by the establishment of many other observatories during the second half of the 20th century. The highest major observatory in the world (at 4205 m) is at Mauna Kea on the island of Hawaii. From a very modest start in 1964, Mauna Kea's astronomical installations expanded greatly and now include the University of Hawaii 2.2 m telescope, the Canada–France–Hawaii Telescope (3.6 m), the NASA Infrared Telescope Facility (3.0 m), the United Kingdom Infrared Telescope (3.8 m), the James Clerk Maxwell submillimeter telescope (15 m), the Caltech Submillimeter Observatory (10.4 m), one of the nine elements of the Very Long Baseline Array (25 m radio telescope), the two Keck telescopes (each 10 m), the Japanese optical and infrared telescope Subaru (8.3 m), the northern Gemini telescope (8.1 m) and the Smithsonian Astrophysical Observatory Submillimeter Array.

At present, the highest established telescopes are the twin 0.7 m reflectors of the Meyer–Womble Observatory at Mt Evans, Colorado (elevation 4313 m). A still higher

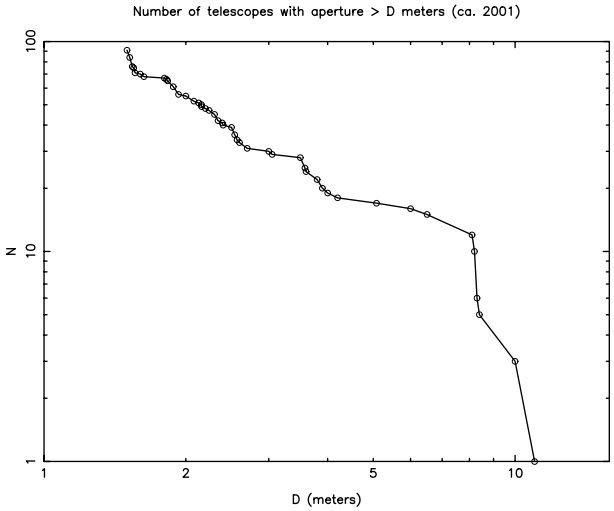

Figure 4. The number of optical and infrared telescopes with primary objectives larger than a given size, ca 2001. We include all telescopes with diameter D greater than or equal to 1.5 m. We count the two 8.4 m diameter elements of the Large Binocular Telescope, the four 8.2 m diameter elements of the Very Large Telescope and the two 6.5 m telescopes of the Magellan Project as separate instruments. Each of the 10 m Keck Telescopes contains 36 hexagonal mirror segments, while the 11 m Hobby–Eberly Telescope has 91 hexagonal segments. (Diagram by Kevin Krisciunas.)

observatory is being built at 5000 m about 40 km east of San Pedro de Atacama in Chile. This is the centimeter-wavelength Cosmic Background Imager, which will investigate the small ripples in the 3 K background radiation left over from the Big Bang. This observatory will have an oxygen-enhanced environment for the operators.

At the time of the publication of this article there will be more than 90 optical or infrared telescopes in operation around the world with diameters of 1.5 m or larger (see figure 4). This includes the now single-mirror 6.5 m MMT at Mt Hopkins, Arizona, the twin 6.5 m reflectors of the Magellan Project (situated at Las Campanas, Chile), the twin 8.1 m Gemini telescopes (one at Mauna Kea, Hawaii, the other at Cerro Pachon, Chile), the four 8.2 m elements of the European Southern Observatory's Very Large Telescope (at Cerro Paranal, Chile), Japan's 8.3 m Subaru Telescope (at Mauna Kea), the two 8.4 m elements of the Large Binocular Telescope (at Mt Graham, Arizona), the two 10 m Keck telescopes at Mauna Kea and the 11 m Hobby–Eberly spectroscopic telescope at Mt Locke, Texas. In fact, by the beginning of the 21st century more than half the *area* of telescopes larger than 1.0 m will be in telescopes larger than 8 m.

Given the expense of such facilities (measured in units of hundreds of millions of dollars), one might naturally ask why so many large telescopes are being built. It is a reflection of the blossoming of extragalactic observational astronomy, the desire to give hard data to cosmologists for testing their models and the wish to discover and study

intrinsically faint objects such as asteroids in the outer solar system, brown dwarf stars and extrasolar planets.

The design and construction of these state-of-the-art telescopes has required the development of computer-controlled mirror mounts, better-ventilated domes (to eliminate as much as possible the degradation of the visibility due to air in the dome), thin mirrors (as in the case of most of the telescopes mentioned above) or multimirror systems (36 hexagonal segments in the case of each of the Keck Telescopes, 91 segments in the case of the Hobby–Eberly Telescope). Modern instrumentation often uses techniques borrowed from spy satellites to achieve diffraction-limited performance. Whereas photographic plates a century ago had a quantum efficiency (QE) of less than 1% and photomultiplier tubes typically had peak QEs of a few per cent, modern instrumentation can achieve QEs of 70%. Such instruments, fed by the large objectives of the present generation of telescopes, are producing many spectacular results. Furthermore, modern computing capabilities are allowing digital celestial surveys which would have been technically impossible only a few years ago.

Observatorio Astronómico Nacional, Colombia

The Observatorio Astronómico Nacional (OAN) was founded by José Celestino Mutis in the framework of the 'Expedicion Botanica' on 20 August 1803. His first astronomer was Francisco Jose de Caldas. By the turn of the century, Julio Garavito worked in celestial mechanics—a crater on the far side of the Moon bears his name.

Nowadays, the OAN leads a postgraduate program, 'Especializacion en Astronomia', and the staff work in areas of celestial mechanics, statistical astronomy, cosmology, stellar structure, instrumentation, national ephemerides and parallel computing. The OAN is situated in Bogotà, Colombia (South America), and at present belongs to the 'Universidad Nacional de Colombia' at the Faculty of Sciences.

Observatorio Astronómico Nacional, Mexico (OAN)

Located in the mountains of the Sierra San Pedro Martir in Baja California. The observatory operates three telescopes—a 2.1 m, 1.5 m and 0.84 m. The observatory offices and workshops are located in Ensenada, beside the Pacific Ocean. OAN is a part of the Instituto de Astronomía of the Universidad Nacional Autónoma de México.

Observatorio del Roque de Los Muchachos

The Observatorio del Roque de los Muchachos, at a height of 2400 m above sea level, is situated on the island of La Palma (Canary Islands) and belongs to the INSTITUTO DE ASTROFISICA DE CANARIAS (IAC). It contains one of the world's most extensive collections of telescopes, which are operated by several countries, the largest being the William Herschel Telescope (4.2 m). Apart from several nocturnal telescopes, the Observatory houses two solar telescopes, an automatic meridian circle and an array of cosmic-ray detectors. In 2003, the Gran Telescopio Canarias (GTC), an optico-infrared telescope of 10 m diameter, is planned to come into operation.

Observatory

A structure from which astronomical observations may be made. In the case of ground-based optical and infrared astronomy, an observatory is a structure within which a telescope is housed and which allows the selected area of sky to be observed while at the same time providing the instrument and observer with protection from the wind and, to some extent, extraneous light. In the context of radioastronomy, where, in most cases, the radiotelescopes are out in the open and the observers in a building, the term 'observatory' relates to the complex of instruments and buildings on the observing site.

The classic design of observatory has an opening slot in a hemispherical dome that rotates on a circular wall. In some cases, the 'dome' is cylindrical (like a cake tin) or polygonal. In others, the entire building rotates or, in smaller sizes, the entire roof slides off to one side. In order to minimize the effects of light pollution, absorption of light in the atmosphere and scattering of light by dust particles suspended in the atmosphere, and to attain the steadiest possible atmospheric conditions, most of the major new and recently constructed telescopes are housed in observatories that are clustered together on one or other of a small number of high, isolated, mountain sites. Among the principal sites are Mauna Kea, Hawaii (at an altitude of 4200 m, the world's highest major concentration of observatories), Cerro Tololo, La Silla and Cerro Paranal, all in the Chilean Andes, La Palma (Canary Isles) and Kitt Peak, Arizona.

Observing Asteroids

The asteroids were so named in the early 1800s by William Herschel as they appeared star like to an observer (figure 1). They appear just like stars when observed with amateur equipment, but stars that move relative to the background star field.

Initially amateurs observed asteroids purely for the thrill of discovery, but in the 1940s, they became known as vermin because they 'contaminated' the sky survey plates taken at the large observatories for mapping the stars and galaxies. Interest returned in the 1960s when the prospect of sending space probes through the main asteroid belt to the outer planets became a reality. The discovery of asteroids in the outer solar system in 1976 and beyond Neptune in 1992 prompted further studies as these were examples of bodies that had formed in the early solar system. There is now much observational activity directed to the discovery and follow-up of NEAR-EARTH ASTEROIDS as realization of the risk and effects of impact have slowly dawned on both scientists and the public at large.

Many amateurs begin asteroid observing by learning to track them down and keeping a log of those viewed. Beyond this 'trophy count' there is quite a variety of observation that can be done visually and much more with the use of a CHARGE-COUPLED DEVICE (CCD) camera. It is possible to image the brighter asteroids with a CCD camera and a 135 mm focal length telephoto lens mounted on an undriven camera tripod (figure 2). With no instrument at all, there is little to be done in the field of asteroid observing—at a favorable opposition 4 Vesta can reach naked eye visibility but even then a clear dark sky is necessary to allow it to be seen. However, with even small binoculars several examples can be seen at favorable opposition and this number increases significantly as the size of instrument used is increased. A permanent record can be made with photographic film or a CCD imager for study later.

Figure 1. Asteroid 15 Eunomia (arrowed) in Pegasus on 11 September 2001—135mm lens and CCD.

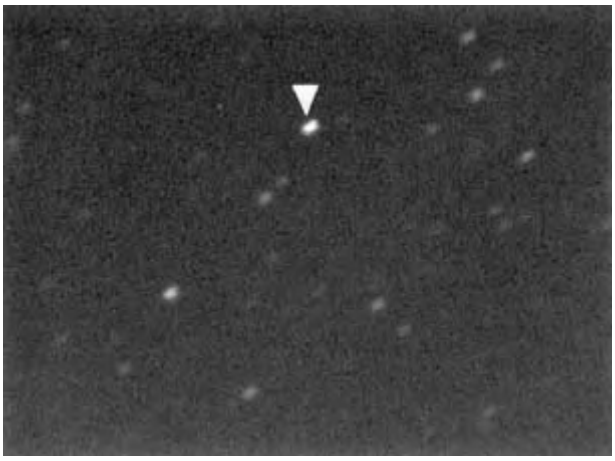

Figure 2. An undriven 4 second exposure of 4 Vesta in Taurus —31 December 2001.

The first task is to find the asteroid. As a minimum it is necessary to plot the position on a star chart to take to the telescope so that a visual identification can be made. On confusing fields where there are a number of possible

stars it is necessary to wait for perhaps an hour to identify which object has moved and is hence the asteroid. I currently use a telephoto lens–CCD on a driven GoTo mount (figure 3) so I only need to know the position to send the imager and can find the asteroid on the resulting image. Modern planetarium-type computer programs, such as GUIDE8 from Project Pluto, can plot a starfield with the asteroid shown and can in some cases also drive the telescope to the field (a far cry from what could be done in the 1950s).

Once the asteroid is found there are a number of things that can be done. The brightness can be deduced either visually or preferably from an image. Suitable comparisons can be taken from GUIDE8 by choosing HIPPARCOS stars of similar color to that of the asteroid. For a CCD image a V-filter should be used to ensure that the light passed is similar to eyeball observation. The Sony chip has a pseudo-visual window and can be used carefully with no filter as long as care is taken in the choice of comparison star. From this an indication of how the asteroid's brightness changes as it comes to and recedes from opposition (figure 4). Taking images of one asteroid over a night allows the rotation period to be determined (figure 5). Typically these are between 6 and 12 h although there are many examples known with periods shorter or longer than this.

Modern computer software allows CCD images to be used for positional measures. This is assuming that the start and end of the exposure is accurately timed and a suitable positional catalog is used (or downloaded from the internet for the field imaged).

Frequently asteroids occult (see OCCULTATION) field stars as they follow their orbital motion. As asteroids are relatively small (most less than 300 km in diameter) the path across the Earth is small. In recent years the positions of the stars and the orbits of the asteroids have been so refined that most predictions now have an uncertainty of typically 100 km—before HIPPARCOS and the orbital work, the uncertainty was 10 times greater or even more. Timing the events (or recording a miss) are

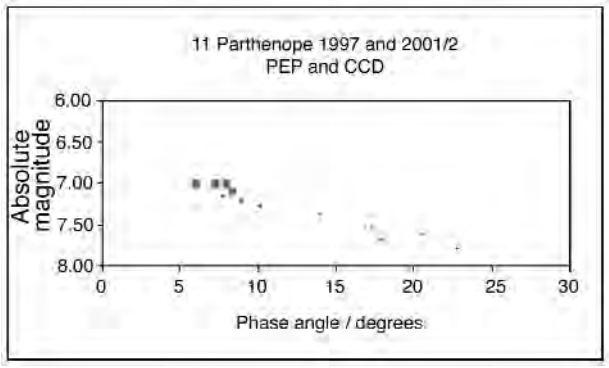

Figure 4. Phase curve for asteroid 11 Parthenope from CCD and photoelectric photometry.

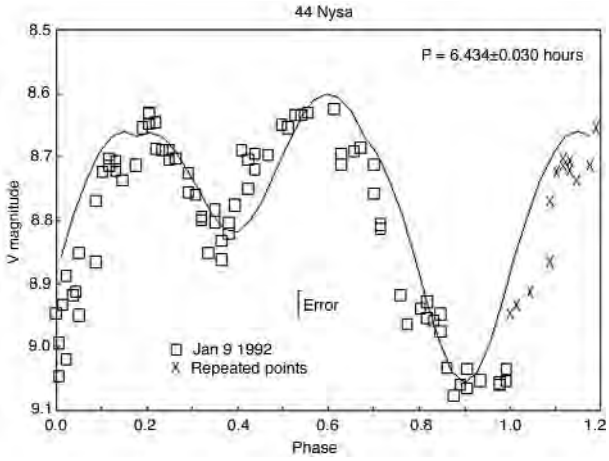

Figure 5. Rotation light curve for 44 Nysa from photoelectric photometry.

used to prepare a shape and size profile of the asteroids. Most of the information we have is from Earth-based observation as there are only a limited number of space missions that can be flown and a larger number of potential targets.

There are many observers who cooperate with professional programs to study near-Earth objects (comets can also be in this group). Very few observers are now discovering new objects (pre 2000 there were many unknown at 16th magnitude) as most discoveries are now 19th magnitude or fainter. Important aspects in this field are follow-up observations to define the orbits or photometry to check the rotation periods. Notices are given for those which will be studied by radar from Arecibo and rotations are studied using CCDs which help with the radar work.

From being a Cinderella field, the study of asteroids is now of high importance. All levels of study can be undertaken using simple equipment or the most modern of technology. As such there is much to interest all levels of observer.

Obsevatoire d'Haute-Provence

The Obsevatoire d'Haute-Provence is situated in south-eastern France at Saint-Michel-l'Observatoire, at an altitude of 650 m. Founded in 1937, it was originally an observational national facility for French astronomers. Now it has become an astronomical institute of the French CNRS with several fields of activity.

A staff of astronomers and post-graduate students are active in fields such as quasars, x-ray binaries, interstellar matter etc. Visiting astronomers use the 1.93 m and 1.52 m telescopes and their high-accuracy spectrographs with which the first extra-solar planets have been discovered (1995). Smaller telescopes are used for educational purposes or specific experiments.

All instrumentation including CCD controllers is observatory designed and built. Partnerships are developed with other institutes for the design of space experiments and the construction of the focal instrumentation of ESO VLT.

Research and development of new technologies related to large arrays of telescopes and interferometry are carried out.

A Department of Geophysics is active in research on the Earth's atmosphere as a member of the 'Network for Detection of Stratospheric Changes'.

Occultation

The motion of celestial bodies sometimes causes their paths to cross on the heavens. One says that the background object (usually a star) is occulted by the front object. Usually, a star is occulted by a solar system body: a planet, a satellite or an asteroid. The occultation of the Sun by the Moon is called a 'solar eclipse'. In fact, an eclipse is the disappearance of a body in the shadow of another one and an occultation (from the Latin *occultare*, to hide) happens when a body hides another body: in a lunar eclipse the Moon is in the Earth's shadow but a solar eclipse is in fact the occultation of the Sun by the Moon.

The occultation of stars by the Moon has been observed for a long time to study the stars. Later, stellar occultations by any solar system objects have been observed to study the planets, their atmospheres and their ring systems and small bodies such as satellites or asteroids. Occultations have now become a tool to explore the environment of other stars.

Lunar occultations

The disappearance of a bright star (Regulus, Antares, Aldebaran) behind the Moon is not a rare phenomenon, even if it is very difficult to observe without resorting to instrumental aid. However, some disappearances are reported in astronomical treatises. Copernicus observed a lunar occultation of Aldebaran in 1497. These observations allow one to deduce the relative proximity of the Moon and the very small apparent size of the stars. Sometimes, the star disappears in two steps, and this is interpreted as being because the light source is a binary. The abruptness of the occultation leads also to the conclusion that the Moon has no or at most a very tenuous atmosphere.

When photographic emulsions became sensitive enough, it was possible to record the rapid fluctuations of the stellar light before its disappearance and to evaluate the star's diameter. By 1980, a hundred star diameters had been measured with this method. The accuracy of the record was such that one had to take into account the fact that the occultation of a star by the Moon is a diffraction phenomenon: this means that the propagation of light when the star approaches the Moon's edge creates interference. The light fluctuates before extinction and reaches a maximum intensity which is 1.37 times the nominal star intensity. This flickering is extremely rapid, two successive peaks being separated by 0.02 s. That is why records on rapidly moving film were necessary to detect the diffraction fringes. We had to await the discovery of photometric detectors sensitive and rapid enough to exploit this phenomenon and obtain accurate measures of stellar diameters.

A tool to explore the solar system

Because they have a very small apparent size, occultations of bright stars by objects of the solar system are rare. Modern instruments, such as rapid aperture-photometers and charge-coupled devices, have allowed one since 1952 (photoelectric record of the occultation of σ Arietis by Jupiter) to observe occultations by planets, satellites, comets and asteroids. These observations are very fruitful tools to explore these objects.

- The exact position of the occulting object can be computed. The mutual occultations (and eclipses) of the satellites of JUPITER and SATURN occur each time the Earth passes through their satellite orbital planes, every 6 yr in the case of Jupiter. The principal value of the observation of these 'mutual phenomena' is in the improvement of our knowledge of the orbits of the satellites but it also allows us to detect small features on the satellites such as volcanoes on Io.
- When an occultation is observed from several observatories, the corresponding sections on the occulting object are separated by the same distance as between the observatories and the comparison of the lightcurves allows us to reconstruct the shape of the occulting object (figure 1). When their mass is known, the extremely precise size of some asteroids obtained with this method has made possible the determination of their density which provides clues to both composition and origin. An unexpected offshoot of minor planet occultations was the detection of possible satellites to some minor planets (Herculina, Melpomene, 146 Lucina), each satellite detected as a brief secondary dip in the occultation lightcurve. The observation by GALILEO of the double asteroid Ida and Dactyl has confirmed the reality of asteroid satellites.

Figure 1. Limb profile of the asteroid 2 Pallas deduced from observations of chords during the 29 May 1983 occultation of 1 Vulpeculae. (From Dunham *et al* 1983.)

- The extinction of a star's light behind a planet's atmosphere reveals the latter's temperature profile and the possible presence of haze but also the presence of gravity waves, some structures which seem to be a constant in all the dense planetary atmosphere from the Earth to Neptune. When the star disappears behind the atmosphere, it strongly sparkles before disappearing. In fact, the atmosphere is not isothermal and local temperature variations betray variation of the refractive index. Just as the warm air above a heater distorts images, so the star twinkles when it passes behind the planetary atmosphere (figure 2 and figure 3). The measurement of these fluctuations provides a way to discover atmospheres. Pluto's atmosphere has been discovered by this method.
- A few lucky occultations have provided information about the shape of the planet's atmosphere. The star's light is focused by a circular atmospheric layer and this creates a bright spot in the middle of the planet's shadow. The oblateness of the atmosphere gives to this spot the shape of a cardioid. If the observatory is at less than few tens of kilometers from the center of the planet's shadow, a scan of this 'central flash' is observed, which gives the global shape of the atmosphere. This phenomenon has been observed for Mars, Neptune, Titan (figure 2) and Triton.
- Observations of occultations led to the discovery of the very narrow (few kilometers) and/or thin rings system of URANUS (1977) and NEPTUNE (1984), which are almost invisible with other methods of observation. The Uranian rings reveal their presence by nine symmetrical brief drops in the stellar flux before the immersion behind the planet and after the emersion. The incomplete rings of Neptune, called arcs, left astronomers puzzled as they observed only one drop. They had not imagined that incomplete rings could exist: in fact they cannot exist without the help of a satellite. This shepherd satellite was predicted by theoreticians after the discovery of the arcs and observed much later by Voyager 2. Thanks to successive occultations, the positions of the Uranian rings are now known with a precision of a few hundred meters.

For these results it is necessary to record the star's light with a very high frequency (100 points s^{-1}) and to know precisely the timing of the occultation: this is now possible with the GPS satellite network. This method of observation is very favorable for Uranus and Neptune, for which some tens of occultations have been observed. Taking advantage of the presence of methane in the atmosphere of these planets, the occultations are observed at the infrared wavelengths of 2.2 and 0.9 μm: at these wavelengths, which correspond to absorption

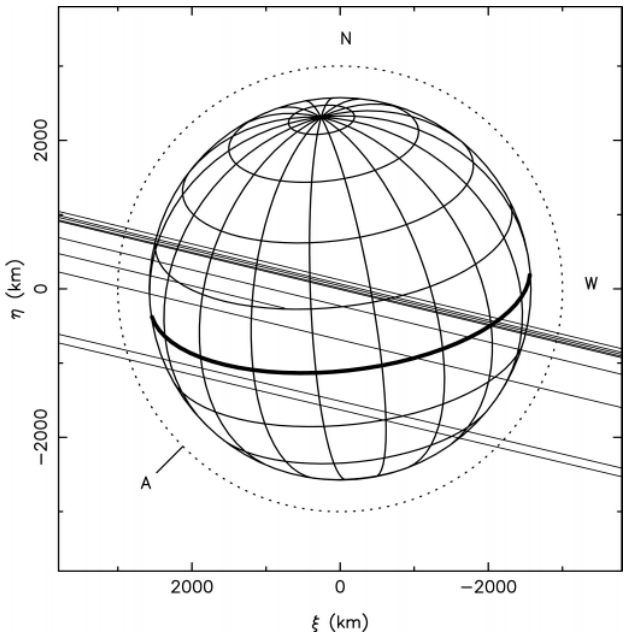

Figure 2. Geometry of the occultation of 28 Sagittarii by Titan, observed on 3 July 1989. W and N denote celestial west and north. The lines are the tracks of various stations in Titan's shadow. Observers move from the right to the left in this diagram. The upper tracks, packed together, correspond to stations in Northern Europe (including Hanover); they pass near the center of the shadow and observe the central flash. The middle and lower tracks correspond respectively to stations in Italy and Israel. The dotted circle is at 425 km altitude, where the atmospheric pressure is 7 μbar. (From Sicardy *et al* 1999.)

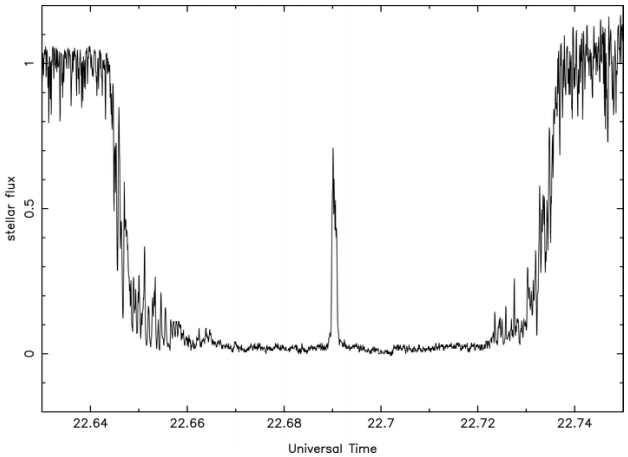

Figure 3. Light curve of the occultation of 28 Sagittarii by Titan, observed from Hanover, Germany, by H J Bode and C Bittner with a 0.4 m telescope at 0.65 μm wavelength. The normalized stellar flux is plotted in term of decimal Universal Time. The spikes visible during the immersion and the emersion are due to local temperature variations of the atmosphere. The central flash is created by the focusing of stellar light by a deep atmospheric layer.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

bands of methane, the planet is darker than in the visible wavelengths, and the signal-to-noise ratio of the light curves is increased. Jupiter and Saturn are not such good candidates for this method of observation because they are too bright. However, in 1989, the very bright star 28 Sagittarii (its visible magnitude is 5.5) was occulted by Saturn and its ring system (see SATURN: RINGS) and, 1 day later, by its moon TITAN: this exceptional event has been a mine of information about the atmosphere of this satellite (see figures 2 and 3).

Predictions and observations of occultations

Satellites, or asteroids, much smaller than the planets, have a smaller chance to occult a bright star; moreover, the necessary task of prediction of occultation is then much more difficult. It is necessary to know as exactly as possible when and where the shadow of the occulting object will sweep the Earth to prepare for the observation. For this, astronomers compare the EPHEMERIDES of the planet or satellite with a sky map. The uncertainty in the shadow trajectory make the observation chancy from a given place. Some scientific teams have developed portable kits with a telescope and an acquisition system. They wait to determine precisely the shadow's trajectory, a few days before the event, and they place the systems at the right location. The short-term predictions, the brevity of the events (less than a second for a ring and roughly 1 h for a giant planet) and their uniqueness make these observations very difficult. However, they are an unequalled tool for the exploration of the solar system, thanks to their high accuracy (up to 1 km) for the determination of the dimensions of solar system bodies.

Prospects for the future

Stellar occultations are the only way to detect small objects in the outer solar system which are too faint to be detected directly: the future will make stellar occultations a tool for exploration of the asteroid family and the small satellites such as Charon or Triton but also of the KUIPER BELT, the residual protoplanetary disk which lies beyond Neptune.

Sometimes, a star of a binary system is occulted by its dimmer companion. These so-called eclipsing binary are observed to determine their relative mass.

An extraordinary object is the star β Pictoris: spectral signatures of objects passing in front of the star are observed and these phenomena are interpreted as comets occulting the star when they fall into it.

The environment of stars can also be explored by searching for the extinction of the primary during the transit of giant planets.

The search for transits of planets in front of the central star is a promising method to detect extrasolar planets: a planet passing in front of the star creates a very faint extinction. Thus, this method needs to detect an extremely small decrease of the stellar flux. The main limit to this method is the scintillation due to the Earth's atmosphere. Observation from space will substantially improve the power of this method.

Oceans

Earth is a planet covered with oceans. This article describes these great bodies of water and the forces that shape their circulations. Also discussed are the latest observational techniques in oceanography with emphasis on remote sensing. Turning to the possibility of oceans on other worlds, the indirect evidence for ice-covered seas on Jupiter's largest moons is reviewed.

D H Lawrence once wrote: 'They say the sea is cold, but the sea contains the hottest blood of all.' These evocative words refer to whales in the sea, and they remind us that the topic of Earth's oceans is larger than just the physics of waves and currents, but also encompasses the biology and ecology of much of the planet's living space.

Humankind has always held a deep-seated fascination for the marine world, and more than just as an abundant source of food and an avenue for transportation. Interestingly, when spoken in reverse the poet's words still make sense. Consider that seawater is about ten times saltier than blood, but that, by mass, ocean salt consists of 55% chlorine (Cl^-), 30% sodium (Na^+), 8% sulfate (SO_4^-), 4% magnesium (Mg^+), 1% potassium (K^+), and 1% calcium (Ca^{2+}). The corresponding percentages in human blood plasma are 51%, 44%, 0.6%, 0.3%, 2% and 0.7%. Except for sulfate and magnesium, which are much reduced in blood, the salt ions appear in roughly similar proportions in blood and seawater. In this sense 'our blood contains the sea'.

Seven seas

Like a map of the constellations, a world map of Earth shows the patterns and locations of the ocean basins as they appear to us in the present epoch. But, just as the last frame of a movie provides only a hint of the plot, so too a world map hides most of the history of the endless movements of the continents. The solar system is 4.6 billion years old, based on radiogenic dating of primitive meteorites, and one need travel back in time only 2% of that age to see the Atlantic Ocean disappear. Continental drift proceeds at a typical rate of about 2 cm yr^{-1}, which adds up to more than two trips around the circumference of Earth over the age of the solar system. The Seven Seas are going places!

The Seven Seas are the Mediterranean Sea, the Indian Ocean, the Red Sea, the Persian Gulf, the Black Sea, the Adriatic Sea and the Caspian Sea. Today, we have a global view of Earth and speak in terms of four oceans, the Pacific, the Atlantic, the Indian and the Arctic.

Arctic Ocean

Earth's south polar region is covered by the continent of Antarctica, but its north polar region has no continental land mass or islands, instead, it is the location of the planet's smallest ocean, the Arctic Ocean. This remote body of water is nearly landlocked, with half of its sea floor made up by continental shelf. There is a central basin that contains three submarine ridges; the deepest point is 4.7 km below sea level.

The majority of the Arctic Ocean is north of the Arctic Circle and hence stays in continuous darkness during the winter and continuous sunlight during the summer. The ocean is mostly covered by sea ice that is 3 to 4 m thick, but where the ice opens up there is abundant life. The salinity of the ocean decreases from wintertime to summertime as the ice cap melts and shrinks in area (sea-ice melt has about one-tenth the salinity of average sea water).

The shortest route between North America and Russia is via the Arctic Ocean, and there are active collaborations between Russian, Canadian and US scientists focused on establishing the ocean's circulation patterns and interactions with the Atlantic Ocean via the Greenland Sea and Pacific Ocean via the Bering Strait. There have even been some recent attempts to find analogies between the morphology of pressure ridges in Arctic sea ice and the linear features seen in spacecraft images of Jupiter's icy satellite Europa.

Indian Ocean

The only ocean included in the original Seven Seas is the Indian Ocean, which is nearest to the world's oldest civilizations. It covers about one-fifth of the Earth's surface and is somewhat smaller than the Atlantic Ocean. It is bordered by Africa and the Arabian Peninsula to the west and Asia to the north, and because of this prime location has had a long, and sometimes contentious, maritime history.

Weather in the Indian Ocean region is dominated by monsoons (which comes from the Arabic word for season). These torrential wind and rain storms start June, with the heaviest rains hitting India in October, November and December. The winds are driven by differences in heating between the land and sea, and because they arise suddenly and cause much damage there is an effort to better monitor the storm breeding grounds in the Indian Ocean using satellite remote sensing.

Near the surface, the Indian Ocean's water is relatively poor in nutrients (it is warm and buoyant and hence resists mixing with nutrient-rich deep water). For this reason, phytoplankton (microscopic plants) do not thrive, and the ocean is not heavily populated by fish. The circulation in the southern basin is counterclockwise and the winds there are relatively mild. In the winter, the monsoon winds reverse the ocean currents around the northern basin from clockwise to counterclockwise.

Effects of rotation

Large-scale circulations in the oceans are affected by the EARTH'S ROTATION in the same manner that winds are affected in the atmosphere. Instead of rushing down-gradient to fill in low-pressure regions, which is the 'nature abhors a vacuum' direction that a fluid takes in a non-rotating system, Coriolis accelerations cause ocean currents to circulate around highs and lows in the water.

The balance between the horizontal pressure-gradient force and the Coriolis acceleration that occurs in all rapidly rotating atmospheres and oceans is called geostrophic

balance. The Earth-orbiting TOPEX/Poseidon and ERS-2 (European Remote Sensing) satellites both generate daily global maps of sea-surface height that can be converted to ocean surface circulations via geostrophy. The Atlantic's Gulf Stream, for example, stands out in surface altimetry data as a sharp ∼1 m step (low on the western side, high on the eastern side). It is a step because sea-surface height is a surrogate for pressure, and it is the pressure gradient that is proportional to the current. It has been demonstrated that the abyssal circulation is controlled by the pressure boundary condition above, meaning that a useful estimate of the circulation throughout the entire ocean can be made by combining satellite altimetry data with numerical models. In addition to correlating undersea circulations with sea-surface height, satellites are also capable of determining ocean wave heights, as was first demonstrated by Seasat in 1978.

There are two major differences between circulations in oceans versus atmospheres. The first is that ocean water is confined to move inside closed basins, which can be viewed as the most confining type of boundary condition encountered in geophysical FLUID DYNAMICS (GFD). In contrast, atmospheres are not closed off, although mountain ranges strongly influence wind patterns on Venus, Earth and Mars. Interestingly, the winds on the 'bottomless' gas-giant planets Jupiter, Saturn, Uranus and Neptune can be viewed as having rather benign boundary conditions since they suffer no mountain ranges or ocean basins, and they all sport east–west circulations.

Given the much greater mass of fluid in Earth's oceans than its atmosphere, it may come as a surprise that the second major difference is that the large-scale ocean circulation is driven by wind stress. The tail wags the dog, so to speak. Take away the atmosphere and its trade winds, and great currents like the North Equatorial Current, which travels the Pacific from east to west at latitude 15°N, would run down.

The winds do not merely push the water, except at the equator. If they did, the result would be confined to a shallow current that would head off perpendicular to the wind-stress direction. Away from the equator where rotational effects are important, two boundary layers called Ekman layers form in the wind-driven circulation, one in the atmosphere that is about 1 km thick and one in the ocean that is about 0.01–0.1 km thick and corresponds roughly to the ocean's well-mixed layer (the upper layer below which there is little response to passing storms). Significantly, the net (vertically averaged) atmospheric transport and net oceanic transport in these boundary layers are in opposite directions, and both are perpendicular to the surface wind-stress direction. This intricate three-dimensional picture emerges because the Coriolis acceleration balances the applied force, causing the bulk mass motion to be perpendicular to the forcing direction.

A horizontal variation in the wind stress leads to convergence or divergence in the oceanic Ekman layer, which leads to water being expelled from or drawn into the boundary layer, respectively. This process is called Ekman pumping. The amount of Ekman pumping is proportional to the curl of the wind stress. This vertical motion, a result of conservation of mass, deforms the constant-density surfaces underneath the boundary layer with the result that an ocean current is set up to achieve geostrophic balance. It is by this indirect mechanism that the wind drives the major ocean currents.

An important practical result of Ekman pumping is that surface water can be drawn away from a coastline by a persistent breeze that blows along the coast in the appropriate direction (depending on the hemisphere). To conserve mass, cold, nutrient-rich deep water (enriched by the settling of dead organisms) then upwells near the coast, which causes the phytoplankton level to rise dramatically, which in turn attracts great quantities of fish. Half the world's fishing relies on this sensitive mechanism. Given that Earth's coupled atmosphere–ocean system can exhibit more than one type of circulation with similar boundary conditions, there is strong economic motivation to discover and understand the feedbacks. For example, in normal years one-fifth of the world's catch is taken off the coast of Peru alone, but during El Niño years the equatorward wind is disrupted and Peruvian fishing declines dramatically.

Western boundary currents

Each ocean basin contains a strong current that runs along its western boundary, the Atlantic's Gulf Stream being a well-known example. In the Pacific, the North Equatorial Current turns into a western boundary current called the Kuroshio as it curves northward past Japan. In three dimensions, these fast moving rivers-in-the-sea have the appearance of writhing snakes.

Why not eastern boundary currents too, or alternatively, no lateral intensification at all? The answer depends on the shape of the planet itself: if Earth was flat instead of round, then there would be no Gulf Stream.

Because planets are round, the angle between their rotation axis and the local horizontal plane of motion changes with latitude. This means that the component of the Coriolis acceleration that is vertical (parallel with the local direction of gravity), which is the component that couples to horizontal motions, vanishes at the equator and is strongest, with opposite signs, at the two poles. The gradient of the Coriolis acceleration with respect to latitude is important because it appears in the equations of motion as a vorticity gradient. It is traditionally denoted β, hence the phrase 'beta effect'. The planetary vorticity gradient would be zero on a turntable Earth. On a sphere, β is zero only at the poles and is positive everywhere else (in both the northern and southern hemispheres); it is largest at the equator.

The spatial anisotropy that generates western intensification in ocean basins comes from the dispersion properties of a particular kind of wave, not a sound wave or a buoyancy wave, but a larger, more slowly moving wave called a Rossby wave (or planetary wave). Rossby waves

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

travel along gradients in the background vorticity (to be precise, gradients in the background potential vorticity, the ratio of the inertial-frame vorticity to any appropriate measure of vertical column stretching). On Jupiter and Saturn, the large amount of local vorticity in the alternating jet streams tends to dominate the beta effect, and consequently the local shape of the wind profile is important to the Rossby wave dynamics. But on Earth, the winds and ocean currents are much weaker and the beta effect governs the behavior of Rossby waves.

Rossby waves are strongly dispersive. A wave packet that reflects off the western boundary of a beta-dominated ocean basin and travels eastward is composed of small wavelengths only, because only small wavelengths have eastward group velocities. Conversely, a wave packet that reflects off the eastern boundary and heads westward is composed of only large wavelengths. Thus, the western boundary is a source of small scales and the eastern boundary is a source of large scales. All models of the western intensification include some type of damping that prevents the small scales generated at the western boundary from leaking into the ocean's interior, but the details do not affect the existence of the boundary current itself, which is a certain feature of ocean basins on a rotating, spherical planet.

Western boundary currents play a role in marine biology and climate. Meanderings of the Atlantic's Gulf Stream regularly pinch off to form drifting vortices called Gulf Stream rings that can transport phytoplankton over large distances. Regarding climate, the warmth of the Gulf Stream moderates the weather of the British Isles and western Europe. In fact, the Scottish islands to the north have a milder climate than the rest of Britain because of their close proximity to the Gulf Stream.

Atlantic Ocean

The Atlantic Ocean is separated from the Indian Ocean by a dividing line at the 20°E meridian between the southern tip of Africa and Antarctica. An association with Atlas in Greek mythology gives the Atlantic its name.

Many gulfs and seas ring the north and south Atlantic basins, including the Mediterranean Sea to the east, the Gulf of Mexico and Caribbean Sea to the west, the North Sea and several seas around Greenland and Canada to the north, and the Weddell Sea off the coast of Antarctica to the south. There is ample fishing in the waters over the continental shelves, which constitute about one-tenth of the ocean's floor.

The northern and southern halves of the Atlantic combine to form a shape like the letter S, and suggestively, the sea floor is dominated by a submerged mountain range with the same shape called the Mid-Atlantic Ridge. The main evidence that first won widespread acceptance of the theory of plate TECTONICS is the fact that the orientation of the magnetic field in magnetic rocks on the ocean floor, which record the direction of Earth's field when they cool below their Curie temperature, alternates in stripes that are mirror symmetric about the Mid-Atlantic Ridge. This demonstrates that the ridge is a sea-floor spreading center. In fact, the Atlantic is only 100 million years old, which makes it the youngest of the four oceans.

In the North Atlantic between the West Indies and the Azores is a stable region away from strong currents that is notable for containing large patches of floating seaweed. This is the Sargasso Sea, named after the Portuguese word for grape, sargaco, which describes the appearance of its most common seaweed, sargassum. The total area of the Sargasso Sea covers about 6% of the Atlantic (not counting adjacent seas). The free-floating seaweed does not hinder ships, although fishing is generally poor in the region because the water is warm and the phytoplankton concentration is reduced by a factor of three from average.

The sargassum plays host to many small marine animals, but there is one fish in particular whose association with this sea-within-a-sea is remarkable, the fresh-water eel. The manner in which eels in eastern North America, Europe and the Mediterranean reproduced had long been a mystery, until it was discovered in the 1920s that they *all* swim to the Sargasso Sea to spawn (details, such as how long the eels live after spawning, are not yet known). One cannot help wondering what sort of sagacious greeting a 30-year-old American eel gives to a 3-year-old Atlantic salmon as they swim past each other on these incredible early autumn reproductive migrations. How and why all this two-way traffic got started is a mystery (a similar puzzle is the migration of sea turtles in the South Atlantic, discussed below). The Pacific is home to many varieties of salmon, but eels spend their long lives inland, and in this respect it is notable that the Atlantic receives river outflow from a drainage area four times bigger than that received by either the Pacific or the Indian Oceans.

Meddies

A simple application of comparative PLANETOLOGY to the solar system's atmospheres and oceans generates the following question: why do Jupiter, Saturn and Neptune have long-lived storm systems, numbering hundreds, a dozen or so, and a couple, respectively, with the largest and most famous being Jupiter's GREAT RED SPOT, whereas Earth has only short-lived storm systems? Where are Earth's great spots? Hurricanes might fit the bill, except they turn out to be a uniquely terrestrial phenomenon that requires surface friction to operate. To be specific, one is looking for free, coherent high-pressure storm systems, called anticyclones, not cyclones like hurricanes.

In fact, EARTH'S ATMOSPHERE does have great high-pressure storm systems. One just needs to know where to look to find them. For example, a stubborn anticyclone called a blocking high often settles over North America or Russia for months at a time. Unfortunately, in satellite images these blocking highs are cloud-free and hence invisible, instead of cloud-filled and easy to visualize like spots on Jupiter. Blocking highs tend to divert rain storms from their normal paths and can cause droughts. One of several reasons they do not last long is simply that

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Earth's atmosphere is so small in horizontal area that its atmospheric eddies jostle against each other incessantly, and so do not remain coherent for long. In constrast, anticyclones on the gas giants have one hundred times more surface area to move around in, which results in fewer eddy–eddy interactions and more predictable weather.

In contrast to its atmosphere, Earth's oceans turn out to be as roomy as the gas-giant atmospheres. The typical ocean eddy is two orders of magnitude smaller than the typical atmospheric eddy because oceans having much slower buoyancy waves, a consequence of much reduced density contrasts. One could go so far as to refer to Earth's oceans as 'basin-giants', to distinguish them from the 'gas-giant' atmospheres of Jupiter and Saturn.

If indeed the Atlantic Ocean was populated with Jupiter-like anticyclones spinning around underneath the surface, how would we know it? Flow visualization for Jupiter requires simply running a movie of the swirling cloud tops that have been photographed from afar by a spacecraft or a space telescope like Hubble, but not so for Earth's oceans. One discovers anticyclones in an ocean by hunting them down painstakingly with well-equipped ships. As it turns out, the hunting is good in the eastern Atlantic.

The reason is that extra-salty water from the Mediterranean Sea regularly breaks away into the eastern Atlantic and forms undersea lens-shaped anticyclones called Mediterranean water eddies, or meddies for short. Large numbers of meddies have been tracked over the last two decades. Individuals persist for several years and travel great distances, and collectively they are responsible for 20–40% of the salt flux coming into the Atlantic from the Mediterranean.

Subsurface SOFAR floats (SOund Fixing And Ranging floats) are used to determine the circulation structure inside meddies. They have core radii of about 20 km and turnaround times of about 4 days, with longer looping periods above and below the core. This is similar to the turnaround times of anticyclones on Jupiter. Because both meddies and Gulf Stream rings are likely to be mathematically similar to gas-giant anticyclones, there is a great deal of interest in both oceanography and planetary science to understand how environmental conditions like shear affect their drift speeds and directions, and how fluid nonlinearities allow them to remain coherent.

Labrador Sea

The general ocean circulation is called the thermohaline circulation because gradients in both temperature and salinity affect the density of seawater. This makes the dynamics of ocean currents particularly interesting. For example, a parcel of seawater can sink because it is cold and salty, or because it is warm and very salty, or because it is fresh and very cold. In addition, the diffusion rates of temperature and salinity are different, and this leads to a set of convective phenomena called double-diffusive convection, which includes unexpected structures like salt fingers and layered convection.

Seawater that becomes dense enough will sink to the bottom of the ocean and then spread out until it is constrained by the effects of planetary rotation. This is especially true in the Arctic Ocean and the poleward borders of the Atlantic Ocean where the formation of sea ice increases the salinity and hence the density of the already-cold underlying water. One accurate method for tracking the deep circulation is to monitor the progress of radioactive isotopes introduced into the oceans by early nuclear bomb tests.

An ongoing campaign that combines observations and numerical modeling from many research groups has the goal of understanding the formation of bottom water and the process of deep, penetrative convection. The Labrador Sea, which is the water between Greenland and Canada, is the unenviable location of the field laboratory for these mid-winter experiments. Often, 'chimneys' of downward convection are found there that have a significantly smaller horizontal scale than the atmospheric forcing above. They may occur preferentially in regions where the ocean stratification is weakened by the presence of pre-existing eddies (with cold centers), or be triggered by topography, or by some other small-scale, destabilizing mechanism.

Understanding the rate of formation of deep water is important for climate studies because it affects the rate in which carbon dioxide is exchanged with the atmosphere, and because deep water circulation contributes to the redistribution of heat from the equator to the poles. The process of Coriolis-influenced deep convection occurs not only in the coldest seas on Earth but also in stars and planets. For example, it may play a role in the formation of hot spots (large holes in the clouds) on Jupiter, like the hot spot that the GALILEO atmospheric probe sampled in December, 1995.

Pacific Ocean

Earth's oldest and largest ocean is the Pacific Ocean. It contains the deepest point on the planet's surface, the Mariana Trench (11.7 km below sea level), and contains the continent of Australia, the island arcs that make up Polynesia bordered by Hawaii, New Zealand and Easter Island, and about 25 000 islands all told. This single body of water covers one-third of Earth's surface. Away from island arcs, their trenches, seamounts and mid-ocean spreading centers like the East Pacific Rise, the bottom of the Pacific basin is basically flat with an average water depth of 4.3 km.

Ocean acoustics

The high opacity of salt water prohibits direct observations of the three-dimensional structure of Earth's oceans. But unlike light waves, sound waves travel readily in the ocean, and for this reason sound is used extensively by marine mammals for echolocation (high-frequency clicks) and communication (low-frequency songs). Physical

oceanographers use acoustic tools as well, like inverted echo sounders (IESs), to exploit the linear relationship that exists between acoustic travel time and interesting properties such as temperature and the depth of the ocean's well-mixed layer. Acoustic tomography uses coded transmissions sent between arrays of half a dozen or so elements that last for around 30 s at a time.

It is known that dolphins coordinate with each other when hunting in groups. Killer whale pods appear to have dialects or accents. During the mating season, humpback whales sing repeating songs that can be heard more than 100 km away. The repertoire of marine mammals is impressive, spanning a range of clicks, rasps, buzzes, whistles, moans and haunting trumpets. Low-frequency man-made sounds ($\sim$120 dB), as from underwater drilling, have caused whales to change their migratory paths, so there are studies underway to determine the impact of military, commercial and scientific noise pollution on marine animals.

Sea monsters

In the process of gaining complete knowledge of the oceans and their inhabitants, we are losing something precious, namely the mystery of the sea and its ability, since antiquity, to fire our imaginations. No one expressed this mystery better than the early map-makers who filled uncharted expanses of ocean with illustrations of sea monsters. Besides the many species of whales in the oceans, there are at least two giants of the deep that have, over the centuries, greatly influenced the cultural view of what a sea monster looks like.

First, consider the world's largest invertebrate, and undoubtedly the source of the Norwegian kraken legend, the giant squid (*Architeuthis dux*). This mysterious behemoth has not yet been photographed alive, and virtually nothing is known about its social organization, but it is thought to live in total darkness a kilometer below the surface of the sea. Only a couple hundred giant squid have washed ashore around the world in the last century. The longest were 20 m long (the length of two school buses). The evidence suggests their typical lifespan is only about 5 years. To grow so large they must be terrific hunters that require an abundant food supply, as can be found in the Kaikoura Canyon off of New Zealand. Although no sunlight reaches the depths favored by the giant squid, most deep-sea fish are bioluminescent, and the giant squid has eyes the size of a human head, the biggest of any animal.

Giant squid have been found in the stomachs of sperm whales, which is the only known predator of the adult squid, and in turn, dead sperm whales with giant sucker marks have been found washed ashore. Even though the sperm whale's favorite food appears to be giant squid and it weighs 30 times more than its prey, the whale does not always hold the advantage in what is present-day Earth's most titantic one-on-one rivalry. Legends of kraken attacks are most likely based on the actions of giant squids that mistook small ships for whales.

Second, consider the world's largest and longest bony fish, and undoubtedly the source of the sea-serpent legend, the crested oarfish (*Regalecus glesne*). This incredible ribbonfish grows to over 10 m in length, and there are old reports of specimens twice that length, which rivals the length of the giant squid. The fish's name comes from a pair of elongated pelvic fins that rotate like oars as it swims. Its dorsal fin runs the length of its back like a red-gold mane, and the first ray at the head extends upwards in the manner of a long feather. When seen swimming on the surface, the oarfish has the appearance of an impossibly long, red, undulating sea serpent. Oarfish are known to inhabit the Mediterranean, the Atlantic and the Pacific, and like the giant squid, they can survive to depths of 1 km. They have large deep-sea eyes, a small toothless mouth, and a silvery appearance that is thought to attract prey. Studies of specimens washed ashore reveal that the fish's stomach runs almost half the length of its body, but amazingly, the oarfish can apparently survive losing the second half of its body to attack by predators, and then regenerate it.

Sightings of the oarfish occur only about once a decade, but unlike the giant squid, an oarfish has recently been photographed underwater. In May 1996, a pair of divers working near New Providence in the Bahamas encountered and photographed an oarfish rising from the depths. It was positioned vertically and was swimming by undulating its dorsal fin without body movement.

Throughout the ages, there have been many detailed eyewitness accounts of sea monsters that can be attributed to giant squid or oarfish (examples of the former include an old report by sailors that describes a whale being pulled beneath the waves by an enormous 'snake', and another that tells how a giant squid crawled up the bow of a ship before being shot off), but there are other stories, from equally credible sources, that appear to require alternate explanations. For now, the fact that the most common undersea vessel, the military submarine, carefully listens to but does not look at its surroundings, means that the reader is free to imagine (and if talent permits to illustrate) the size and shape of unknown deep-sea creatures that occasionally glide by.

Remote sensing

Providing a complementary perspective of the inner space of the sea from the relative safety of outer space, oceanography's newest observing platform is the orbiting satellite. The remote sensing of Earth's oceans is, in many respects, similar to any other astronomical observation, except for the 180° turn of the space-borne telescope and the inherent advantages of proximity to the subject. Space-based detectors have generated so much high-quality data in so short a time that modelers are struggling to keep pace. They are developing optimized data assimilation techniques like those used in meteorology to gain the greatest accuracy from the blending of observations with numerical models.

Sea-surface temperature

In addition to sea-surface height and spectroscopic information, satellites produce maps of sea-surface temperature (SST). Surface temperatures range in approximately zonal bands from freezing at the poles to 20–30 °C in the tropics.

Changes in SST reflect changes in the transfer rate of energy between the air and sea. For example, hurricanes are known to develop in regions where the surface temperature is greater than 26 °C. Since most tropical depressions do not grow into hurricanes, an energetic threshold must be overcome. Strong winds produce large evaporation rates that increase the moisture content of the atmosphere, which enhances the convection and has a positive feedback on the winds. Modelers are working on developing a reliable means of predicting which disturbances will become hurricanes and what specific field observations are needed to do so.

Since December 1998, the Geostationary Operational Environmental Satellites (GOES) have been producing hourly SST estimates, with the ability to sample a position 48 times per day with a 4 km field of view. Sea-surface temperatures cannot be determined over cloudy areas. This disadvantage is turned into an advantage by observers who exploit the fact that SST maps show precisely the location of cloudy areas, which is useful for other studies.

Sea turtles

Satellites are not only having a positive effect on the study of physical oceanography, but also on the study of marine biology, as the following example illustrates.

In the middle of the Atlantic Ocean, just 80 km east of the Mid-Atlantic Ridge, at coordinates 7.95°S, 14.37°W, there is a solitary island less than 90 km^2 in surface area that World War II pilots were fond of quipping about, dryly, saying 'If you miss Ascension, your wife gets a pension'. Across half the ocean, about 2300 km west of Ascension Island, is the coast of Brazil in South America. For the past 100 million years since the birth of the Atlantic, plate tectonics has increased the distance between the Mid-Atlantic Ridge and Brazil by a few centimeters per year.

Based on tagging studies, a remarkable group of green sea turtles (*Chelonia mydas*) are known to use Ascension Island as their only nesting site. Females return every 2 to 4 years to their favorite beach on the island to lay eggs. No one can say for sure how long these turtles have been nesting exclusively on Ascension Island, but it is known that they have unique mitochondrial DNA that implies females do not trade places with other females. The species itself is many millions of years old.

What makes Ascension turtles remarkable is that their feeding grounds are along the coast of Brazil. The pioneer of sea turtle studies, Archie Carr, first suggested the idea that plate tectonics has slowly but incessantly stretched the turtles' foraging path from a reasonable foray millions of years ago into today's mighty migration.

The study of marine animal migrations has become a precise science with the advent of satellite tracking, which has been applied not only to green sea turtles but also to loggerhead turtles (*Caretta caretta*) and to elephant seals. As an example, six Ascension green turtles were outfitted with Telonics ST-14 satellite transmitters between April and July 1997 and then tracked as they migrated to Brazil. Of course, the 'if you miss Ascension' return trip would be even more interesting to track, but it is hard to predict when a turtle is going to leave Brazil, and current transmitters have relatively short lifetimes. The signal from one of the six turtles was lost after only 19 days, during which time she did not head off to Brazil but went on an eastward exploratory path that eventually looped back to the island. The other five turtles headed west towards Brazil in a no-nonsense fashion, with three of them separately following indistinguishable paths during the first 300 km. The data show that the trip to the coast takes the turtles about 6 weeks (in this particular study all of the transmitters failed just shy of Brazil).

The tracking results establish that turtles are able to swim in a straight line for weeks at a time with no islands or coastlines to guide them across the deep sea. They also like to punctuate their journey with occasional exploratory meanders that are then followed by the appropriate course corrections. The ability of sea turtles to achieve such precise navigation is not well understood. The satellite data show that most turtles tend to slow down somewhat at night, but the position of the Moon does not affect their navigation, and since they are known to be severely nearsighted when their heads are above water, they cannot focus on stars, which is one trick used by migrating birds. The leading hypothesis is that sea turtles are sensitive to both the intensity and inclination of Earth's magnetic field and can navigate it like a grid. This ability has been established for hatchling by controlled experiments. Earth's magnetic field is known to have changed some of its details in just the last 100 years, so the complete story has yet to be uncovered; however, the turtles will undoubtedly be patient with us as we try to come up to speed with them using the latest satellite technology.

Icy satellites: the case for an ocean

Of the nine planets, Earth's orbit alone occupies the narrow corridor where surface liquid water is stable by virtue of sunlight, which happens to occur at about one hundred solar diameters from the Sun. However, sunlight is not the only heat source in the solar system, there is also geothermal energy, and with it, the possibility of underground oceans.

There is no lack of potential sites for such an ocean in the solar system. Jupiter is the closest gas giant to the Sun and has four large moons, CALLISTO, GANYMEDE, EUROPA and IO, which are referred to collectively as the Galilean satellites in honor of their discovery in 1610 by Galileo, and which are easily seen with binoculars in the night sky. These are planets in their own right — in fact, to within 2% Callisto has the same radius as Mercury, while

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Ganymede, the largest moon in the solar system (out of 62 and counting), is 8% bigger. Saturn's moon Titan is also 6% bigger than Mercury (much more will be learned about Titan's surface and interior during the Cassini mission).

But, what Mercury has in over abundance these moons lack, namely proximity to the Sun and its warming rays. Surface temperatures on Europa do not exceed 130 K and average 103 K, which is $-170\,^{\circ}$C. Given this, why are icy satellites viable candidates for bodies that might harbor subsurface seas?

Firstly, one needs a ready supply of H_2O in some phase, and the icy satellites are aptly named in this regard. Their $\sim$2–3 g cm^{-3} bulk densities imply a substantial icy component to their make up, moment-of-inertia gravity data place the ice predominantly in a 200–300 km outer shell (depending on satellite), and the spectroscopic signature of ice has long been detected on the surfaces of Callisto, Ganymede and Europa. No water has been detected on Io's surface, which is covered by sulfurous volcanic material, mostly SO_2 frost. Excluding Io, much of the effort in icy-satellite spectroscopy is to peer through the strong H_2O absorption lines and determine the composition of the small amount of dirt that is mixed in and to determine whether there are salts like $MgSO_4$ on the surface.

Secondly, one needs to melt the ice. At a pressure of 1 bar $= 10^5$ Pa, or approximately sea-level pressure on Earth, the melting temperature is 273 K. The lowest temperature possible for *pure* liquid water is 251 K at a pressure of 2080 bar, which is the pressure found a few hundred kilometers below the surface of an icy satellite. This depth is likely to be past the icy shell and into the rocky mantle on Europa. However, it is not hard to make antifreeze out of water by adding small amounts of ammonia or salt, which lowers the freezing point by many tens of degrees. It is also beneficial that when ice forms it leaves a large portion of these contaminants behind and this increases the brininess of the remaining liquid. If enough ammonia is present, the target minimum temperature for liquid water will be less than 200 K. The trick, then, is to raise the temperature from the surface value of about 100 K to the melting temperature as near as possible to the surface.

Sources of heating

To form liquid inside an icy satellite requires a source of heating. One source is the decay of naturally occurring radioactive ISOTOPES, called radiogenic heating. The amount is dependent on how much silicate-rock is mixed in with the ice, since it is this component that bears trace amounts of radioactive uranium, rubidium, samarium, potassium and thorium. It is reasonable to assume that these elements occur in proportions similar to what is measured in meteorites, so an estimate of the ice-to-rock ratio yields a heating rate.

Tidal dissipation has the potential to produce a great deal more heating inside an icy satellite than radioactivity, which is the case for Io and Europa. By TIDES and tidal dissipation is meant the flexing of the body, both its solid and liquid components, in response to changes in the external gravity field. Flexing a solid object repeatedly produces an impressive rise in temperature, as can be demonstrated by bending a paperclip back and forth several times. Io, the innermost Galilean satellite, experiences so much of this heating that it is more volcanically active than Earth, in spite of the fact that Io has nearly the same size and density as Earth's Moon.

The reason that Io and Europa have high tidal heating starts with the fact that their orbits are continuously forced to be slightly elliptical. This is the price they pay for cooperating with Ganymede to form a 4:2:1 orbital-period resonance called the Laplace Resonance. Io is the closest to Jupiter and hence the fastest orbiter, with a period of 42 h. The result of the three-body resonance is a forced eccentricity for Europa of about 0.01 and for Io of about 0.004. These seemingly small values turn out to be not so small when one carries out tidal stress calculations, as was first done by Peale, Cassen and Reynolds in 1979, who correctly predicted widespread volcanism on Io just a week before VOYAGER discovered the same.

Orbital eccentricity is converted into tidal flexing, and ultimately into heating that could be maintaining a subsurface ocean today, by two means. A small amount of flexing is generated by the change in the strength of the external gravity field as a satellite moves closer to and then farther away from its planet during each orbit. However, for synchronous rotators like Io and Europa, that is, satellites that keep the same face pointed towards their planet in the same manner that the Moon points towards Earth, most of the flexing arises because each satellite rotates around its axis at a constant rate like a clock but revolves at a variable rate described by KEPLER'S LAWS, moving along its orbit faster when closer to the planet and slower when farther away. This produces a constant nodding back and forth across the satellite–planet direction that is called 'optical libration'.

Estimates of Europa's present-day heat flux, based on theoretical evolution models, run as high as 5 K km^{-1}, which implies melted ice only 20 or 30 km below the surface. There are many details left to be worked out, for example solid-state convection of ice may replace conduction as the primary heat transfer mechanism for ice thicker than about 10 km. In any case, the strong tidal heating on Europa and Io cause these bodies to have two of the most intriguing and beautiful surfaces seen anywhere.

Magnetometer data

Is Europa's beauty only skip deep? There have been some tantalizing signals obtained by the Galileo Orbiter's magnetometer that suggest a subsurface ocean may be a reality. Jupiter's strong magnetic field is tilted about 10° from its rotation axis and rotates with the planet on a 10 h cycle, which means the background magnetic field in which the Galilean satellites are immersed changes its direction every few hours. If an icy satellite has a global conductive component, for example a briny interior

sea, then an alternating magnetic field will be induced that could be distinguished from a permanent dipole by sampling the satellite's magnetic field at different phases of Jupiter's rotation.

Surprisingly, the outermost and most heavily cratered Galilean satellite, Callisto, has yielded a positive initial result to this experiment. The first two passes of Callisto by Galileo (passes C3 and C9; the notation signifies that the third and ninth orbits involved close encounters with Callisto) revealed that the satellite has a magnetic field with a surface strength of about 15 nT (4000 times weaker than Earth's surface magnetic field). Significantly, there was a flip in direction of the satellite's field that matched the large change in the rotational phase of Jupiter between the two flybys. The conductivity of a hypothetical ionosphere on Callisto is insufficient to provide the needed current path, but an ocean as salty as on Earth that is about 10 km thick, and at most only 100 km below the surface, can account for the data. This caught the Galileo team off guard, because Callisto has a much older surface than Europa and it is not part of the 4:2:1 orbital resonance.

At Europa, an induced-field model like the one that works for Callisto can fit the Galileo magnetometer data obtained from orbits E4, E11, E12 and E14 (magnetometer data were not acquired on pass E6). However, for these orbits the picture is complicated by Europa's interaction with the plasma caught in Jupiter's magnetosphere. In particular, large magnetic fluctuations in the data can be attributed to ions that are sputtered off of the satellite itself. Also, for these passes the rotational phase of Jupiter was not as distinct as it was for Callisto. To settle the question, the E26 orbit on 3 January 2000 was designed to make it clear whether or not the north pole on Europa moves with Jupiter's magnetic field. The experiment netted a positive result. Europa's north pole is moving and thus it is likely that there is a salty ocean somewhere in the outer 100 km of Europa. At the time of this writing the jury is still out for an induced field at Ganymede, but there are more encounters to come as part of the extended Galileo Millennium mission, which will also feature simultaneous observations of Jupiter by Cassini in December 2000 as it slingshots towards Saturn.

Europa's surface versus terrestrial sea ice

The reason that the spotlight has been on Europa is that Voyager discovered it has very few craters and no large mountains, implying that its surface has unusually ductile underpinnings. Additionally, Europa's darkest regions are all lighter in color than the lightest regions on Callisto and Ganymede—it is truly an ice world. But is it a sea-ice world like the Arctic?

Voyager images reveal many long, thin dark–light–dark markings called triple bands that criss-cross Europa's surface and some dark, wedge-shaped bands that imply more than 20 km of lateral spreading. On Earth, various processes modify the appearance of sea ice on horizontal scales ranging from kilometers down to the size of ice crystals, and it is instructive to make comparisons with Europa where possible. Caution is needed, however, because in some cases the formation mechanisms for ridges and jumbled terrain in sea ice are not completely understood, and so, even after accounting for the much lower surface temperature and gravity on Europa, one must always be conservative when attempting analogies. (Recall that before the 1960s, cloud-covered Venus was thought to harbor tropical rainforests by analogy with Earth's tropics; when in truth, the Venusian surface is hotter than the inside of a self-cleaning oven.)

Europa's triple bands often exceed 1000 km in length and this is much longer than any open cracks (called leads) or pressure ridges observed in Earth's sea ice. An important deformation mechanism on Europa is global-scale tidal flexing, whereas on Earth the shape of the ice is governed by local changes in temperature, sea currents, and the wind. Also, mature terrestrial sea ice reaches an average thickness of only 3 to 4 m, which is three orders of magnitude thinner than models suggest for Europa. The large difference in thickness, plus the large difference in temperature, prevent simple comparisons of ice-plate deformations on the two worlds.

The best geological hints of water inside Europa are revealed in high-resolution imagery taken by the Galileo orbiter; reports of all the Galileo imaging results are collected together in a special issue of *Icarus*, (vol 135, 1998). The spacecraft passed close enough to photograph Europa's surface at 20 m/pixel, which is 100 times better resolution than obtained by Voyager. A type of terrain dubbed 'chaos' was discovered that consists of $\sim$ 1 km and larger broken blocks that have been obviously rotated, translated and in some cases tilted, and appear to be frozen into an ice field. There is an active debate as to whether a global ocean is needed to explain the chaotic terrain. Alternative ideas include having only a local 'slush field', or having no liquid at all, just an underpinning of soft ice that, given enough time, could yield the same jumbled appearance.

Evidence for local cryovulcanism is found in some moderate-resolution Galileo images that show flowlike masses covering portions of ridges, and in some high-resolution images that show small, smooth areas that appear to be frozen flood plains. Efforts to discover current cryovolcanic activity, for example by looking for scattered light from erupting particles while Europa is in Jupiter's shadow, have yielded null results to date, but the Galileo observations are by no means exhaustive and the search continues.

Life on Europa?

Assume for the sake of argument that Europa contains an ice-covered salty ocean. Given what we know about the robustness of life on Earth, which routinely surpasses the expectations of even the experts, what are the chances that there is life on Europa today? Slim to none, is the present estimation, because of a lack of fresh oxidants.

In addition to water and nutrients, which we are assuming Europa has, life requires both a source of energy

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

to grow and reproduce and a mechanism for harnessing that energy. On Earth, the primary source of energy is sunlight. The most that can be expected of sunlight at Europa is a weak illumination of the frigid surface and a penetration to depths of a few tens of meters, which is at best one-thousandth of the 20 km distance needed to reach an interior ocean.

Even so, energy is not the main problem for life on Europa, for two reasons. First, life on Earth is thought to have started before photosynthesis evolved. Simpler chemical reactions involving reduction–oxidation (redox) pairs of chemicals, kept in disequilibrium by deep-sea hydrothermal vents, were apparently an early means by which Earth's organisms harnessed energy. Second, present-day Earth has impressive biota associated with these hydrothermal vents (called 'black smokers' because of their appearance) that are disconnected from other biological systems and see no sunlight, and yet are thriving. By analogy, we can say that as long as Europa has something like hydrothermal vents, its inhabitants would not have to suffer from an energy crisis.

It is the chemistry needed to harness that energy that is the bigger problem, in particular, the oxidant budget. Present-day terrestrial vent organisms rely on redox reactions involving SO_4^{2-}, O_2 and CO_2, which are oxidants that are delivered to the deep sea from the ocean surface. Other energy-producing reactions exist that involve elemental sulfur or the production of methane (CH_4), but these are low-energy alternatives that do not meet the needs of terrestrial organisms. In other words, Earth's current vent biota is thriving because it is chemically connected to the surface.

By occasionally turning over some of the ice on Europa (after all its surface is relatively young) some oxidants could be transported to the ocean below. However, calculations suggest that, at best, the resulting energy flux is a thousand times weaker than what is needed to support ecosystems on Earth. If the low-energy alternatives are to be used, then without terrestrial-style plate tectonics to keep Europa's rocky mantle from becoming a reducing agent, mature hydrothermal vents will yield CH_4 instead of CO_2, in which case biological methane-producing reactions would be pre-empted and therefore shut down.

The study of terrestrial lifeforms living in extreme environments, and their implications for life on icy-satellites, is a young research field that continues to develop. Experience with hearty strains of bacteria provides an optimistic note for life on Europa, namely, that we should be guarded against being too guarded when the topic is the tenacity of life. For example, there exist unusual bacteria that gain energy by using hydrogen to reduce minerals, and these are perhaps not too different from what a Europan might be like.

With regard to Earth-like planets orbiting other worlds, NASA engineers are busy designing the Terrestrial Planet Finder, a space-based telescope system consisting of four 4 m wide mirrors. The goal is to be able to detect (or rule out) planets as small as Earth orbiting stars that are within 50 light-years, starting around 2010.

Lights in the dark—an anecdote

It has been pointed out, rightly, that astronomy is the study of outer space and oceanography is the study of inner space, and that we have only just begun to uncover the mysteries of both. There is much beauty in each that transcends scientific description. If the reader has ever been lucky enough to be at the sea on a still, clear night, then he or she has hovered between the blackness of both worlds, and at such a time, who does not sense a bit of mystery in the lights flickering above and below?

For the writer, such a moment came with a group of fellow geophysical fluid dynamics students late one August night as we were wading and whispering in calm seawater near Woods Hole, Cape Cod. We were enchanted by the discovery that any movement of our arms and legs through the water elicited green, glowing bioluminescence that trailed like pixie dust, and was punctuated by flashing disks of blue light from tiny, harmless jellies, while above the occasional trail of a falling star could be seen.

Apparently, such a transcendent moment can only be a fleeting one. The following night our attempt at a sequel was brought to an end by the appearance of a darkened patrol car called in by annoyed residents to contain the most recent outbreak of after-hours hotbloodedness on their beach.

Octans

(the Octant; abbrev. Oct, gen. Octantis; area 291 sq. deg.) A southern circumpolar constellation which lies between Indus/Pavo and Chamaeleon/Mensa, and includes the south celestial pole. It was named after the reflecting quadrant invented by John Hadley in 1731 by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2.

A small, inconspicuous constellation, the brightest star in Octans is ν Octantis, magnitude 3.7. There are no other stars brighter than fourth magnitude. σ Octantis, magnitude 5.5, is the closest naked-eye star to the pole, being situated just over 1° away. Interesting objects include λ Octantis, a close binary with yellow and orange (G8 and K0) components, magnitudes 5.6 and 7.3, separation $3.2''$.

There are no bright star clusters, nebulae or galaxies in Octans.

Odierna [Hodierna], Gioanbatista [Giovan or Giovanni Battista] (1597–1660)

Polymath, born in Ragusa, Sicily, became a priest, and was supported as chaplain and parish priest of the town of Palma di Montechiaro in Sicily by the Dukes of Palma. They made him court mathematician and gave him an apartment on the top floor of their palace for his astronomical observations. Observed the three comets of 1618–19, and later published *De Systemate Orbis Cometici* (1654). His studies on the satellites of Jupiter were intended to help the determination of longitude at sea, by timing their eclipses (Odierna timed the first such eclipse recorded, in 1652). His observations were published in *Medicaeorum Ephemeredes* (1656). He wrote on Saturn and astrology, and compiled a catalog (*De Admirandi Coeli Caracteribus* 1654) of some 40 nebulous stars, including 19 real nebulae found with a simple Galilean refractor of magnification 20. Believing that all nebulous objects were actually clusters of stars he classified his objects *Luminosae* (stars visible to the naked eye), *Nebulosae* (nebulous for the naked eye, but resolved in a telescope) and *Occultae* (nebulosity unresolved even in a telescope). His observations include an independent rediscovery of the Andromeda nebula (M31), and at least nine (probably 10) own true discoveries. Odierna made one of the earliest surviving drawings of the Orion nebula, M42. He was also interested in natural phenomena in meteorology, the rainbow and the spectrum, and he invented a microscope or camera obscura with which he studied the eyes of insects and the poison glands of vipers.

Ohio State University Radio Observatory

The Ohio State University Radio Observatory (OSURO), Columbus, Ohio, started in 1951. Its Director, John Kraus, designed, built and operated radio telescopes including a 96-helix array and the 'Big Ear' which ceased operation in 1998.

Achievements include: the Ohio Sky Survey, which measured over 19 000 sources, over half previously undetected; the Ohio Specials, sources with unusual radio spectra, which led to the discovery of the two most distant objects in the universe; overlays to the Palomar Sky Survey prints; master lists of radio sources and non-stellar optical objects; and the 'Wow!' signal, the strongest narrowband signal detected (its origin is still unknown).

Okayama Astrophysical Observatory

The Okayama Astrophysical Observatory (OAO) is a branch Observatory of the NATIONAL ASTRONOMICAL OBSERVATORY, JAPAN. Its main facilities are 188 cm and 91 cm telescopes, equipped with newly built instruments with CCD/IR cameras (e.g. OASIS). OAO accepts nearly 300 astronomers a year, according to the observation program scheduled by the committee.

OAO conducts observations of various astronomical objects and phenomena, including the Sun, solar system objects, stars, galaxies and quasars. Its information and data archives are open to outside researchers and institutes through the network. OAO accepts around 30 000 public visitors a year.

Olbers, Heinrich Wilhelm (1758–1840)

Doctor, astronomer, born in Arbergen, Germany, enthusiast for astronomy. He discovered several comets. In 1800 he joined the team of 24 'celestial police', organized by FRANZ VON ZACH, who were to patrol a share of the zodiac looking for the planet missing (according to BODE'S law) between Mars and Jupiter. On New Year's Day 1801 PIAZZI discovered Ceres, and, in March 1802, Olbers discovered Pallas. Both planets were small, leading to the name 'minor planet', or asteroid, and Olbers suggested, to preserve Bode's law, that they were fragments of a full-sized planet. This in turn suggested that there might be other fragments and in 1807 Olbers discovered Vesta. In contemplation of more distant problems, he formulated *Olber's paradox*, asking the question 'why is the night sky not as uniformly bright as the surface of the Sun?' If the universe has infinitely many stars, any line of sight should end up on the surface of a star, and the sky should be as bright as the Sun. Olbers' paradox can be traced as far back to KEPLER (1610), HALLEY and DE CHESEAUX. The explanation is that the universe is expanding, so distant stars are red-shifted into obscurity, and young, so distant light has not reached us yet.

Olbers' Paradox

A paradox relating to the darkness of the night sky that was discussed by Heinrich Olbers (1758–1840) in 1826, but which had been noted previously by other scientists. Essentially the problem is that if the universe were infinite, static and uniformly populated with stars, the whole of the night sky should be as bright as the surface of a star (no matter in what direction one looked, eventually one would be looking at the surface of a star). The fact that the sky is dark at night clearly demonstrates that at least one of these assumptions is wrong.

It had been suggested that the paradox could be resolved if it were assumed that space is filled with matter that absorbs starlight (clouds of interstellar dust do, indeed, exist). However, the absorbed light would cause the dust to heat up and glow. We now know that stars are clumped into galaxies and are not themselves uniformly distributed through space. Even so, in an infinite static universe, a similar paradox could be posed for galaxies. The observed expansion of the universe resolves the paradox. If galaxies are receding with speeds proportional to their distances, the more distant they are, the greater the redshift of their radiation (wavelengths emitted by these galaxies are stretched to longer wavelengths). Beyond a certain range, the intensity of their radiation would be so greatly reduced by the redshift that they could not be detected (even if the universe were infinite). Likewise, if the universe has a finite age (as the Big Bang theory implies), there has not been sufficient time for light to reach us from galaxies beyond a certain range. The paradox is also resolved if the universe is finite in extent.

Oljato

An Apollo asteroid discovered by Henry Giclas in 1947, designated (2201) Oljato. About 2 km in diameter, it follows an orbit that shifts chaotically as a result of frequent close approaches to Earth and Venus. Its present orbit takes it from within the orbit of Venus at perihelion (0.67 AU) to the outer reaches of the main asteroid belt at aphelion (3.72 AU); its mean distance from the Sun is 2.18 AU (325 million km), period 3.20 years, inclination 3°, eccentricity 0.71. The rotation period is roughly 24 h. Oljato was lost after its discovery and not recovered until 1979. It is very high on the list of potentially hazardous asteroids, with a potential closest approach of less than 75 000 km. Its reflection spectrum bears no resemblance to that of any other asteroid, meteorite or comet so far obtained. It may well be an extinct comet nucleus.

Olympus Mons

The largest volcano on Mars, and the largest in the solar system, centered at 18.4 °N, 133.1 °W. It coincides with the albedo feature visible from Earth known as Nix Olympica, the 'Snows of Olympus', after the mountain in Greece which in legend was the home of the gods. Olympus Mons rises to a height of 27 km above Mars's mean surface level, and in its greatest horizontal dimension measures 624 km. The central caldera has a diameter of about 90 km; from there, undulating flanks slope away at an average gradient of 4° toward the peripheral cliff, whose walls tower up to 6 km above the surrounding plateau. This huge volcanic edifice contains a hundred times the mass of the Earth's largest volcano, Hawaii's Mauna Loa, which is 120 km long and rises to just over 9 km above the Pacific Ocean floor. On the Earth, plate tectonics operates to carry a volcano away from the underlying source of magma. With no such movement on Mars, volcanoes could continue to grow for as long as magma was available.

Ondrejov Observatory

The Ondrejov Observatory is located 20 miles from Prague in the village of Ondrejov. It was established in 1898 as a private observatory and donated to the state of Czechoslovakia in 1928. Since 1953 it has been part of the Astronomical Institute, Academy of Sciences of the Czech Republic; there are 40 astronomers.

The observatory's instruments include: 2 m stellar telescope, photometric telescope, multichannel solar flare spectrograph, solar magnetograph, solar telescope, solar radiospectrographs, meteor radar and photographic zenith tube. The observatory is part of the photographic European fireball network.

Onsala Space Observatory

The Onsala Space Observatory (OSO), the Swedish National Facility for Radio Astronomy, operates two radio telescopes: the 20 m diameter millimeter and the 25 m decimeter wave telescopes at Onsala and the Swedish–ESO Submillimeter Telescope, SEST, in Chile.

OSO was the first European observatory to participate in high-resolution observations of radio sources using the very long baseline interferometry (VLBI) technique. This technique is used in astronomy and geodesy when transatlantic distances are measured with high precision. OSO is a pioneer of VLBI at millimeter wavelength, providing images of AGN with 50 microarcsec resolution. Important VLBI observations of hydrogen absorption reveal tori around AGN; VLBI shows methanol masers delineate rotating protostellar disks.

Research includes millimeter wave astronomy used for spectroscopy of interstellar molecules in the Galaxy, and external galaxies; molecular distribution in Magellanic Clouds measured with SEST. Several molecules have been discovered by Onsala scientists—molecules detected in distant galaxies in absorption against even more distant quasars leading to chemistry of the early universe ($z > 1$).

Oort Cloud

The Oort cloud is a huge, spherical swarm of some 10^{12}–10^{13} comets surrounding the solar system and extending roughly halfway to the nearest stars. The cloud is named for the Dutch astronomer JAN OORT who first suggested its existence in 1950 in order to explain the orbits of the observed LONG-PERIOD (LP) COMETS.

The orbits of COMETS in the Oort cloud are so distant—typical APHELION distances are on the order of 30 000 to 60 000 AU—that they are perturbed by random passing stars, giant molecular clouds and the tidal field of the Galactic disk and core. These external perturbers randomize the orbits and occasionally send comets back into the planetary system where they can be observed. However, the comets in the Oort cloud likely did not form at these great distances from the Sun where the density of the solar nebula must have been exceedingly low. Rather, the comets likely formed as icy PLANETESIMALS in the region of the giant planets and were ejected to distant orbits by the growing proto-planets early in the solar system's history. Icy planetesimals that formed beyond the orbits of the giant planets remained in a low-inclination, low-eccentricity belt of comets, which is known as the KUIPER BELT. The Oort cloud and the Kuiper belt serve as long-lived storage reservoirs for comets in the outer solar system.

LP comets are defined as comets with orbital periods exceeding 200 yr. The definition is somewhat arbitrary and is based on the fact that we only have good orbital records over the past 200–300 yr. LP comets passing through the planetary region have highly eccentric, near-parabolic orbits that take them out to very large distances from the Sun. Indeed, many of the orbits appear to be hyperbolic, that is they appear to come from beyond the solar system, from interstellar space. This is shown in figure 1(*a*) where the orbits of the observed LP comets are plotted as a function of the inverse of their semimajor axes, $1/a$, which is proportional to their orbital energies. About one-third of the comets have negative values of $1/a$ which correspond to positive energies. These are the apparently hyperbolic orbits. The remainder of the LP comets have positive values of $1/a$, corresponding to negative or bound energies. These comets are in elliptical orbits around the Sun, although ones of exceedingly long period. These apparent or instantaneous orbits are known as 'osculating' orbits.

However, if one integrates the orbits backwards in time, to a point before the comets entered the planetary region, and then references the orbits to the barycenter (center of mass) of the solar system, rather than to the Sun, the distribution of orbital energies changes radically. These are known as the 'original' orbits. The distribution of inverse 'original' semimajor axes, $1/a_o$, is shown in figure 1(*b*). Almost all of the apparently hyperbolic orbits are shifted to bound, elliptical orbits. Also, the distribution is characterized by a large spike of comets at near-zero but positive (bound) values of $1/a_o$ and a low continuous distribution of comets in more tightly bound, less eccentric

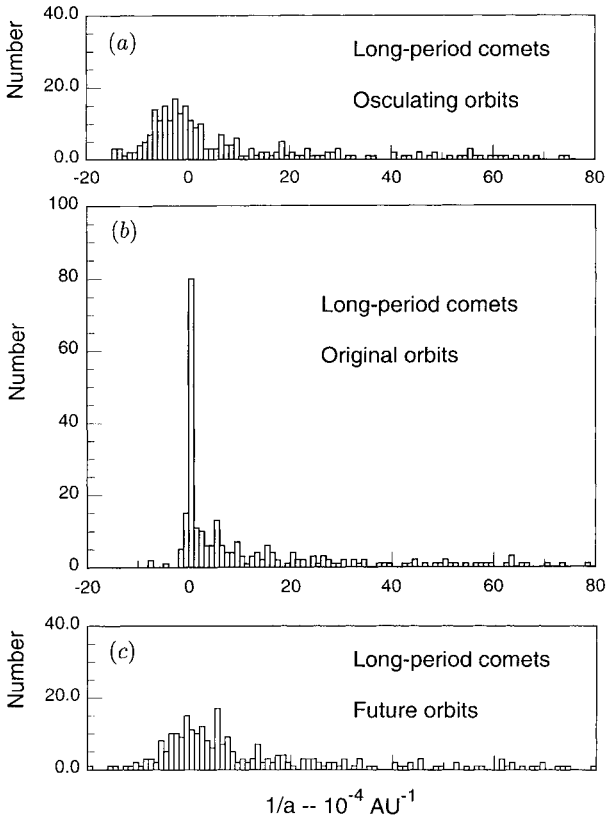

Figure 1. Distribution of inverse semimajor axes, $1/a$, for the observed LP comets: (*a*) for the instantaneous or 'osculating' orbit as the comet passes through the planetary system, (*b*) for the original orbit, integrated backwards in time to before the comet entered the planetary system, and (*c*) for the future orbit, integrated forward in time to after the comet has left the planetary system. The sharp 'spike' of comets at near-zero but bound energies in (*b*) is the 'dynamically new' comets from the Oort cloud. The few hyperbolic comets in (*b*) are likely the result of errors in their orbit determinations.

orbits. Comets in the spike have orbital semimajor axes between 10^4 AU and infinity and orbital periods greater than one million years. A small number of comets still appear to have hyperbolic orbits, but these have been attributed to small errors in their orbit determination and to jetting forces from the icy cometary nuclei, which also act to change the energy of the orbits. In the 1940s researchers showed that Jupiter would perturb the orbits of comets passing through the planetary system so as to spread them randomly in orbital energy, giving rise to the low, continuous distribution. However, what then was the explanation for the spike of comets?

Oort recognized that the spike had to be the source of the LP comets, a vast, spherical cloud of comets at distances greater than 10^4 AU from the Sun, but still gravitationally bound to it (the spherical nature of the Oort cloud is revealed by the distributions of orbital elements for the LP comets, which show that they appear from all directions on the sky). Oort showed that comets in the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

cloud are so far from the Sun that distant perturbations from random passing stars can change their orbits and occasionally send some comets back into the planetary system. On their first pass through the planetary system, random planetary perturbations, primarily by Jupiter, eject roughly half of the 'new' comets to interstellar space, while capturing the other half to more tightly bound, less eccentric orbits. Only about 5% of the new comets are returned to Oort cloud distances. On subsequent returns the comets continue to random walk in orbital energy until they are ejected, captured to a short-period orbit, collide with a planet or the Sun, or are destroyed by one of several poorly understood physical mechanisms. Analysis of the observed cometary orbits shows that the average 'dynamically new' LP comet entering the planetary system from the Oort cloud comes from an aphelion distance of $\sim 4.3 \times 10^4$ AU.

Interestingly, speculations by EDMOND HALLEY in his classic work on comets in 1705 could be interpreted as implying a distant comet cloud. Halley was only able to fit parabolic elements to the 24 comet orbits he derived, but he argued that the orbits would prove to be elliptic, writing,

> For so their Number will be determinate and, perhaps, not so very great. Besides, the Space between the Sun and the fix'd Stars is so immense that there is Room enough for a Comet to revolve, tho' the Period of its Revolution be vastly long.

It is possible to simulate the dynamical evolution of comets in the Oort cloud using computer-based Monte Carlo simulation models. These models include the effects of dynamical perturbations by the planets, random passing stars and nongravitational forces and of physical loss due to collisions, random disruption (splitting) and loss of volatiles (sublimation of ices). By 'tuning' such a model to fit the observed data in figure 1, some insight into the possible physical and dynamical loss mechanisms can be obtained.

The dynamical simulations suggest that ~65% of the LP comets are dynamically ejected from the solar system on hyperbolic orbits, 27% are randomly disrupted—10% on the first PERIHELION passage—and the remainder are lost by a variety of processes such as loss of all volatiles and collision with the Sun and planets. The average hyperbolic ejection velocity is only 0.6 km s^{-1}. Some comets may become unobservable owing to the formation of nonvolatile lag deposits, or 'crusts', on their surfaces, which would cut off further cometary activity. The average LP comet with perihelion distance less than 4 AU makes only five passages through the planetary region before arriving at one of the physical or dynamical end-states, with a mean lifetime of 6×10^5 yr between the first and last passages.

Another way to illustrate the dynamical evolution of LP comets from the Oort cloud is shown by the scatter diagram in figure 2, which plots each observed LP comet as a function of its perihelion distance and inverse original semimajor axis (omitting those comets for which only parabolic orbital solutions are available). The dynamically new, Oort cloud comets appear as a horizontal band of objects at near-zero $1/a_o$. As comets are perturbed by the giant planets, they random walk vertically in the figure (planetary perturbations of the perihelion distance, q, are typically small unless a very close approach occurs). However, if a comet random walks to a negative value of $1/a_o$, it escapes the solar system and does not return.

Cometary fading

Some researchers have proposed that the height of the low, continuous distribution of returning comets seen in figure 1(*b*) is too low relative to the height of the Oort cloud spike. This problem was also noted by Oort. These researchers suggest that comets fade sharply after their first appearance. However, the problem is a complex one involving both observational selection effects and poorly understood physical processes in comets. Oort cloud comets on their first perihelion passage are often anomalously bright at large heliocentric distances, and thus their probability of discovery is considerably enhanced. Indeed, as seen in figure 2, most observed LP comets with perihelion distances greater than 3 AU are Oort cloud comets. Suggested explanations for this anomalous brightness include a veneer of volatiles accreted from the interstellar medium and lost on the first perihelion passage near the Sun, blow-off of a primordial cosmic-ray-processed nucleus crust or the amorphous-to-crystalline water ice phase transformation that occurs at about 5 AU inbound on the first perihelion passage. When these Oort cloud comets return, they are not observed unless they come within 3 AU of the Sun, where water ice can begin to sublimate at a sufficient rate to produce an easily visible coma (see COMA, COMETARY). The failure to observe returning LP comets with perihelia greater than 3 AU must be an observational selection effect, as there is no recognized physical and/or dynamical mechanism for preferentially removing them.

On the other hand, physical 'fading' of comets is not well demonstrated. Suggestions of fading in some SHORT-PERIOD COMETS have largely been explained by changes in instrumentation and observing techniques. Observations of three well-known intermediate-period comets (those with periods between 20 and 200 yr), 1P/Halley, 109P/Swift–Tuttle and 55P/Tempel–Tuttle, have been traced back up to two millennia in human records. The observations suggest that these comets have remained remarkably constant in maximum brightness during that time and have not faded appreciably (if the comets had been brighter in the past then they should have been detected on additional past apparitions; this is not seen).

A physical mechanism that might explain fading is the formation of nonvolatile lag deposits on the surfaces of COMETARY NUCLEI. As cometary ices sublimate, the evolving

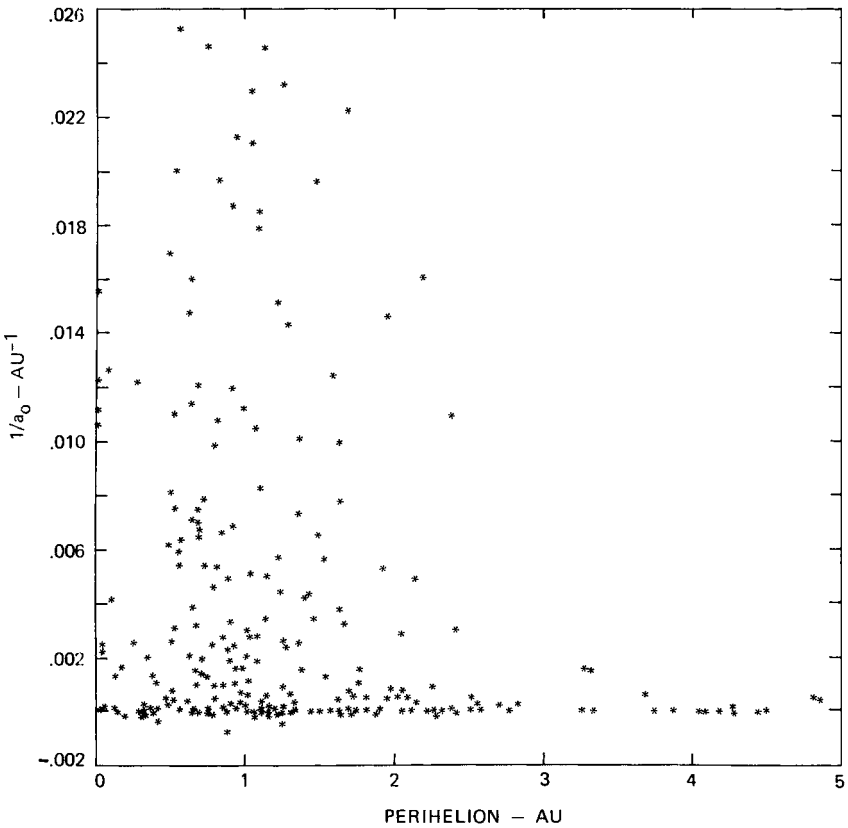

Figure 2. Scatter diagram in perihelion distance and inverse original semimajor axis for the observed LP comets. The horizontal band of comets at near-zero $1/a_o$ are comets making their first perihelion passage from the Oort cloud. Comets diffuse up and down in the diagram as a result of planetary perturbations, primarily by Jupiter (from Weissman 1996).

gases carry grains of dust and ice into the cometary coma. However, large grains may be too heavy to be lifted off the nucleus surface by the evolving gases, and thus would form a lag deposit. The effect of this lag deposit is to insulate the ices below from solar heating, thus decreasing the sublimation rate and the resulting observable cometary activity. Thermal models have suggested that a layer of nonvolatile grains only a few centimeters thick could completely insulate the underlying icy-conglomerate material from solar insolation. Thus comets may slowly 'turn off' as these lag deposits build up on their surfaces. Observed outbursts in comets have been attributed to the sudden blow-off of surface crusts as the pressure of evolved gases builds up beneath them.

It should also be recognized that random disruption, one of the physical loss mechanisms mentioned above, can mimic the apparent effect of cometary fading, removing a fraction of the LP comets on each perihelion passage. Disruption events which do not totally destroy the cometary nucleus may still result in smaller nuclei less capable of producing visible coma, i.e. faded comets.

Oort cloud perturbers

Since first proposed in 1950, Oort's vision of a cometary cloud gently stirred by perturbations from distant passing stars has evolved considerably. Additional perturbers have been recognized: giant molecular clouds (GMCs) in the Galaxy, which were unknown before 1970, and the Galactic gravitational field itself, in particular the tidal field of the Galactic disk. GMC encounters are rare, occurring with a mean interval of $\sim 3 \times 10^8$ yr, but can result in major perturbations on orbits in the Oort cloud.

The Galactic field sets the limits on the outer dimensions of the Oort cloud. The cloud is a prolate spheroid with the long axis oriented toward the Galactic nucleus. Maximum semimajor axes are about 10^5 AU for direct orbits (relative to Galactic rotation) oriented along the Galactic radius vector, decreasing to about 8×10^4 AU for orbits perpendicular to the radius vector, and increasing to 1.2×10^5 AU for retrograde orbits (opposite to Galactic rotation).

In addition, random stars will occasionally pass directly through the Oort cloud, ejecting a substantial number of the comets and severely perturbing the orbits of others. A star passage drills a narrow tunnel through the Oort cloud, ejecting all comets within a radius of $\sim$200 AU, for a 1 solar mass star passing 10^4 AU from the Sun at a velocity of 40 km s^{-1}. Over the history of the solar system, $\sim 10^4$ stars have passed within 10^5 AU of the Sun,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

ejecting about 10% of the Oort cloud population. Although the ejected comets will all be positioned close to the path of the perturbing star, comets which are thrown into the planetary system in a 'cometary shower' can come from any location in the spherical Oort cloud.

Galactic tidal perturbations result from the different distances of the Sun and a comet in the Oort cloud above the Galactic plane and (to a lesser extent) their different distances from the Galactic nucleus. Galactic tidal perturbations peak for orbits with their line of apsides at Galactic latitudes of $\pm 45^\circ$ and go to zero at the Galactic equator and poles. The distribution of Galactic latitudes of the aphelion directions of the observed LP comets mimics that dependence. Although a lack of comet discoveries near the Galactic equator could be the result of observational selection effects (e.g. confusion with Galactic nebulae), the lack of comets near the poles appears to confirm the importance of the Galactic tidal field on the Oort cloud.

The Galactic tide acts to step the cometary perihelia in a regular fashion, as compared with the random walk nature of stellar perturbations. Thus the tide results in comets being brought into the observable region more efficiently, making it easier to overcome the dynamical barrier that Jupiter and Saturn present to cometary diffusion into the inner planets region.

The Oort cloud perturbers discussed above are all evaluated assuming the Sun's current position in the Galaxy, its current velocity relative to the local standard of rest (LSR) and the current perturbing environment of stars, GMCs and the Galactic gravitational field. However, the Sun's motion has likely varied considerably over the history of the solar system, precisely because of random encounters with GMCs. Also, there is some evidence that the Sun and solar system may have formed closer to the Galactic center, at about 6 kpc, as compared with its current estimated distance of 8.5 kpc.

The Sun's past motion can only be reconstructed statistically, and thus one can only give probabilities as to the perturbation history of the Oort cloud from stars, GMCs, and the Galactic tide. An interesting feature of the Sun's current motion is that the Sun moves anomalously slowly relative to neighboring stars, as compared with stars with similar ages. The Sun's current velocity is only $\sim$16–20 km s^{-1} relative to the LSR, as compared with an rms velocity dispersion of $\sim$42 km s^{-1} for G-type stars. The effect of this lower velocity is to decrease the rate of encounters with stars and GMCs but to increase the perturbing effect of those encounters that do occur. Also, the low velocity restricts the Sun to moving in a low-eccentricity orbit around the Galactic center, and an orbit that does not carry it very far out of the Galactic plane. The Sun's current Galactic orbit has it moving 'inward' towards Galactic periapsis and 'upwards', having recently passed through the Galactic plane.

The inner Oort cloud

As a result of this better understanding of the roles of Oort cloud perturbers, it is now estimated that the mean dynamical lifetime of comets in the cloud is only about 60% of the age of the solar system; some researchers have estimated even shorter lifetimes. The Oort cloud must somehow be replenished, either by capture of comets from interstellar space or from a more populous inner Oort cloud reservoir, comets in orbits closer to the Sun that are pumped up to replace the lost comets.

Cometary capture is a highly unlikely process because a three-body gravitational interaction is required to dissipate the excess hyperbolic energy. The probability of capture is proportional to V_∞^{-7}, where V_∞ is the hyperbolic excess velocity. Capture is possible at encounter velocities $\leq$1 km s^{-1}, but is highly unlikely at the Sun's velocity of $\sim$16–20 km s^{-1} relative to the LSR.

On the other hand, Monte Carlo simulations have shown that the dynamical evolution of icy planetesimals formed in the giant planets' zone would naturally lead to an inner Oort cloud. The icy planetesimals would be perturbed by the forming proto-planets into eccentric long-period orbits with semimajor axes of several times 10^3 AU or more. Stellar and Galactic perturbations at aphelion would raise the perihelia of such orbits to heliocentric distances greater than Neptune's semimajor axis, detaching the comets from planetary perturbations. In this manner, an inner Oort cloud reservoir, with a population about 2–5 times that of the outer cloud, could be formed.

Note that the difference between the inner and outer Oort clouds is one of definition only. The two are really one continuous cloud of comets, formed coevally and evolving under the same combination of external perturbers. The difference is defined by the different dynamical regimes. The outer Oort cloud is 'dynamically active'; perturbations on the orbits of comets in the outer cloud are sufficient to throw the comets back into the planetary region where they can be observed. The comets in the inner cloud are dynamically less active, unless the cloud undergoes a major perturbation. The transition between the inner and outer Oort clouds is generally taken to be at semimajor axes of $\sim 10^4$ AU, or at heliocentric distances of $\sim 2 \times 10^4$ AU. As comets are stripped away from the outer Oort cloud by close stellar and GMC encounters, the same perturbations will pump up the orbits of comets in the inner Oort cloud to replace them.

An example of a Monte Carlo simulation of Oort cloud formation is shown in figure 3 for four different times in the solar system's history. Initially the comets are confined to the ecliptic plane (which is inclined approximately 62° to the Galactic plane). As perturbations drive the orbits outward, their inclinations relative to the ecliptic plane slowly increase. At the end of 4.5×10^9 years, the cloud is essentially randomized in both inclination and eccentricity beyond about 6×10^3 AU from the Sun. However, inward of that distance the cloud remains flattened toward the ecliptic plane and the orbits remain highly eccentric.

Approximately 40–60% of the original comets ejected to the Oort cloud (both inner and outer) have been lost over the history of the solar system. Comets are

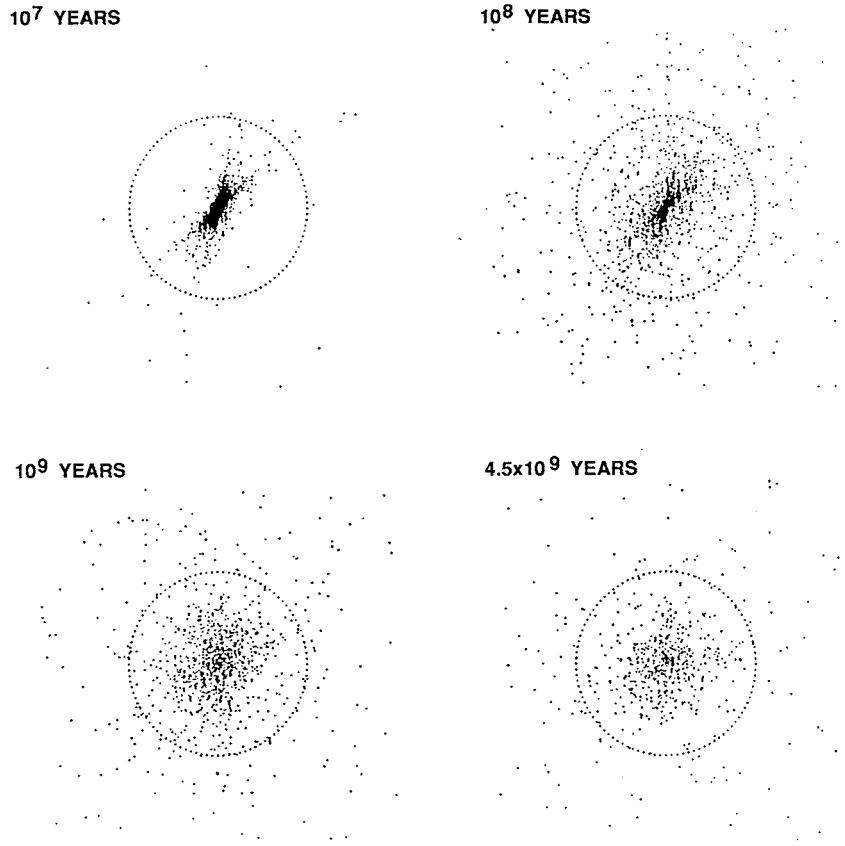

Figure 3. Dynamical evolution of a hypothetical cloud of comets ejected out of the giant planets' zone, at several times during the history of the solar system, under a combination of Galactic, stellar and planetary perturbations (projected onto a plane perpendicular to the Galactic plane). The dotted circle is at a radius of 2×10^4 AU, the approximate boundary between the inner and outer Oort clouds (from Duncan *et al* 1987).

lost by direct ejection due to close stellar passages, by diffusion back into the planetary region where Jupiter and Saturn perturbations will eject them hyperbolically or where they will be physically destroyed and by the slow growth of some orbits to distances greater than the Sun's gravitational sphere of influence, $\sim 2 \times 10^5$ AU (1 pc).

The population, mass and angular momentum of the Oort cloud

Estimates of the population of the Oort cloud can be made by comparing the results of dynamical simulations with the observed flux of comets in the planetary region. To account for the observed flux, Oort estimated that the population of the cometary cloud was 1.9×10^{11} objects. More recent dynamical models have produced somewhat higher estimates, by up to an order of magnitude. These result in part from higher estimates of the flux of LP comets through the planetary system and in part from a recognition of the role of the giant planets in blocking the diffusion of cometary orbits back into the planetary region. Comets perturbed inward to perihelia near the orbits of Jupiter and Saturn will likely be hyperbolically ejected before they can diffuse to smaller perihelia and be observed. Thus, the terrestrial planets' region is under supplied in LP comets as compared with the outer planets' region.

About ten new LP comets are discovered each year, with about two or three of those having perihelia inside the Earth's orbit. However, researchers have shown that many comets are missed because of observational selection effects. This is particularly true for comets that reach their greatest brightness on the opposite side of the Sun from the Earth. Estimates of the incompleteness range from 50% to 95%. Using these numbers, the best current guess for the population of the outer, dynamically active Oort cloud is about 1×10^{12} comets. The population of the inner Oort cloud is estimated at 2–5 times that of the outer cloud. These population estimates refer to comets brighter than absolute magnitude $H_{10} = 11$. Absolute magnitude 11 corresponds to a nucleus mass of $\sim 4 \times 10^{15}$ g, or a nucleus radius of 1.2 km, assuming a density of 0.6 g cm^{-3} (although there is not good agreement on the cometary mass–brightness relationship).

The population estimates depend on the assumption

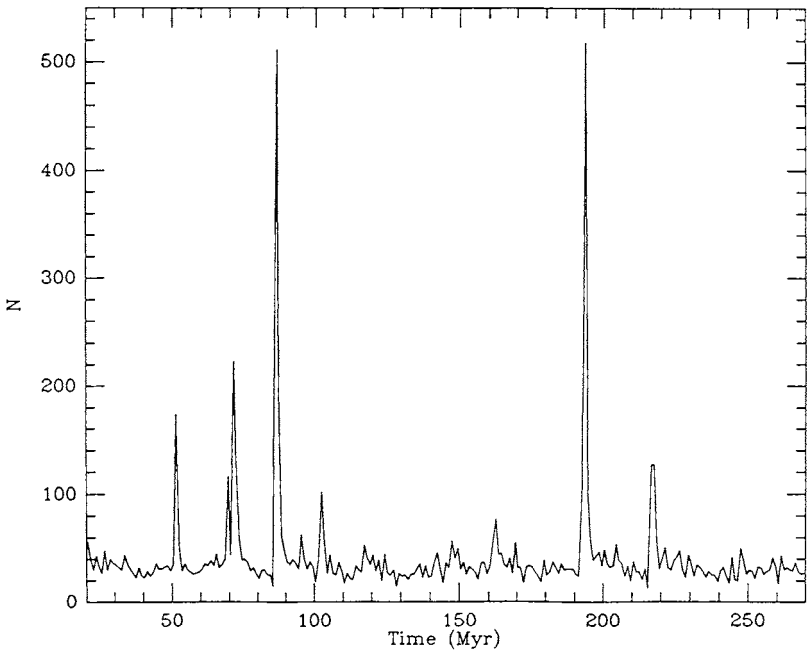

Figure 4. Number of new LP comets from the Oort cloud entering the terrestrial planets' region, $q < 2$ AU, versus time, based on a Monte Carlo simulation that included random passing stars and Galactic tidal perturbations. The large spikes are comet showers due to random stars penetrating the Oort cloud (from Heisler 1990).

that the currently observed LP comet flux through the inner planets region is equivalent to the long-term average flux. If the current flux is enhanced owing to a recent perturbation on the Oort cloud, then the population estimate for the cloud is too high, and vice versa. However, it has been pointed out that the Galactic latitude dependence of the observed LP comet aphelion directions would not be present if most comets seen were the result of a recent major perturbation on the cloud by a close stellar passage or by a GMC. Also, researchers have shown that the $1/a_o$ distribution does not exhibit any indication of a recent major perturbation on the comet cloud. Thus, the Oort cloud population estimates above may be lower limits.

The mass of the Oort cloud is highly uncertain because both the nucleus size distribution and the bulk density of cometary nuclei are not well known. Estimates of the density of the nucleus of COMET HALLEY range from 0.2 to 1.2 g cm^{-3}, with an even larger range of uncertainties. Measurement of the bulk density of recovered interplanetary dust particles which are believed to be of cometary origin finds values of ~0.7–1.9 g cm^{-3}. Researchers found a bulk density of 0.6–1.1 g cm^{-3} for the progenitor nucleus of comet Shoemaker–Levy 9, based on computer simulations of the tidal disruption of that comet.

The cometary mass distribution is even more uncertain. Several attempts to derive the mass distribution have been based on the observed distribution of cometary magnitudes (including coma), H_{10}, after correction for observational selection effects. Another method is to estimate the size of cometary nuclei from their observed brightness at large distances from the Sun, when they presumably are inactive: this method also requires one to assume an albedo for the nucleus surface; actual cometary albedos have only been measured in a few cases. A third method has been to construct a size or mass distribution from estimates of the population of the Kuiper belt in various size ranges. Using these various methods, a plausible value for the average nucleus mass is $\sim 4 \times 10^{16}$ g. Assuming a bulk density of 0.6 g cm^{-3}, the average nucleus would have a mean radius of 2.5 km. Using this value, a current best guess for the total mass of the Oort cloud is $\sim$(1.2–2.4) $\times$ 10^{29} g or ~20–40 Earth masses, assuming an outer Oort cloud population of 10^{12} comets and an inner Oort cloud population of (2–5) $\times$ 10^{12} comets.

Assuming that population and mass, and distributions of cometary orbits from dynamical simulations, the total angular momentum of the Oort cloud at the present time is (3–6) $\times$ 10^{50} g cm^2 s^{-1}. The original angular momentum of the comet cloud at the time of formation was approximately a factor of 5 less than the present value; angular momentum has been pumped into the cloud by stellar and GMC perturbations. The original angular momentum is ~3 times that of Uranus and Neptune combined, which is consistent with estimates of the total mass of icy planetesimals originally in that zone.

Temporal variations in the cometary flux

The cometary flux into the planetary region is expected to vary as a result of major perturbations on the Oort

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

cloud and as a result of the variation in the Galactic tidal perturbation. The latter results from the solar system's harmonic motion above and below the Galactic plane, which currently carries the planetary system ∼75 pc out of the plane. The period of the oscillation is ∼(62–68) × 10^6 yr. This is expected to cause the cometary flux to vary sinusoidally by a factor of 4 over that period, with the maximum flux occurring just after passage through the Galactic plane. However, the role of stellar perturbations during the oscillation has not been evaluated and they may act either to enhance the variations in the flux or to actually mitigate the variations. The solar system has just passed through the Galactic plane in the last few million years, so the current steady-state flux is likely at a local maximum.

Random close approaches by stars can cause more extreme, although short-lived, changes in the cometary flux. A computer-based simulation of the flux of dynamically new comets perturbed to perihelion distances <2 AU is shown in figure 4. The large spikes are the result of close stellar passages which actually penetrate the Oort cloud to <10^4 AU.

These extreme increases in the cometary flux caused by penetrating stellar passages are of particular interest. A $1M_\odot$ star passage at 20 km s^{-1} at 3 × 10^3 AU from the Sun would perturb a shower of ∼5 × 10^8 comets into Earth-crossing orbits, raising the peak flux by a factor of 300 or more, and lasting (2–3) × 10^6 yr. Contributing to the very high flux rate is the fact that the shower comets from the inner Oort cloud start from shorter-period orbits than outer Oort cloud comets, and returning comets tend to be perturbed to even shorter-period orbits. They thus make many returns in a relatively brief period of time. The temporal profile and fraction of surviving comets for a major cometary shower are shown in figure 5.

Fortunately, major cometary showers as a result of deep, ∼3 × 10^3 AU, penetrating stellar encounters are rare, occurring perhaps once every (3–5) × 10^8 yr. Cometary showers should also occur with a similar frequency owing to random encounters with GMCs, but with perhaps an order of magnitude less total flux into the planetary region. Lesser showers from more distant, but still penetrating stellar passages at heliocentric distances ∼10^4 AU occur more frequently, on the order of every (3–5) × 10^7 yr. Cometary showers have also been suggested as a possible cause of biological extinction events on the Earth. LP comet impacts, including comet showers, are expected to account for approximately 10–25% of the craters larger than 10 km diameter on the Earth and Moon.

The suggestion that biological extinction events on the Earth repeat with an approximately 26 Myr period led to several hypotheses in the 1980s that each invoked cometary showers as the cause of the extinctions. These hypotheses involved (1) a dwarf companion star to the Sun in a distant, eccentric, 26 Myr period orbit with its perihelion deep in the Oort cloud, (2) a 10th planet circulating in a highly inclined, precessing orbit at about 150 AU from the Sun, at the inner edge of the inner Oort cloud, (3) the solar system's epicyclic motion above and below the Galactic plane with a half-period of 32–34 Myrs, with GMC encounters at Galactic plane crossings. There is an apparent coincidence between Galactic plane crossings by the solar system and some terrestrial extinction boundaries.

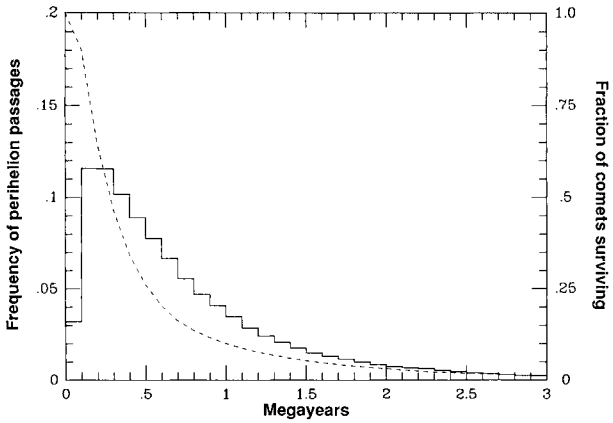

Figure 5. Dynamical evolution of a shower of comets from the inner Oort cloud due to a close, penetrating stellar passage at 20 km s^{-1} at 3 × 10^3 AU from the Sun. The solid histogram is the relative number of comets crossing the Earth's orbit versus time; the dashed curve is the fraction of the original shower comets still evolving in the system. On the order of 5 × 10^8 comets (brighter than $H_{10} = 11$) are expected to be thrown into Earth-crossing orbits by the $1M_\odot$ star's passage (from Hut *et al* 1987).

However, a variety of dynamical problems have been identified with each of these hypotheses, and no evidence in support of any of them has been found. As a result, periodic comet shower hypotheses have not gained wide acceptance. Questions have also been raised about the reality of the periodicity in the fossil extinction record.

Physical processing of comets in the Oort cloud

It had generally been thought that the Oort cloud is a fairly benign storage location for the LP comets. The typical spacing between comets in the outer cloud is ∼15 AU, and in the inner cloud it is ∼1 AU. The typical temperature is that of interstellar space, <10 K. However, it is now recognized that a variety of processes combine to act on the cometary nuclei, in particular their surface layers, over the history of the solar system. These include (1) irradiation, sputtering, and polymerization by Galactic cosmic rays, (2) heating by passing stars and nearby supernovae, (3) gardening by debris impacts and (4) the accretion of interstellar dust and gas and the accompanying erosion by hypervelocity dust impacts. In addition, the interiors of the nuclei may have been warmed by long-lived radionuclides, and even melted if short-lived radionuclides such as ^{26}Al are there in similar abundances to those found for some primitive carbonaceous meteorites.

The combined effects of these competing processes are not well understood. They may lead to the development

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of a permanent nonvolatile crust over the nucleus surface before it ever enters the planetary system, or they may simply result in a heterogeneous collection of unbound, highly processed materials in a well-gardened nucleus regolith. Surface heating may cause both loss and inward diffusion of the more volatile cometary species, while internal heating will also mobilize volatile species and could conceivably result in the nucleus core transitioning from amorphous to crystalline ice, or even perhaps being melted and refrozen.

Extra-solar Oort clouds and interstellar comets

Presumably, the same processes that led to the formation of planetesimals and their ejection to form the Oort cloud in our planetary system can also occur around other forming stars. However, researchers have suggested that stars younger than about 10^7 yr ($M_* > 7M_\odot$) likely do not have sufficient time to form Oort clouds during their main sequence lifetimes. Also, the formation of Oort clouds is likely dependent on the presence of giant planets at distances greater than 3 AU from the central star (where ices could form) in order to eject enough comets to Oort cloud distances.

Because the typical dimensions of Oort clouds are so large, ~0.1–0.5 pc, it may be possible to actually detect and resolve such comet clouds. Astronomers have searched for excess thermal emission from cometary dust around nearby stars in data from the Infrared Astronomical Satellite. Their results were negative. However, this was expected, since dust at Oort cloud distances will be very cold ($T \approx 10$ K at 10^3 AU from the Sun), and radiation pressure and collisions with interstellar dust and gas should rapidly sweep fine dust from the comet clouds.

Astronomers have also proposed searching for Oort clouds around RED GIANT STARS. These stars are sufficiently luminous that the comets in their Kuiper belts, if they had them, would be actively sublimating at rates comparable with the gas production rates of comets at 1 AU in our own solar system. Observed OH-IR stars may be an example of this phenomenon.

It is interesting to speculate on the fate of the many comets ejected to interstellar space in forming the Oort cloud and over its history. Dynamical ejection is the most common loss mechanism for comets in the cloud, either due to close stellar and GMC perturbations or as a result of Jupiter perturbations during passage through the planetary system.

No comet on a clearly interstellar trajectory has been observed passing through our planetary system. This fact sets an upper limit on the space density of interstellar comets of $\sim 4 \times 10^{12}$ comets pc^{-3}. For comparison, this is ~100–300 times less than the density of material in the solar neighborhood, $\sim(0.07\text{–}0.18)M_\odot$ pc^{-3}, so interstellar comets cannot contribute significantly to the 'missing mass' in the galaxy. Note also that this value is about half the mean density of comets in the outer Oort cloud, assuming a population of 10^{12} comets in a sphere of radius 10^5 AU centered on the Sun. Thus, the limit is not very strict.

It is also possible to compare the limit above with the estimated space density of interstellar comets, if one assumes that all stars produce cometary clouds. Dynamical models estimate that between 2 and 20 times as many comets are ejected by the proto-planets as are placed in the Oort cloud. Another factor of 2–3 comes from the comets lost from the Oort cloud over the history of the solar system. Thus, taking a nominal current Oort cloud population of 3×10^{12} comets, the solar system has ejected $\sim 10^{13}$ to 2×10^{14} comets to interstellar space. Taking a mean volume per star in the solar neighborhood of ~12 pc^3 and assuming that all stars produce comet clouds, the predicted space density is 10^{12}–2×10^{13} comets pc^{-3}. This is 0.25–5 times the upper limit noted above.

The lower limit in the above calculation is obviously not a problem. Since half of all stars form in multiple systems, and that process may prevent the formation of a PROTOPLANETARY DISK leading to cometesimals (although that conjecture has not actually been demonstrated), factors of a few times the interstellar comet density limit are also likely not a cause for great concern. However, a factor of 5 excess is not consistent with the Oort cloud models and population estimates presented here. This may suggest that Oort clouds are efficient at capturing a significant fraction of the planetesimals ejected from giant planet zones, rather than allowing them to escape to interstellar space. Alternatively, it may be that only a small fraction of stars actually produce Oort clouds.

Oort, Jan Hendrik (1900–92)

Astronomer, born in Franeker, Netherlands, became director of the Leiden Observatory, confirmed BERTIL LINDBLAD's hypothesis of galactic rotation by analysing motions of distant stars, with our Sun orbiting around the mass of the Galaxy which lies inside its path. The *Oort constants* are measurements of the Galaxy's rotation, and from them Oort was able to calculate the distance of the Sun from the center of the Galaxy and the period of its orbit. During the Second World War, Oort inspired HENDRIK VAN DE HULST to calculate the 21 cm radio spectral line from hydrogen, and led the Dutch group which co-discovered and used the line to map hydrogen gas in the Galaxy, discovering spiral structure and the galactic center. He suggested the existence of a sphere of primordial cometary material surrounding the Solar System. He proposed that comets detached themselves from this *Oort cloud*, and went into orbits about the Sun. Oort showed that light from the Crab nebula is polarized, confirming IOSIF SHKLOVSKII'S suggestion that it was synchrotron radiation.

Oosterhoff, P Th (1904–78)

Dutch astronomer, shared with JAN OORT the administration of the Leiden Observatory. Was in charge of the Leiden southern station in South Africa. His main interest was in variable stars and photometric systems. He discovered the *Oosterhoff dichotomy*, that the type-ab RR Lyrae variable stars in globular clusters are divided into two groups with different average periods, connected with the abundance of metals in the atmospheres of the stars in the globular clusters.

Ophiuchus

(the Serpent-bearer; abbrev. Oph, gen. Ophiuchi; area 948 sq. deg.) An equatorial constellation which lies between Hercules and Scorpius, and culminates at midnight in mid-June. The ecliptic cuts across the southern part of Ophiuchus, but the constellation is not included among the constellations of the zodiac. Ophiuchus is usually said to represent Asclepius, the Greek god of medicine, and is shown on early celestial charts as a man holding a huge snake (represented by the neighboring constellation of Serpens). The brightest stars of Ophiuchus were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A large constellation, the brightest stars in Ophiuchus are α Ophiuchi (Rasalhague), magnitude 2.1, η Ophiuchi (Sabik), magnitude 2.4, and ζ Ophiuchi, magnitude 2.5. There are 11 other stars brighter than fourth magnitude. Interesting stars include ρ Ophiuchi, a multiple system consisting of three bluish-white (B2, B9 and B3) components, magnitudes 5.1, 7.1v and 7.0, separation 152″ and 156″, embedded in a reflection nebula (IC 4604), that have the same proper motion, the former and last of which are close binaries with a bluish-white (B2) component, magnitude 5.7, separation 3.1″, and a magnitude 8.7 component, separation 0.4″, respectively. Other interesting binaries include 70 Ophiuchi, which has yellow (K0) and orange (K4) components, magnitudes 4.3 and 6.3, separation 1.6″, period 88 years, and 36 Ophiuchi, which has two orange (K2) components, both of magnitude 5.2, separation 4.7″, period about 550 years, and a third orange (K5) component, magnitude 6.3v, separation 12′ north-east, which has the same proper motion and parallax. The latter system is about 20′ north of the 'stem' of the Pipe Nebula, a large area of dark nebulosity which extends east-west for several degrees and is visible to the unaided eye.

Other interesting stars include Barnard's Star, magnitude 9.5, which, at a distance of 5.9 light-years, is the second closest star to the Sun and has the highest proper motion of any star, RS Ophiuchi, a recurrent nova (range 4.3–12.5), which is normally between tenth and eleventh magnitude but flared up to naked-eye visibility in 1898, 1933, 1958, 1967 and 1985, and Kepler's Star (V843 Ophiuchi), the most recent example of a supernova in our Galaxy, observed by Kepler in 1604.

Other interesting objects in Ophiuchus include NGC 6572, an eighth-magnitude planetary nebula, and IC 4665 and NGC 6633, two open clusters, both of a few dozen stars of seventh magnitude and fainter, but the constellation is renowned for its globular clusters, of which over two dozen are known. Of the globular clusters, the finest are M12 (NGC 6218), M10 (NGC 6254) and M62 (NGC 6266), all sixth magnitude, and M14 (NGC 6402) and M19 (NGC 6273), which are seventh magnitude. The Milky Way crosses the southern part of Ophiuchus and many of the globular clusters in this region appear fainter than they would otherwise, owing to interstellar absorption.

Opposition

The position of a planet in its orbit when it and the Earth are aligned such that it is directly opposite the Sun in the sky, so that it has an elongation of 180°. The term is also used for the time at which this alignment occurs. Only superior planets (those outside the Earth's orbit) can come to opposition. As this brings them closer to the Earth than at any other position in their orbit, opposition is the most favorable time for observing them. This applies in particular to Mars: because Mars's orbit is markedly eccentric, its distance from the Earth at opposition varies considerably. At *aphelic opposition*, when the planet is farthest from the Sun, the distance is 101 million km, while at *perihelic opposition*, when it is closest to the Sun, it is only 56 million km from the Earth.

See: elongation.

Optical Astronomy

Optical astronomy is the subset of astronomy that is studied through use of light (and near infrared) from the universe. It comprises the most common observational techniques used by astronomers and accesses a wide range of celestial objects.

It is increasingly common for astronomers to concentrate on their subject matter, rather than the observational techniques which they use, and thus to use a variety of multiwavelength techniques to study their specialty subjects. Nevertheless, the different techniques of astronomy are individually complex and astronomers also, in practice, specialize in observational techniques too. They form collaborations with others when they venture outside their specialty technique to make the necessary observations of their specialty subject matter.

Spectral range

The spectral range of optical astronomy is set, not by the physical properties of its objects, but by its technology, which stems from the spectral response of the human eye. Two astronomical environmental considerations have, however, helped to define the optical spectral range. (i) The peak of the energy distribution of the Sun lies near to 550 nm, at which wavelength there is the maximum illumination of the Earth. (ii) The Earth's atmosphere has evolved to contain oxygen produced by living creatures, and therefore ozone and water vapor, which set respectively a sharp lower and fuzzy upper boundary to a transparency window between about 330 nm and, say, 1.4 μm.

Of course, there were strong biological factors in the development of the spectral response of the eye. In the evolution of primates, biological considerations favored light as a means to inspect vegetation, rather than, as in snakes, favoring infrared with which to detect thermal emission from warm-blooded prey. Together with these important biological considerations, astronomical considerations have presumably been at least minor factors to pull the evolution of the human eye to respond to light.

The precise spectral response of the eye is also a matter of the photochemical reactions of the retina and absorption in the material of the eye lensing system. The optical range fits within the atmospheric window, from 400 nm to 700 nm. Shortwards of 400 nm lies the ultraviolet, longwards of 700 nm lies the infrared. This spectral range is overlapped by the spectral responses of the photographic emulsion and CCD detectors, developed industrially to mimic human vision through the use of cameras fed by transparent lenses, and adopted as imaging and recording technology by astronomers (see DETECTORS: PHOTOGRAPHY, CHARGE-COUPLED DEVICE).

These rather ill-connected but consistent considerations define optical astronomy as in practice the study of the constituents of the universe that emit in the spectral range from 330 nm to say 1 μm. Beyond about 1 μm, optical detectors must be replaced by suitable infrared detectors, but optical telescopes give adequate performance up to about 2.4 μm. Above this wavelength, the increasing thermal emission from telescope and atmosphere becomes a major limitation. Ground-based telescopes can be made which mitigate the problems. Ground-based INFRARED TELESCOPES look more or less like optical telescopes, but are used with special techniques. They are usable up to a wavelength of, say, 35 μm at most. The spectral band from 330 nm to, say, 35 μm is termed 'optical–infrared' or OptIR.

By contrast with astronomy using much longer wavelengths (radio and millimeter), telescopes for OptIR astronomy are of manageable size. By contrast with astronomy using longer wavelengths (long-wavelength infrared to submillimeter), telescopes and detectors for OptIR astronomy operate at ordinary temperatures under the atmosphere (although with limitations of atmospheric seeing, and perhaps in cold mountain locations). By contrast with astronomy using shorter wavelengths (ultraviolet and x-ray), telescopes for OptIR astronomy have high throughput and do not have to be operated in space. Because of the commercial importance of optical detectors, they have been developed into panoramic detectors for astronomy with many detector elements (pixels) and produce rich amounts of data.

These considerations account for the historical primacy of optical astronomy. It was the sole area of astronomy up to the Second World War period. A large proportion of astronomers and observatories still work in OptIR astronomy. It remains the broad basis for astronomy. Often in the last 50 yr, of course, it has been fed by exciting and innovative discoveries made in other wavebands. Non-optical emission from a celestial object is a flag which waves 'look at me, I am interesting' and distinguishes its optical counterpart from the numerous similar-looking optical stars or galaxies. Even so, as the technology of OptIR telescopes develops, for example to larger-sized telescopes with greater collecting area, or through access by OptIR telescopes to space (HUBBLE SPACE TELESCOPE, Next Generation Space Telescope), its own capability for discovery is undiminished.

Subject matter of optical astronomy

The cosmic bodies that emit OptIR constitute a rich proportion of the material contents of the Universe. Not coincidentally (because of the connection between the evolution of the human eye in a location near to the Sun), many stars are of a surface temperature such that they emit significant radiation in this waveband. Not coincidentally (because the human eye is made of a molecular fluid and photochemical in the nature of its detector, and it operates under an atmosphere), many of the weaker electronic transitions in atoms and some in molecules involve photons in the optical range.

Optical astronomy therefore consists mainly of the study of

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

- thermal emission from stars of temperature above, say, 1000 K,
- thermal emission from collections of stars such as clusters and galaxies and
- spectral lines from atoms and ions in stellar atmospheres and nebulae.

Because SYNCHROTRON RADIATION has a broad band nature, synchrotron sources are also seen through optical astronomy, even if relatively weak.

The OptIR band brings into the subject matter for study

- thermal emission from cooler stars and the dust material that surrounds them, at temperatures down to about 150 K, and
- spectral lines of a number of molecules.

Techniques of optical astronomy

The broad range of techniques that lie in the science of optics have been applied to OptIR astronomy. Glass is transparent to the OptIR spectral range. Ionic impurities can limit the spectral range of transmission, a limitation to the wider spectral range of glass or an exploitable asset as color FILTERS.

Mirrors reflect light and infrared. At first mirrors were of polished metal (speculum) and later of glass or ceramic material coated with aluminum, silver or gold (depending on the spectral region within or near the OptIR range that is most important). Lenses and mirrors can be used to focus and filter light and form optical images for detection and analysis.

The DISPERSION properties of transparent materials produce a means to form spectra for analysis. The different dispersion properties of different transparent materials form the basis to compensate for defects of optical systems caused by it. The wavelength of light is longer than the separation of atoms and substructure in glass masses, so parallel scratches can create DIFFRACTION GRATINGS. The wavelength is not so small that the scratch separation or the controlled separation of parallel planes of glass is outside technological reach. The wavelength is small enough that a large density of scratches is feasible, making high spectral resolution possible in the dispersed light. These considerations facilitate spectroscopy, spectral line analysis and measurement of radial velocities at the levels common in the motions of stars and nebulae.

The mechanical rigidity of glass materials and their relatively low thermal expansion coefficient make large telescope lenses and mirrors possible. This has enabled optical telescopes to reach low flux limits and drawn into consideration a substantial fraction of the universe of stars and galaxies. The limits to mechanical and thermal stability also ultimately set limits on the size of the ground-based telescopes that can be made, even with the active control systems now possible. Because of the flux gradients from celestial objects such as the Sun and Moon, thermal stability remains a limit to the performance of OptIR telescopes even in space, such as the Next Generation Space Telescope.

Optical Double

This term is used for an observed double star that consists of two quite unrelated stars which just happen to lie in almost the same line of sight, and therefore appear to be close together in the sky. They may in fact be at very different distances from us and each other. If one of the stars is sufficiently close to have a measurable parallax, the true nature of the system can be quickly established. For most pairs this is not the case, and only measurements of their separation and position angle repeated over many decades will confirm that they have no orbital motion and do not constitute a true binary system.

Optical Interferometers

Optical INTERFEROMETERS are astronomical instruments designed to provide higher angular resolving power than is possible with a conventional optical telescope or, in other words, the capacity to measure smaller angles and to discern finer details in an image.

The ability of a telescope to resolve fine detail in an astronomical object is fundamentally limited by the wavelength (color) of the light used for the observations and the diameter of the mirror or lens that collects light from the object. In practice the Earth's atmosphere imposes a limit on the resolution achievable unless special techniques are used, but even above the atmosphere the only way to see finer detail with a telescope would be to observe at a shorter wavelength (bluer light) or to build a larger telescope.

The measurement of the sizes of stars was the challenge that led to the development of optical interferometry. The size of a star cannot be measured directly but, if its angular size $\theta_\star$ and its distance $D_\star$ can be determined, its diameter $d_\star$ can be calculated from $d_\star = D_\star \times \theta_\star$, as illustrated in figure 1. From above the Earth's atmosphere the images of all but a very few stars appear as points of light blurred only by the wave nature of light. From the ground, turbulence in the Earth's atmosphere corrupts the light from a star and blurs its image so badly that no star, other than our own Sun, can have its size determined from its image. Astronomers call this blurring effect 'SEEING'.

FIZEAU (1868) was the first to propose an interferometric method to overcome the effects of seeing. He noticed that when a star was viewed through a small aperture its image was blurred but was otherwise regular in shape—unlike that from a large telescope where the image is blurred but also continually changing. This led him to the idea of putting a mask with two small holes in front of a telescope and observing the superimposed images of the star. The combined image would be crossed by interference fringes—alternate bright and dark bands. Fizeau realized that the contrast of the fringes, the difference in brightness of the bright and dark bands, would diminish as the separation of the apertures was increased, and that the fringes would vanish at a separation directly related to the angular size of the star. Stephan (1873) tested Fizeau's idea but was unable to observe the disappearance of the fringes since the largest telescope available had an aperture diameter of only 0.8 m, which was too small. Nevertheless, Fizeau's idea is the basis of modern optical interferometers which, by measuring the fringe contrast as a function of the separation of the apertures, are able to determine the angular sizes of stars and the angular separations of close binary (double) stars as illustrated in figure 1.

The first measurement of the angular diameter of a star was by MICHELSON and PEASE in 1920 when they measured the angular diameter of Betelgeuse, the bright red supergiant star in the constellation of Orion. Because even the 100 inch (2.5 m) Hooker telescope on

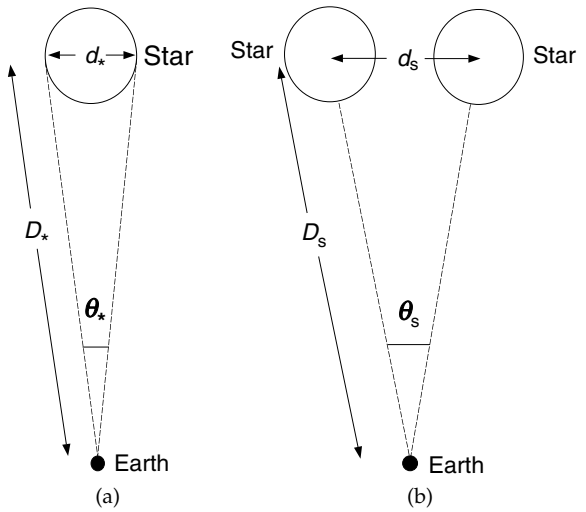

Figure 1. The angular diameter of a star $\theta_\star$ and the angular separation θ_s of the components of a binary, or double star.

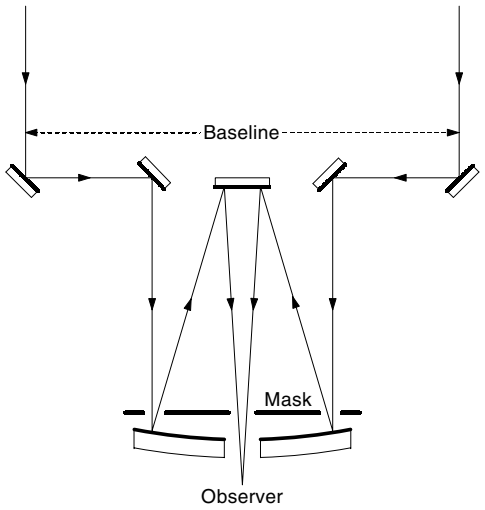

Figure 2. Cross section of the Michelson stellar interferometer mounted on the 100 inch Hooker telescope on Mount Wilson in California.

Mount Wilson in California was too small to observe the disappearance of the fringes, Michelson had the brilliant idea of attaching a long beam across the front of the telescope to carry mirrors to relay starlight from separations greater than the telescope aperture into the telescope. A diagram of Michelson's stellar interferometer is shown in figure 2.

In the absence of a turbulent atmosphere even the largest optical telescopes, with aperture diameters of 8–10 m, would only reveal about a dozen stars as images whose sizes could be measured. While interferometric techniques, like speckle interferometry and developments of the masking interferometry originally proposed by Fizeau, have enabled telescopes to measure stars to the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

limits set by their aperture diameters and the wavelength of light, interferometry has moved on to combine the light from separate apertures in order to increase the angular resolution. This development required new technology in the form of laser metrology, adaptive optics, fast electronics and computer control and, since the driving force was primarily the measurement of stars and binary stars, most instruments have been called stellar interferometers. The increasing sensitivity and capabilities of interferometers offer other possibilities that are exciting astronomers and astrophysicists as the potential of interferometry is recognized. For example, these include the determination of accurate stellar positions (ASTROMETRY), the search for EXOPLANETS (planets other than those in the solar system) and the measurement of the sizes of cores of ACTIVE GALAXIES.

Basic theory

The minimum angle $\theta_{\min}$ resolvable by a circular aperture of diameter d at a wavelength λ is given by

$$\theta_{\min} = \frac{1.2\lambda}{d} \text{ radians.}$$

For a 10 m telescope $\theta_{\min}$ is 0.012 arcsec at a wavelength of 500 nm. The angular diameters of all but a few stars are less than a very few milliarcsec (mas) and interferometers with aperture separations (baselines) in excess of 10 m are required to resolve them.

The combination of the light from two separate apertures is similar to a Young's double-slit experiment with interference fringes being formed in the combined images of the source. A measure of the contrast of the fringes is Michelson's fringe visibility V defined as

$$V = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}}$$

where $I_{\max}$ and $I_{\min}$ represent the maximum and minimum intensities in the fringe pattern.

A more sophisticated approach involves consideration of the coherence of the light at the two apertures. The complex degree of coherence $\gamma_{12}(\tau)$ can be expressed in terms of a modulus $|\gamma_{12}(\tau)|$ and a phase $\phi_{12}(\tau)$, where τ is the difference in arrival time of the two beams at the point of combination and the subscripts 1 and 2 represent the two apertures:

$$\gamma_{12}(\tau) = |\gamma_{12}(\tau)| \exp[\mathrm{i}\phi_{12}(\tau)].$$

When the intensities from the two apertures are equal, the fringe visibility $V_{12}(0) = |\gamma_{12}(0)|$. The complex degree of spatial coherence $\gamma_{12}(0)$ (i.e. with $\tau = 0$) and the angular distribution of intensity across the source I_α are a Fourier transform pair—the van Cittert–Zernike theorem.

$$\gamma_{12}(0) = \int_{-\infty}^{\infty} I_\alpha \exp\left(\frac{-2\pi \mathrm{i}\alpha}{\lambda}\right) \mathrm{d}\alpha.$$

If $|\gamma_{12}(0)|$ and $\phi_{12}(0)$ are measured over an appropriate range of baseline lengths and orientations, the angular intensity distribution (I_α) of the source can be found. The fringe phase $\phi_{12}(0)$, as a function of the aperture separation, provides information on asymmetries in the angular intensity distribution—for a symmetrical source the fringe phase will be zero or 180° for all aperture separations.

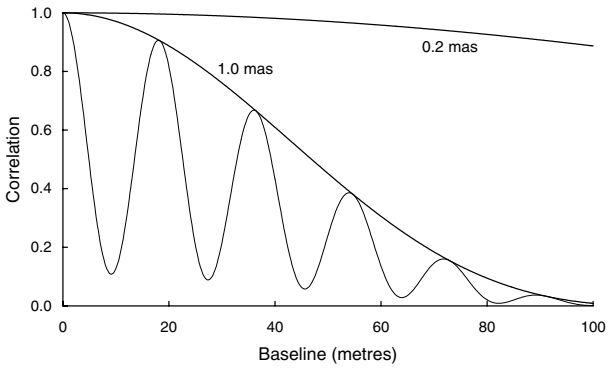

Figure 3. The variation of correlation with baseline for two single stars whose angular diameters are shown in the figure. The oscillating curve is the response for a binary star. The primary star of the binary has an angular diameter of 1 mas and is twice as bright as the secondary. The angular separation of the two stars is 10 mas.

In practice, the Earth's turbulent atmosphere disrupts the phase and, for observations made with a single baseline at a time, only the degree of coherence $|\gamma_{12}(0)|$ is measurable. In the absence of the phase, departures from symmetry in the intensity distribution cannot be detected. Thus, measurements with a single baseline yield only the visibility, and these are interpreted as the angular size of an equivalent strip source or the angular diameter of a radially symmetrical disk source. To obtain images it is necessary to measure both the modulus and phase for at least three baselines simultaneously.

In practice, many interferometers measure the square of the fringe visibility, which is usually called the correlation $C_{12}(\tau)$. Thus

$$C_{12}(\tau) = [V_{12}(\tau)]^2 = |\gamma_{12}(\tau)|^2.$$

As an example of the variation of correlation with baseline figure 3 shows the relationships for two stars with different angular diameters, both assumed to be uniformly bright across their circular disks. Also shown is the response for a BINARY STAR.

If there is a path difference between the beams in an interferometer at the point where they are combined there will be a loss in fringe visibility and in correlation. The magnitude of the loss depends on the spectral bandwidth used for the measurements. The wider the bandwidth, the greater the loss. The reduction in correlation can be expressed in terms of the coherence length of the light Δl, which is given by $\Delta l = \bar{\lambda}^2/\Delta\lambda$, where $\Delta\lambda$ is the spectral bandwidth and $\bar{\lambda}$ is the mean wavelength.

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

The Fourier transform of the intensity distribution across the spectral bandpass is the complex degree of coherence and, as an example, the correlation for a flat-topped spectral bandpass is given by

$$C_{12}(\Delta\mathrm{OPL}) = [V_{12}(\Delta\mathrm{OPL})]^2 = \left|\frac{\sin x}{x}\right|^2$$

where $x = \pi\,\Delta\mathrm{OPL}/\Delta l$ and ΔOPL is the optical path length difference between the beams (optical path length is the product of the geometrical path length in a medium and the refractive index of the medium).

In order to obtain accurate measurements of fringe visibility or correlation, the optical paths from the source to the point of combination of the beams must be equal to within a small fraction of the coherence length ($\Delta\mathrm{OPL} \ll \Delta l$).

Overcoming the effects of atmospheric turbulence

The effect of atmospheric turbulence on incoming light is to distort the shapes of wavefronts and introduce randomly varying phase shifts, wavefront tilts, and wavefront curvatures. The significance of these effects for interferometry depends on the observing wavelength. The spatial scale of the wavefront distortions is measured by the parameter r_0, which is the diameter of a circle on a wavefront over which the phase fluctuations have an rms value of one radian. The temporal scale of the phase fluctuations is represented by t_0, the time interval at the end of which the rms value of the phase fluctuations is one radian.

Both r_0 and t_0 vary as $\lambda^{6/5}$ so both improve for longer wavelengths. Observed values depend on the site, and both vary from night to night and during the course of each night. Typical values for the visual region of the spectrum are $r_0 \sim 10$ cm and $t_0 \sim 5$ ms.

In order to overcome the effects of atmospheric turbulence most optical and infrared interferometers use apertures of diameter less than r_0 and signal sampling times less than t_0. In addition, tilts in the sections of the wavefront accepted by the apertures of an interferometer are individually measured and corrected in real time by tip-tilt mirrors (first-order ADAPTIVE OPTICS). This ensures that the beams from the apertures are combined optimally for the measurement of the interference fringe contrast.

In principle, instrumental loses and residual seeing effects are calibrated by observing unresolved stars between observations of the star or object to be measured.

Two-aperture interferometers

Modern optical/infrared interferometers operate with baselines ranging from a few metres up to a few hundred metres (see INTERFEROMETRY: GROUND). This necessitates mounting the input apertures on separate structures anchored to the ground. Because of the short wavelengths involved, extremely good stability and freedom from vibration is essential. With the input apertures at fixed locations the arrival time of the light from a star will differ at the input apertures and an internal variable optical delay must be incorporated in the instrument to equalize the optical path lengths at the point of beam combination. One method of achieving this is shown in figure 4.

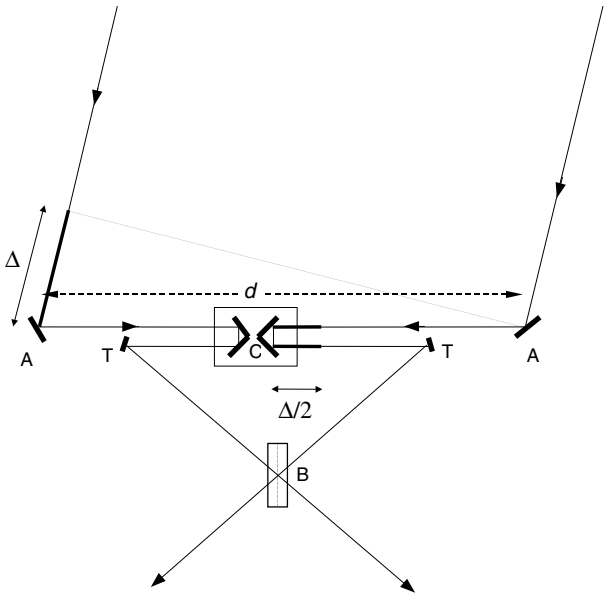

Figure 4. A simplified layout for a long-baseline optical interferometer illustrating the main features. A represents the input apertures and T the wavefront tip-tilt correcting mirrors, Δ is the difference in path length for the two beams of starlight at the input apertures, C is the path-equalizing carriage, B is the beam-combiner and d is the baseline of the interferometer. Further details are discussed in the text.

For interferometers in which the light from only two apertures at a time can be combined, only the fringe visibility or the correlation is measurable since the phase is disrupted by the atmosphere. For such measurements, made with only a single baseline at a time, the Fourier transform yields the intensity distribution for the equivalent strip source (i.e. the source intensity distribution reduced to the equivalent strip source parallel to the baseline direction). No information on asymmetries in the intensity distribution across the source can be derived and true images cannot be constructed. For angular diameter determinations and studies of binary systems this is generally of no concern—the relative brightnesses of the components of a binary system can be determined but with a 180° ambiguity in the orientation of the system. The combination of stellar angular diameters with complementary measurements made with conventional telescopes enables fundamental stellar properties such as surface fluxes, effective temperatures, radii and luminosities to be determined. For many binary stars radial velocities can be determined spectroscopically. For such systems stellar masses and distances can also be found.

Multiple-aperture interferometers

In order to form images with an interferometer it is necessary to use more than two apertures simultaneously. For each pair of apertures in an imaging array the same constraints must be met as for a single-baseline instrument. This includes matching the optical paths to within a small fraction of the coherence length, dealing with the effects of wavefront distortion, and using rapid signal sampling to limit phase smearing during each observational sample period.

Even though the phase measurement for a single baseline is corrupted by the atmosphere, it is possible to determine a 'closure phase', free of corruption, for each independent triangle of baselines formed by three apertures of an array. A closure phase is solely a function of the fringe phases due to the source since, in the calculation of the closure phase, the atmospherically induced phase differences cancel out. Closure phases are a property of the angular intensity distribution across the source and, together with the fringe visibilities measured for the baselines, enable an image of the source to be constructed. This technique, first developed for radio wavelengths, has been adapted to optical and infrared wavelengths.

Multiple-aperture interferometric arrays are aimed at imaging a range of astronomical phenomena including the birth of stars and planetary systems, close binary systems and the cores of active galaxies and quasars.

Modern optical interferometers

Table 1 contains a list of optical/infrared interferometers and interferometric arrays with the acronyms by which they are generally known. The instruments shown as having two apertures combine the light from only two apertures at a time. In most of these cases there is either an array of apertures, from which the two to be used can be selected, or there is the possibility of moving input optics between stations to provide a range of baselines. Instruments listed with three or more apertures are generally intended to combine the light from several, or all, of the apertures simultaneously for the construction of images.

Interferometers and interferometric arrays intended for astrometric measurements are similar in principle to other interferometers and arrays, but differ in having extensive monitoring of the instrument stability by laser metrology and an optical delay compensator operating in vacuum. Astrometric interferometers are of two broad types—global and narrow-angle (differential). Global astrometric interferometers, such as the NPOI Astrometric Array in Arizona, measure the relative positions of stars over the whole sky with the aim of maintaining the Hipparcos frame and improving proper motion determinations by extending the timebase of measurements. Narrow-angle interferometers are effectively double interferometers with each interferometer linked to the other by precision laser metrology. One interferometer is phase locked to a reference source while the second is locked to the target source to search for relative motion produced by a faint unseen companion such as a brown dwarf or planet.

An alternative interferometric technique for the detection of exoplanets is the nulling interferometer. By working in the infrared, and suppressing the stellar flux by combining the star's light out of phase, it should be possible to detect planets down to Earth size but with an instrument operating in space.

Figure 5 shows an aerial view of SUSI, which is located in northern New South Wales in Australia. SUSI has the

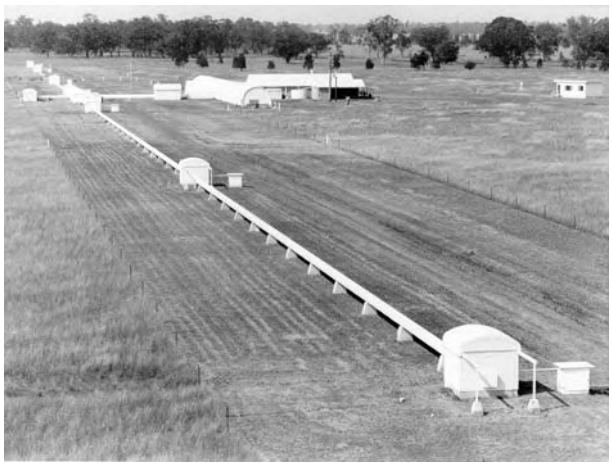

Figure 5. The Sydney University Stellar Interferometer (SUSI) seen from the northern end of its 640 m long baseline array.

distinction of having the longest baseline array of any optical/infrared interferometer. Since it can only observe with two apertures at a time it does not form images. Instruments such as NPOI, the CHARA Array on Mount Wilson in California, and COAST in England all have arrays of input apertures arranged along three arms like the letter Y in order to form images by combining the light from three or more apertures simultaneously. The Keck interferometer and ESO's VLTI will combine the light from separate 8–10 m class telescopes for imaging of fainter objects.

Optical and infrared interferometry and interferometric imaging is in its infancy but promises to make significant contributions to astrophysical research in the 21st century.

Bibliography

An overview of optical interferometry and its potential for astrophysics, as presented at a NATO Advanced Study Institute written by authors expert in various aspects of the field is contained in *High Angular Resolution in Astrophysics* ed A-M Lagrange, D Mourard and P Léna (Dordrecht: Kluwer, 1997).

A large proportion of reports on the developments in optical and infrared interferometry is contained in the proceedings of international symposia and workshops. However, the key technical papers in the development of optical interferometry have been collected in *Selected Papers on Long Baseline Stellar Interferometry* SPIE Milestone Series, Volume MS 139, ed P R Lawson (Bellingham, WA: SPIE, 1997).

The theory of interference with partially coherent light is treated comprehensively by Born M and Wolf E 1975 *Principles of Optics: Electromagnetic Theory of Propagation, Interference, and Diffraction of Light* 5th edn (Elmsford, NY: Pergamon).

A review of the scientific potential, particularly for interferometric arrays involving large aperture telescopes, is presented in *Science with the VLT Interferometer* ed F Paresce (Berlin: Springer, 1997).

Orbit

The path pursued by a body moving in a field of force. In most astronomical contexts we consider motion in a gravitational field, but the term applies equally well to motion under the action of other types of forces, for example to charged particles moving in a magnetic field. Bodies moving freely in the gravitational field of a massive body (e.g. the planets moving around the Sun or an artificial satellite moving around the Earth) follow conic orbits, which may be elliptical, circular, parabolic or hyperbolic. The precise orbit that such a body will pursue depends upon the strength of the gravitational field and the velocity of the body. A planetary orbit is completely described by six geometric properties called its elements. From these the future positions of a planet can be calculated. In the case of a binary system, where the masses of the stars are unknown, seven elements are required.

Orbital Elements

The parameters required to define the shape and orientation in space of an orbit and to fix the position in that orbit at any time of the planet or satellite moving in that orbit. For a planet moving around the Sun, six elements are required and these would be as follows:

- a the semi-major axis of the ellipse
- e the eccentricity of the ellipse
- i the inclination of the orbit to the plane of the ecliptic
- Ω the longitude of the ascending node, i.e. the angle measured anti-clockwise in the ecliptic from the vernal equinox to the point of intersection of the orbit with the ecliptic at which the planet passes from south to north of this plane
- ω the longitude of perihelion (sometimes called the 'argument of perihelion'), i.e. the angle, measured anti-clockwise in the orbit plane, from the ascending node to perihelion
- T the time at which the planet passed perihelion.

The Sun occupies one of the two foci of the ellipse of a planet's orbit. A line drawn through the point of the planet's perihelion and aphelion passes through the Sun and is called the line of apsides or major axis of the orbit. One-half of this line's length is the semi-major axis, equivalent to the planet's mean distance from the Sun. The eccentricity of an elliptical orbit is a measure of the amount by which it deviates from a circle; it is found by dividing the distance between the focal points of the ellipse by the length of the major axis. The position of a planet at any time can be predicted if it is known when it passed through any definite position; for example, its time of perihelion passage.

For a satellite in orbit around the Earth, the ascending node and inclination would be referred to the plane of the celestial equator.

In the case of a binary system of unknown mass, a seventh element is necessary: the orbital period P, or the mean motion, $n(=2\pi/P)$. In the case of the solar system this additional element, although sometimes listed, is related to the value of the semi-major axis (a) by Kepler's third law. T, in the case of a binary system, relates to the time of periastron passage (the instant at which the two stars make their closest approach to each other).

Orbiting Astronomical Observatory (OAO)

Series of four NASA satellites. No data were returned from OAO-1 or OAO-B. The second satellite (OAO-2) operated for four years. It carried two experiments which surveyed the sky at ultraviolet wavelengths. Most successful was COPERNICUS (OAO-3), which was launched in August 1972 and operated for nine years.

Oresme, Nicole (1320–82)

Born in Allemagne, France, became dean of Rouen and chaplain to King Charles V. He invented coordinate geometry before DESCARTES, finding the logical equivalence between a function and a graph. He taught the motion of the Earth, 200 years before COPERNICUS. He argued that there were objections to the 'proofs' that the Earth was stationary. These were that (i) the Sun and the stars are observed to rotate around the Earth, (ii) a great wind from the east would be expected if the Earth rotated, and (iii) a stone would be expected to fall in a curved path if the Earth rotated. But in the end he lost confidence in his own objections and ended back with a stationary Earth.

Orientale Basin

A large multiringed structure on the Moon, about 930 km across in its largest dimension. It is partly on the nearside and partly on the farside, centered at 19.4 °S, 92.8 °W, and at best is only poorly visible from the Earth, and then only when libration brings it partly into view. It has been only partly filled by basaltic lava flooding, to form the Mare Orientale, 327 km across at its widest. (This name means 'Eastern Sea'; its longitude demonstrates that the convention for directions on the Moon has not always been the same.) The surrounding ring structure is the best preserved of any of the Moon's large impact features. The mountain range forming the outer ring is named Montes Cordillera, and the inner ring is Montes Rook. Orientale is the youngest of the Moon's large impact features, having been excavated around 3.8 billion years ago, which explains why the structure is largely intact. Ejecta from the impact traveled up to 1000 km, and the basin is surrounded by chains of secondary craters and other radial features, including a number of lunar valleys.

Origin of The Solar System

The origin of the SOLAR SYSTEM, and of the Earth in particular, is one of the most fundamental problems in astronomy. Apart from the intrinsic fascination of understanding how and when our planet was formed, a plausible solution to that problem could suggest an answer to a more general question: is the formation of a planetary system a normal feature of STAR FORMATION, or a rare accident? Are planetary systems likely to be so abundant throughout the universe that the chance of communicating with other civilizations is high, or is life on Earth the lonely exception in a dead galaxy?

Before the 18th century, European astronomers believed that God created the Solar System in its present state only a few thousand years ago. In the 1700s, speculations proliferated about physical processes that might have formed the Sun and planets over a longer period of time. The French naturalist BUFFON imagined a close encounter of the Sun with a comet, which drew from it hot gases that later condensed to form the planets. He estimated that the Earth had cooled down over a period of about 75 000 years.

The nebular hypothesis

During the 19th century most astronomers accepted the 'nebular hypothesis' proposed in 1796 by the French theorist Pierre Simon de LAPLACE and the German–British astronomer William HERSCHEL. Laplace stressed the uniformity of motions in the Solar System: all planets go in the same direction around the Sun in nearly the same plane and rotate in the same direction around their own axes, and all satellites go in the same direction around their primaries. Such uniformity would be extremely improbable if these bodies had been formed independently. For NEWTON that was a proof that the system had been designed by God; for Laplace it showed that the system had developed by a unitary physical process. (He was not worried by exceptions such as the satellites of Uranus.)

Laplace suggested that the atmosphere of the Sun originally extended throughout the entire space now occupied by planetary orbits; it was a hot, luminous rotating cloud of gas, gradually losing its original heat to the cold surrounding space. As the cloud cooled it contracted, rotated faster, flattened into a disk, and broke up into rings, which then condensed to planets. Satellites could be formed by a similar process from clouds surrounding the planets. The remaining central portion became the Sun (see figure 1). (There is one obvious defect of the theory: the Sun should rotate faster than the speed of revolution of Mercury around the Sun, but in fact it rotates much more slowly.)

Herschel suggested that stars are formed by contraction from nebulae like those he observed through his telescope. Thus the Laplace–Herschel nebular hypothesis, a 'monistic' process requiring no outside stimulus to start

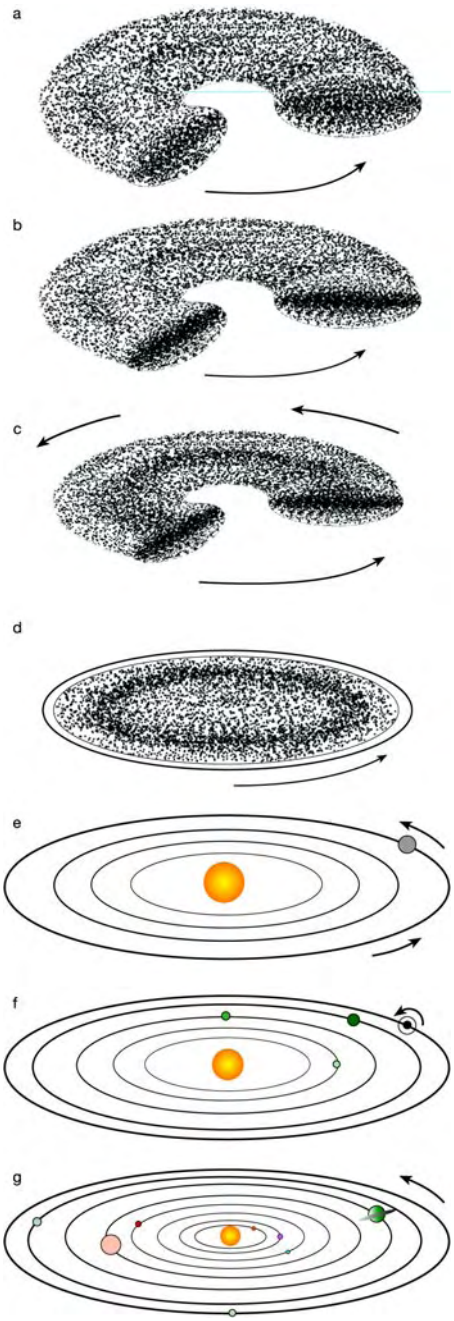

Figure 1. Nebular hypothesis. (a) Rotating spherical cloud has started to flatten. (b) Most of the material has fallen to equatorial plane, forming a flat disk. (c) Disk cools and contracts, spins faster (conservation of angular momentum). (d) When the outside of the disk spins so fast its centrifugal force equals gravitational attraction of material inside the disk, it no longer contracts but is left as a ring. (e) This process is repeated, forming several rings. Material in the outer ring condenses to a protoplanet. (f) Each ring forms a protoplanet; outer protoplanets spin off rings which form satellites. (g) All rings have formed planets, most planets have satellites and one (Saturn) also has a flat ring that did not condense into a satellite.

the development of the system, implied that planetary formation is a universal accompaniment of the birth of stars, and that with sufficiently powerful telescopes we should be able to observe the later stages of the process occurring in our Galaxy right now. Also, it would seem likely that life has arisen or will arise on some of these many planets. A 'dualistic' process like Buffon's, on the other hand, would be much rarer, especially when it is realized that the foreign body would have to be another star rather than a comet.

The German scientist Hermann von HELMHOLTZ, in 1854, modified the Laplace–Herschel theory by assuming that the primordial nebula was cold rather than hot; gravitational contraction would convert mechanical energy to heat (in accordance with the Law of Conservation of Energy), and thus account for the present high temperature of the Sun.

The nebular hypothesis was closely connected with 19th-century geological theories, which generally presumed that the Earth had been formed as a hot fluid ball and then cooled down, solidifying on the outside first.

The British physicist Lord Kelvin (William THOMSON) used the cooling model to estimate the age of the Earth and found it to be only 20–100 million years, compared with the several hundred million years assumed by geologists to have been available for slow processes like erosion to produce their observed effects. Adopting Helmholtz's hypothesis of heating by gravitational contraction, Kelvin also estimated that the Sun could not be much older than 20 million years. Kelvin's estimates caused difficulties for Charles Darwin's theory of biological evolution, since Darwin had assumed, following the geologists, that long periods of time would be available for present-day species (including humans) to emerge by the slow process of natural selection.

At the beginning of the 20th century the credibility of the Laplace–Herschel–Kelvin scenario for the development and present state of the Earth was undermined by the discovery of radioactivity. The Earth's crust contained enough radium, the highly radioactive element isolated by Marie and Pierre Curie in Paris, to generate the heat needed to replace that lost from the Earth's crust by conduction into space; the Earth might actually be warming up rather than cooling down. Analysis of the amounts of uranium, radium, lead and helium in rocks quickly led to estimates that these rocks are several hundred million years old. In 1953 the American geochemist Clair Cameron Patterson used very accurate determinations of lead isotopes in rocks and meteorites to arrive at the presently accepted value for the age of the Earth: about 4500 million years.

Similarly it was proposed that radioactivity (or, later, nuclear fusion reactions) in the Sun could provide enough energy to keep it shining for much longer than 20 million years; thus the evolution of the Solar System also took place over thousands of millions of years.

Planetesimal and tidal theories

Even before radioactivity had cast doubts on the 19th-century cooling Earth model, the American geologist Thomas Chrowder CHAMBERLIN had proposed to replace that model by a completely different hypothesis about the origin of the Earth and other planets. His researches on past Ice Ages led him to doubt the doctrine that the Earth had cooled down from an initial temperature of several thousand degrees. With the help of the American astronomer Forest Ray MOULTON, he showed that the nebular hypothesis could not satisfactorily explain the physical properties of the Solar System (for example, the fact that the giant planets have most of the angular momentum rather than the Sun).

Chamberlin proposed that the planets and satellites had been formed by the aggregation of small cold particles, which he called 'PLANETESIMALS' (meaning 'infinitesimal planets'). The formation process would generate enough heat to bring them up to their present temperatures.

Having rejected Laplace's theory of the formation of the Solar System, Chamberlin still seemed to be attached to Herschel's old idea that the nebulae one sees in the sky are associated with the early stages of stellar evolution. Looking at photographs of spiral nebulae taken by the American astronomer James KEELER, Chamberlin speculated that the two prominent arms belonged to two previously distinct celestial objects. From this thought, and contemplation of solar prominences, he was led to the idea that a planetary system could be generated when another star passed close to the Sun. Just as the Moon raises tides on the near and far sides of the Earth, the gravitational force of the intruder would cancel the gravitational force holding in the solar gases on the near and far sides of the Sun, allowing two filaments of material to flow out; the filaments would then be curved by the continued action of the intruder as it receded. Chamberlin assumed that the filaments would eventually condense into small solid particles, which would be captured into orbits around the Sun (see figure 2).

When it became clear in the 1920s that spiral nebulae are galaxies rather than objects that could be as small as planetary systems, Chamberlin dropped this part of his theory but retained the assumption that two stars interacted in order to release into space the material from which planets formed. As it happened, the British geophysicist Harold JEFFREYS and the British physicist–astronomer James Hopwood JEANS independently proposed a similar assumption in 1916 and 1917, respectively. It became known as the 'tidal' theory of the origin of the Solar System. But Jeans and Jeffreys rejected Chamberlin's planetesimal hypothesis, retaining instead the older assumption that the planets formed from fluid balls (see figure 3).

Astronomers realized that any theory that required the close encounter of two stars in order to form planets would entail an extremely small number of planetary systems in the universe (and an even smaller number of planets that could support the evolution of life). This was

Dirac House, Temple Back, Bristol, BS1 6BE, UK

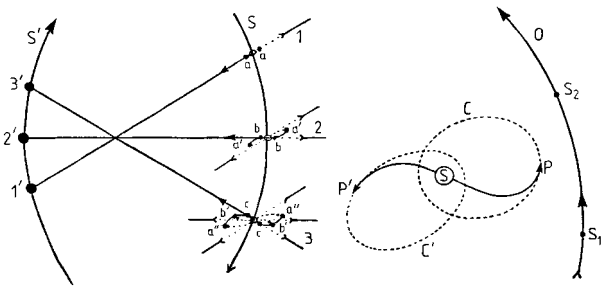

Figure 2. Creation of the Solar System by tidal action of a passing star on the Sun (Chamberlin's version). Chamberlin, inspired by Keeler's photographs of spiral nebulae, imagined that such a nebula could be produced when an intruder star S' (in successive positions 1', 2', 3') exerts a tidal force on the Sun S (in successive positions 1, 2, 3). As a result, material is drawn out of the Sun on near and far sides (a). In the second stage, more material (b) has emerged from the Sun, but it will experience a force in a different direction because of the subsequent motion of S' from 1' to 2'; similarly for material (c) emerging in the third stage. The resulting curvature of the filaments produces the spiral-arm appearance. The gaseous filaments condense first to small solid particles (planetesimals) which then aggregate into planets.

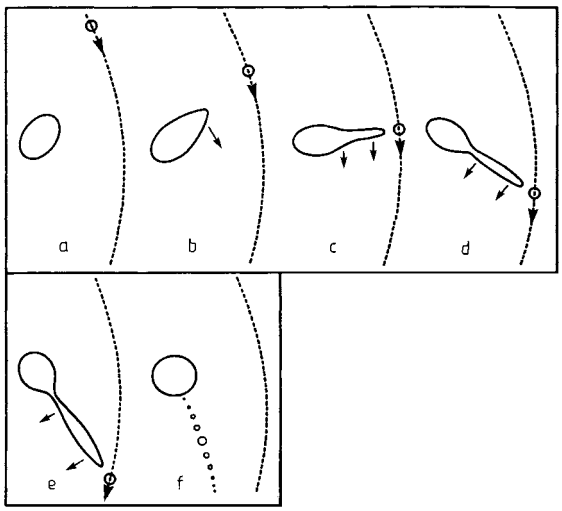

Figure 3. Creation of the Solar System by tidal action of a passing star on the Sun (Jeans' version). Jeans imagined that the Sun would first be deformed by the tidal force of the passing star, then a single coherent filament would be detached and subsequently break up into several fluid blobs which would condense directly into planets. According to Jeans 'This sequence of six diagrams (a, b, c, d, e, f) is intended to suggest the course of events in the Sun, or other star, when its planets were coming into existence. For simplicity the second star is represented throughout by a small circle, although actually this would, of course, also experience deformation and possible break-up'.

consistent with the failure to find convincing evidence for planetary systems surrounding other stars than our own. Jeans seemed to take perverse pleasure in the idea that we are the result of a chance event that has happened only once in the history of the universe and (because the stars are decaying and thinning out by expansion) will probably never happen again.

The tidal theory, whether the Chamberlin–Moulton or Jeans–Jeffreys version, was generally accepted by astronomers until 1935, even though it was never worked out in sufficient detail to provide a convincing explanation of the quantitative properties of the Solar System. Its supporters believed that the tidal theory could overcome the major defect of the nebular hypothesis by showing at least qualitatively how most of the original angular momentum could have been given to the major planets rather than to the Sun.

But the tidal theory turned out to have serious defects as well. The American astronomer Henry Norris RUSSELL found two major objections. First, theories of stellar structure developed by A S EDDINGTON and others in the 1920s indicated that the gases drawn from the interior of the Sun would be at such a high temperature—on the order of a million degrees—that they would dissipate into space before they could condense into planets. Second, a simple dynamical calculation showed that it would be impossible for the tidal encounter to leave enough material in orbits at distances from the Sun corresponding to the giant planets. (In other words, like the nebular hypothesis it failed to explain the distribution of angular momentum in the Solar System.)

There was now *no* satisfactory theory of the origin of the Solar System, since the earlier objections to the nebular hypothesis still seemed valid.

Revival of monistic theories after 1940

New ideas and observations provided a plausible basis for reviving a monistic theory after 1940. For example, the Swedish plasma physicist Hannes ALFVÉN proposed that the early Sun had a strong magnetic field and was surrounded by an ionized gas. Lines of magnetic force, rotating with the Sun, would be trapped in the ionized gas and transfer angular momentum to it. In this way one might explain why most of the angular momentum of the present Solar System is carried by the giant planets, rather than by the Sun. Alfvén's 'magnetic braking' mechanism to slow the Sun's rotation was adopted by several theorists in the 1950s and 1960s even though they rejected other aspects of Alfvén's theory of planetary formation.

Another problem with the nebular hypothesis was the implausibility of the assumption that the nebula would start to condense by itself. As Jeans and the French mathematician Henri POINCARÉ had pointed out early in the 20th century, if the total mass of the planets and Sun were uniformly distributed throughout the entire volume of the Solar System, the density would be so small that (unless the temperature is very low) the atoms would simply dissipate into space rather than condensing. This difficulty could be avoided if the nebula had originally been much more massive, then (after the condensation process started) lost most of its mass. The clue as to how

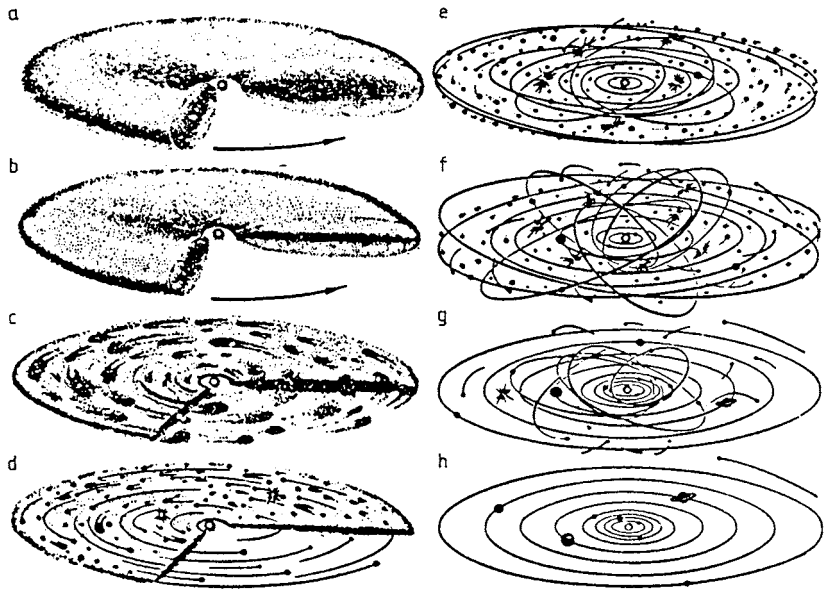

Figure 4. Origin of the Solar System according to Schmidt, Safronov and colleagues. The primordial gas–dust cloud begins its evolution somewhat as described by Laplace but does not form rings and large protoplanets at an early stage. Instead it condenses to small solid particles (planetesimals) which then aggregate to the planets.

this could have happened was furnished by Cecilia PAYNE-GAPOSCHKIN's discovery, in 1925, that the Sun is mostly hydrogen and helium. Yet both planets and Sun are supposed to be formed from the same nebula. Since the planets are composed mostly of heavier elements, perhaps the nebula started with a large amount of hydrogen and helium (the same proportion as in the present-day Sun) but lost it after the formation of the planets. That idea provided the basis for monistic theories proposed in the 1940s and 1950s by C von Weizsäcker, G P KUIPER, and H C UREY.

The revival of monistic theories began with a 1944 paper by the German astrophysicist C F von Weizsäcker. At the same time Alfvén and the Russian astronomer Otto Schmidt developed theories that were dualistic, insofar as they postulated previously formed clouds of material captured by the Sun, but their theories concentrated on the subsequent development of the Solar System and eventually became monistic theories.

Schmidt's theory was developed by Victor Safronov and other Soviet scientists throughout the 1960s and 1970s. It became primarily a model for the accumulation of small solid particles (Chamberlin's planetesimals) from the protoplanetary cloud into planets. Safronov's model was adopted, with some modifications, by the American geophysicist George W Wetherill, who explored its consequences with the help of computer calculations. The Safronov–Wetherill model is now considered the most plausible one for the formation of the terrestrial planets, though it does not yet account quantitatively for their properties (see figure 4).

After the 1950s, a major role in ideas about the origin of the solar system was played by 'ISOTOPIC ANOMALIES'. These are discrepancies between the average abundances of isotopes estimated for the Solar System and the abundances found in particular meteorites. Although these anomalies have little bearing on most of the traditional problems of planet formation, they were believed to offer important clues to the initial stages of formation and contraction of the solar nebula, relating them to nuclear processes in the Sun and other stars. The best-known example was the 'supernova trigger' hypothesis, based in part on the excess ^{26}Mg found in the ALLENDE METEORITE which fell in 1969. The anomaly was established by Typhoon Lee, D A Papanastassiou and G J Wasserburg at Caltech in 1976, and was ascribed to the earlier presence in the Solar System of ^{26}Al, which has a half- life of only 700 000 years. It was generally supposed that the ^{26}Al must have been synthesized in a supernova less than a few million years before the formation of the Solar System. Since a supernova explosion also produces a shock wave that might compress rarefied material to densities high enough for them to become unstable against gravitational collapse, the isotopic anomalies might indicate that the supernova *caused* the Solar System to form.

The most influential advocate of the supernova trigger hypothesis was the Canadian–American astrophysicist Alistair Graham Walter Cameron. But Cameron abandoned the hypothesis in 1984 when astrophysical observations indicated that other modes of synthesis were probably responsible for producing ^{26}Al. (He revived it later for other reasons.) In the meantime Cameron had developed a quantitative theory of the collapse of the solar nebula and the formation of protoplanets. He argued that turbulent viscosity, rather than magnetic braking, is primarily

Dirac House, Temple Back, Bristol, BS1 6BE, UK

responsible for the transfer of angular momentum from Sun to planets.

In the 1990s, theorists were challenged to explain the proliferating observations of extrasolar planets (see EXOPLANETS). These discoveries, suggesting that many stars are surrounded by planets, seem to favor the monistic theory, although they do not exclude the possibility that supernovae could have triggered the formation of several systems at once. But the assumption, based on our own Solar System, that every system would have a few dense 'terrestrial' planets in orbits close to the central star, with gaseous 'giant' planets located further out, has been thrown into doubt.

It now seems likely that the next few decades will see a revolution in theories of the origin of planetary systems, with important consequences for our understanding of our own system: which of its features are the result of general laws, and which are accidental?

Orion

(the Hunter; abbrev. Ori, gen. Orionis; area 594 sq. deg.) An equatorial constellation which lies between Taurus and Monoceros, and culminates at midnight in mid-December. Its origin dates back to Sumerian times, when it was identified with the hero Gilgamesh and his fight against the Bull of Heaven (represented by Taurus), but today it is associated with the son of Poseidon, in Greek mythology, a mighty hunter who is accompanied in the sky by his two dogs (the constellations Canis Major and Canis Minor) in pursuit of a hare (the constellation Lepus). The brightest stars of Orion were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A conspicuous constellation and one of the few that even remotely resembles the object after which it was named, Orion is easily recognized by a quadrilateral of first and second magnitude stars, α, γ, β and κ Orionis, marking the hunter's right and left shoulders, left foot and right knee, respectively, within which lies a trio of second-magnitude stars, δ, ε and ζ Orionis, in a straight line, marking his belt, and below the belt another line of fainter stars, 42, θ and ι Orionis, marking his sword.

The brightest stars in Orion are β Orionis (Rigel), a triple system consisting of two bluish-white (B8 and B5) components, magnitudes 0.2 and 6.8, separation 9.5″, the primary of which is the seventh brightest star in the sky, and a third, unseen component which revolves around the latter in a period of 9.86 days, α Orionis (Betelgeuse), a red giant semiregular variable (range 0.0–1.3, average period about 2335 days), which is usually considered to be the tenth brightest star in the sky, γ Orionis (Bellatrix), magnitude 1.6, ε Orionis (Alnilam), magnitude 1.7, ζ Orionis (Alnitak), a close binary with bluish-white (O9.5 and B0) components, magnitudes 1.8 and 4.0, separation 2.4″, κ Orionis (Saiph), magnitude 2.1, and δ Orionis (Mintaka), a multiple system consisting of a bluish-white (O9.5) eclipsing binary (range 2.14–2.26, period 5.73 days) with a third, very close companion, magnitude 3.8, separation 0.27″, and a fourth, bluish-white (B2) component, magnitude 6.3, separation 53″. There are nine other stars brighter than fourth magnitude.

Another interesting multiple system is σ Orionis, which consists of a very close binary with bluish-white (O9.5 and B0.5) components, magnitudes 3.8 and 5.2, separation 0.2″, period about 170 years, and three other bluish-white (A2, B2 and B2) components, magnitudes 8.8, 6.9 and 6.6, separations 11″, 13″ and 43″ respectively.

Other interesting objects include the middle star in the sword of Orion, θ Orionis, which is a wide double with components θ^1 and θ^2 135″ apart. Each component is itself multiple, θ^2 consisting of a bluish-white (O9.5) primary, magnitude 5.0, and a fainter, magnitude 8.3, secondary, separation 0.4″, while θ^1 has four main components: A (also known as V1016 Orionis), a bluish-white (O7) eclipsing binary (range 6.7–7.7, period 65.43 days), B (also known as BM Orionis), another bluish-white (B0) eclipsing binary (range 7.9–8.7, period 6.47 days), separation 8.8″, C, a bluish-white (O6) star, magnitude 5.1, separation 12.8″, and D, another bluish-white (B0.5) star, magnitude 6.7, separation 21.5″. The latter four stars, known as the Trapezium, are the brightest members of an open cluster at the heart of the Orion Nebula (M42, NGC 1976), one of the brightest emission nebulae in the sky, just visible to the unaided eye as a faint misty patch.

The Orion Nebula is an area of ionized hydrogen (HII) associated with a region of mostly molecular hydrogen (H_2) that forms part of the Orion Molecular Clouds, which extend across the constellation. These are believed to be sites of star formation, and infrared observations have detected the presence of several young stars and star clusters, such as the Becklin–Neugebauer (BN) object and the Kleinmann–Low (KL) cluster, embedded in the gas.

Another well-known nebula is the Horsehead Nebula (Barnard 33), an protuberance of dark nebulosity silhouetted against a swathe of emission nebulosity (IC 434) that extends south from ζ Orionis. There are no bright galaxies in Orion.

The Orionid meteor shower appears to radiate from the constellation.

Orion Arm

The local spiral arm of the Milky Way Galaxy within which the Sun and the star-forming region of Orion are embedded. The stars and clouds of gas and dust that comprise the Orion arm curve outwards (relative to the galactic center) from the general direction of the constellation of Cygnus to the constellation of Vela. The Orion region, which includes the hot young stars of the Orion O, B association, the Orion Nebula and the Orion molecular cloud, is the most prominent star-forming complex in the local arm. Sometimes referred to as the 'Orion spur', the Orion arm is believed to be an extended arm segment rather than a major arm that originates directly in the central bulge of the Galaxy.

Orion Nebula (M42, NGC 1976)

An emission nebula in the constellation Orion, position RA $05^{\mathrm{h}}\ 35.4^{\mathrm{m}}$, dec. $-05^{\circ}\,27'$. At fourth magnitude and measuring $66'$ by $60'$, it is the most prominent emission nebula in the sky and is visible to the naked eye. It surrounds the quadruple star θ^1 Orionis, known as the Trapezium, ultraviolet light from which energizes the nebula. The northwestern part of the nebula is designated M43 (NGC 1982). A dark lane of dust, named the Fish Mouth from its shape, separates M43 from M42. The Orion Nebula abuts onto OMC-1, the largest of many molecular clouds which occupy much of the constellation Orion. This is a region of active star formation, the Trapezium stars being some of many young, hot stars associated with the nebulosity. The Becklin–Neugebauer Object and the Kleinmann–Low Nebula lie behind the Orion Nebula.

Orionids

A meteor shower that takes place in late October. The radiant lies in the constellation Orion, near the border with Gemini. The Orionids occur when the Earth intersects the ascending node of the meteor stream from Halley's Comet; the Eta Aquarids in May are produced by the Earth's passage through the descending node. Because Halley's orbit is retrograde, Orionid meteoroids impact the Earth at a high relative velocity and produce very fast meteors. This is a less active shower than the Eta Aquarids, because in October the Earth encounters the meteor stream off-center.

Orrery

A mechanical model that illustrates the relative positions and motions of bodies in the solar system. The name derives from the fourth Earl of Orrery, Charles Boyle, for whom such a device was constructed, probably by George Graham (d. 1751) about 1725.

Oscillating Universe

A universe that expands and contracts in a cyclic fashion. The universe is expanding at present but the rate of expansion is generally believed to be slowing dow. If the expansion comes to a halt at some time in the future, the universe will then begin to contract, slowly at first, then ever more rapidly until it collapses back into a hot, highly compressed state (the 'big crunch'). The oscillating universe theory suggests that the collapse of the universe is followed by a new 'Big Bang' and a new cycle of expansion and contraction. If this theory is valid, the current cycle of expansion and contraction may have been preceded by an indefinite, possibly infinite, number of cycles and will be followed by an indefinite number of cycles.

There is no known physical process that could cause a collapsing universe to 'rebound' in this way, although some have suggested that a hitherto unknown force or forces may come into play to prevent the universe from collapsing to a genuine singularity (a point of infinite compression) and to trigger a new expansion phase. It has also been argued that if the universe is indeed oscillating, then each successive cycle will expand further, and last longer, than its predecessor. This argument is based on the contention that because the evolution of stars converts matter to radiation as the universe ages, and the radiation content of the universe is blue-shifted to higher energies during the collapse phase, the energy content of the 'big crunch' and the subsequent expansion cycle will be greater than that of the previous 'Big Bang'.

Osiander, Andreas (1498–1552)

A theologian, born Gunzenhausen, Bavaria, Germany. A minister, Osiander had mathematics as his hobby and came into contact with COPERNICUS. In his old age, Copernicus had been persuaded to publish his theory of the heliocentric universe. He entrusted the publication of his work *De Revolutionibus* to GEORGE JOACHIM RHETICUS. The young Rheticus was forced to leave Nuremberg by a particularly attractive offer which he could not refuse of a job with a high salary, and, even knowing Osiander's prejudices against the motion of the Earth, he left Osiander in charge of the publication of the book. It was Osiander who inserted an anonymous preface to Copernicus' book, denying that the book intended to propose more than a mathematical hypothesis, useful for calculations—'not necessarily true or even probable'. This was at first damaging to Copernicus' credibility. In Rheticus' own copy of the book he has angrily crossed out Osiander's preface with red crayon.

Osservatorio Astronomico di Bologna

Astronomy in Bologna has a long history. Official records of systematic teaching of astronomy at the Bologna 'Studio' date back to 1297. Records of systematic observing work can be traced back to the beginning of the seventeenth century, when G D Cassini built a huge sundial in the major church of the city.

The present institute has a staff of about 70 people, half of whom are scientists. It manages a 1.5 m telescope in Loiano. Research activity is mainly addressed to stellar population, extragalactic astrophysics, cosmology and high-energy astrophysics. The Observatory is affiliated to the National Institute of Astrophysics (INAF), the main financial support coming from the National Ministry for Scientific and Technological Research.

For further information see
http://www.bo.astro.it.

Osservatorio Astronomico di Brera

The Observatory (OAB) is a world leader in x-ray mirror technology. (The mirrors of the Beppo-SAX, JET-X, and XMM satellites have been made using the electro-forming technology developed in Milan.) Important progress is now being made also in x-ray mirror multilayer technology.

In ground-based instrumentation, OAB is part of both national and international teams to build various spectrographs: Dolores for the Italian National Telescope, NIMOS, VIMOS and AVES for the ESO-VLT. The research issues mainly address observational cosmology, high-energy astrophysics and stellar astronomy. The ESP survey has allowed a robust estimate of the local luminosity function for galaxies, and the Reflex survey is giving fundamental data about the large scale structure of the universe. A group of Brera scientists was the first to detect, using Beppo-SAX alert and the ESO-VLT, polarization from gamma ray bursts (GRBs). The Observatory is now involved, in collaboration with the USA and the UK, in a satellite (Swift) designed for detection and study of GRBs.

The Astronomical Observatory of Brera, located in Milano Via Brera 28, dates back to the year 1764 when it was conceived by Ruggiero Boscovich, who became the first Director in 1770. Later, in 1923, the construction started of the observing station in Merate and, in 1926, the first telescope, a Zeiss reflector of 102 cm aperture, started operations.

At present the Observatory consists of two Institutes, one in Milan and one in Merate. The administration and accounting are kept in Milan while all the laboratories—clean rooms, advanced metrology and design—are situated in Merate. The present staff consists of 30 astronomers; 38 staff technicians, research engineers, and administrative personnel; 5 post-docs and about 15 students. A very tight collaboration exists with the universities of Milan, Como and Pavia.

Funding originates from the Ministry of Research and Technology (MURST), from the Italian Space Agency (ASI), from the Italian Consortium of Astronomy and Astrophysics (CNAA) and from the European Community and European Southern Observatory in the case of finalized projects.

Osservatorio Astronomico di Roma

The Osservatorio Astronomico di Roma is a non-profit institute dedicated to astrophysical research. It was founded in the early nineteenth century, and moved to its present residence, the ancient Villa Mellini, not far from St Peter's Cathedral, in 1935.

It has also acquired a second site at Monteporzio Catone, in the scientific area of Frascati, close to Rome. Completed in 1965, the Frascati buildings were originally intended to serve as headquarters of the national observational facilities, but the rapid expansion of the Rome urban area forced to abandon this project. The Rome Observatory was then entrusted with its management.

The observatory also runs a mountain station at Campo Imperatore. Its 60–90 cm Schmidt telescope is used to search for supernovae.

Research interests include globular clusters, the distribution of galaxies on cosmological scales and the distribution and properties of Lyman-α clouds in the early universe. Theoretical work covers solar activity, binary stars, active galactic nuclei, the properties of galaxy clusters in the optical and x-ray bands and open stellar clusters.

Instrument work concerns the development of CCDs and the development of infrared spectral instruments.

The Astronomical Museum of the Observatory was originally assembled in 1873 as a Copernican Museum on the occasion of the fourth centenary of Nicholas Copernicus' birth.

Owens Valley Radio Observatory

The Owens Valley Radio Observatory (OVRO) is located in a deep dry valley 400 km north of Pasadena, California, where the California Institute of Technology—which operates the Observatory—is located. It was founded in the mid 1950s and the first major instrument was an interferometer composed of two 26 m antennas. These dishes moved on east–west and north–south tracks and so the pair provided excellent resolution in two dimensions. At the time it was the largest such system in the world, and made many high-resolution studies especially of extragalactic radio sources. In the late 1960s a 40 m paraboloid was constructed. For many years it was the major west-coast station of the Very Long Baseline Interferometer, which linked radio telescopes around the world to get angular resolution as fine as one-thousandth of an arcsec. More recently it has been used to study pulsars and the microwave background radiation.

At present the major instrument at OVRO is an interferometer comprising six 10 m telescopes, and operating at millimeter wavelengths. These dishes are on tracks and the system can synthesize a 0.5 arcsec beam at 1 mm wavelength. Extensive studies are being undertaken in star formation, molecular studies in the Milky Way and other galaxies, and in studies of galaxies at high redshift.

Oxygen (O)

A gas that makes up 20.95% by volume of the Earth's atmosphere at ground level, 89% by weight in seawater and 46.6% in the Earth's crust. It appears to be the third most abundant element in the universe (after hydrogen and helium), but its abundance—in terms of number of atoms—is only about 1/1500 that of hydrogen. The chemical symbol is O, and it normally occurs in the atmosphere in molecular form (two atoms linked), O_2. Triatomic oxygen, O_3, called ozone, and monatomic oxygen, O, are more predominant in the upper atmosphere, where ozone shields the Earth from the Sun's ultraviolet radiation. Pure oxygen is 1.1 times heavier than air. Its atomic mass is 15.99 and its atomic number 8. Oxygen molecules are essential to the sustenance of human and animal life on Earth. Oxygen combines with most other elements and, when this reaction occurs rapidly with the release of heat and light, we describe the reaction as combustion, or burning. Oxygen liquefies under normal pressure at about $-183\,^{\circ}$C and it becomes solid at about $-218\,^{\circ}$C. Liquid oxygen (LOX) is commonly used as the oxidant in the propellant of chemical rockets.

Free molecular oxygen is almost entirely absent from the atmospheres of Venus and Mars.

Ozone Hole

The ozone hole is a recent seasonal phenomenon which corresponds to a significant reduction in the total amount of ozone in the EARTH'S ATMOSPHERE during springtime over Antarctica. Evidence that this phenomenon is caused by human activities through the release into the atmosphere of man-made chlorine and bromine compounds has been building up over the last 15 years. The depletion of the ozone layer is not restricted to Antarctica, but unlike the sudden and near total loss of ozone over this region at certain altitudes, ozone depletion at mid-latitudes is much less and much slower (only a few per cent per year). It is nevertheless a worrying trend which is the subject of intense scientific research at present. In view of this global phenomenon, regulations to restrict the release of man-made chlorine and bromine compounds were promptly decided with the Montreal Protocol in 1987 and successive amendments in 1990 and 1992. Full compliance with the protocol should lead to a recovery of the ozone layer by the middle of the twenty-first century. However, other environmental changes such as CLIMATE changes might impact the time of the recovery.

The ozone layer

Ozone (O_3: three OXYGEN atoms) occurs naturally in the atmosphere. It is mainly found in two regions of the Earth's atmosphere (see figure 1). Most ozone (about 90%) resides in a layer located in the 10–50 km altitude range, a region called the *stratosphere*. This stratospheric ozone is commonly known as the 'ozone layer'. The remaining ozone is located in the *troposphere*, the region which extends from the Earth's surface up to about 10 km. Even in the stratosphere, ozone represents a very small fraction of the atmospheric gas with a maximum of about six ozone molecules for every million air molecules. Despite this small amount, ozone plays a vital role in the atmosphere: stratospheric ozone absorbs most of the biologically damaging ultraviolet sunlight (called UV-B), allowing only a small amount to reach the Earth's surface. The absorption of UV radiation by ozone creates a source of heat, which actually forms the stratosphere itself. Ozone thus plays a key role in the temperature structure of the Earth's atmosphere. On the other hand, ozone at the Earth's surface can be harmful to living systems: it reacts strongly with other molecules and high levels of ozone are toxic to living organisms and biological life.

The amount of ozone in the Earth's atmosphere is governed by the balance between permanent ozone production through molecular oxygen photolysis and ozone destruction through chemical processes which involve numerous constituents whose abundance can be very low (less than one molecule for every billion air molecules). Besides, although ozone is mainly formed in the tropics where the solar radiation is strongest, the ozone layer is thinnest in the tropics (around the equator) and denser towards the poles due to the transport processes which redistribute the ozone over the globe. The amount of ozone above a point on the Earth's surface is measured in DOBSON UNITS (DU), typically 300 DU in global average, with large seasonal fluctuations. This quantity corresponds to the integrated ozone column density above one point, generally called 'total ozone'. As a convention, it is reduced to the standard pressure and temperature conditions of the Earth's surface (respectively 1 atmosphere and 0 °C). In these conditions, the thickness of a pure ozone layer above the Earth is about 3 mm. As a comparison, the total thickness of the atmosphere defined in the same conditions amounts to 8 km. The Dobson unit is defined as 10^{-5} m of ozone at standard pressure and temperature conditions.

The first theory on ozone equilibrium was introduced by Sydney Chapman around 1930. According to this theory, ozone equilibrium is governed by a cycle referred to now as the Chapman cycle. According to this cycle, production occurs when ultraviolet light breaks down oxygen molecules, while destruction involves chemical reactions among oxygen compounds:

$$O_2 + \text{radiation} \rightarrow O + O \quad (1)$$

$$O + O_2 + M \rightarrow O_3 + M \quad (2)$$

$$O_3 + \text{radiation} \rightarrow O_2 + O \quad (3)$$

$$O_3 + O \rightarrow O_2 + O_2 \quad (4)$$

where M is any air molecule.

Later ozone measurements showed that this cycle produces amounts of ozone which are too high. This led to the introduction of other atmospheric compounds to balance ozone production by reactions (1) and (2). The concept of a catalytic cycle was then introduced, where a constituent X participates in ozone destruction through the following reactions:

$$X + O_3 \rightarrow XO + O_2 \quad (5)$$

$$XO + O \rightarrow X + O_2. \quad (6)$$

The net budget of reactions (5) and (6) corresponds to reaction (4) which destroys ozone and X is re-formed at the end of the cycle. The main components acting on ozone equilibrium involve hydrogen, oxygen, nitrogen, chlorine and bromine compounds. These constituents are produced chemically from source gases such as methane, water vapor, nitrous oxide (N_2O), chlorine and bromine compounds, including the man-made chlorofluorocarbons or CFCs and the halons which contain bromine. Chlorofluorocarbons were mainly used in refrigerators, air conditioners and as industrial solvents. After their emission into the atmosphere through physical, chemical or biological processes, these gases, chemically inert in the lower atmosphere, diffuse towards the stratosphere due to the permanent mixing of air in the atmosphere. After 7 to 10 years, they reach the stratosphere where the molecules are broken down by the more and more intense solar radiation as a function

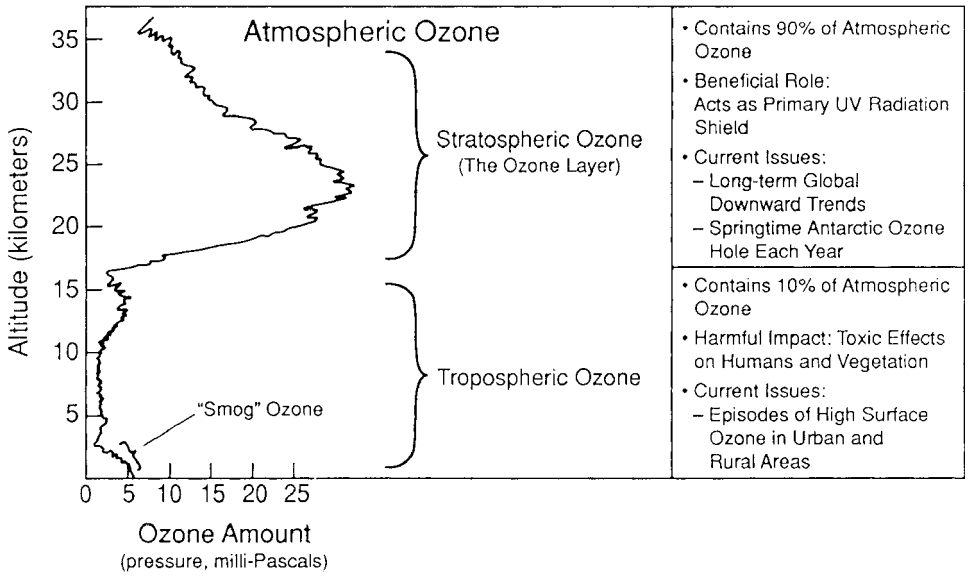

Figure 1. The ozone layer.

of altitude. Chemically active compounds are produced, which destroy ozone through chain reactions at the end of which they are re-formed. This means that one molecule of these active compounds can destroy 1000 to 10 000 ozone molecules, before being eliminated by recombination processes.

The ozone hole

Worries about the fate of the ozone layer first arose in the 1970s when nitrogen and chlorine compounds involving man-made products were introduced into the ozone catalytic cycles. The role of nitrogen compounds was suggested by Paul Crutzen in 1970 while Molina and Rowland pointed out the danger of increasing emission of chlorofluorocarbons in 1974. A ban on aerosol sprays containing CFCs was made by the USA in the late 1970s. These investigations, as well as their subsequent studies on the ozone hole, led to the award to these authors of the Nobel Prize for Chemistry in 1995.

Up to the mid-1980s, all the analyses of the impact of increasing chlorine levels on the ozone layer led to rather small decreases, so the first report on the Antarctic ozone hole was mostly unexpected. It was first reported in 1984–5 that ozone losses reached 50% as compared with the measurements performed in October during the previous decades from 1957 to 1975 (see figure 2). Such measurements were obtained in the Syowa station and Halley Bay Antarctic station. Subsequent satellite measurements showed that the ozone hole was spread over the whole Antarctic continent. In parallel, measurements of the ozone vertical profile revealed a destruction of more than 95% in the 16–22 km altitude range (figure 3). The intensive experimental and theoretical investigations which followed the discovery of the ozone hole allowed the link between the man-made chlorine and bromine compounds and the rapid ozone depletion during the Antarctic springtime to be precisely established: they showed that the ozone hole results from the conjunction of two conditions—high levels of stratospheric chlorine and bromine and the specific meteorological conditions which prevail in the polar stratosphere during winter.

The first condition is ensured by the continuous horizontal and vertical mixing of the Earth's atmosphere over the globe. Thus, while human emission of CFCs and halons occurred mainly in the northern hemisphere, these constituents are present in the Antarctic stratosphere, where they have been measured. After emission at the Earth's surface, they are rapidly mixed in the troposphere. This well-mixed air rises into the stratosphere essentially at tropical latitudes. Winds then move this air poleward, so that air throughout the stratosphere contains nearly the same amount of chlorine and bromine.

The second condition is due to the particular location of the polar stratosphere: during the winter polar night, sunlight does not reach the south pole, leading to the development of strong circumpolar winds in the middle to lower stratosphere. These strong winds are known as the 'polar vortex' which isolates the air over the polar region from the surrounding mid-latitude regions. Since there is no sunlight, the air within the polar vortex can get very cold, so cold that special clouds can form once the air temperature gets below about $-80\,^{\circ}$C. These clouds are called polar stratospheric clouds (PSCs). These PSCs are formed of liquid and solid particles whose composition includes nitric acid, sulfuric acid and water. Their exact composition and formation temperature is still the subject of intense scientific debate. As the temperature gets colder, below $-85\,^{\circ}$C, larger droplets of water-ice with nitric acid

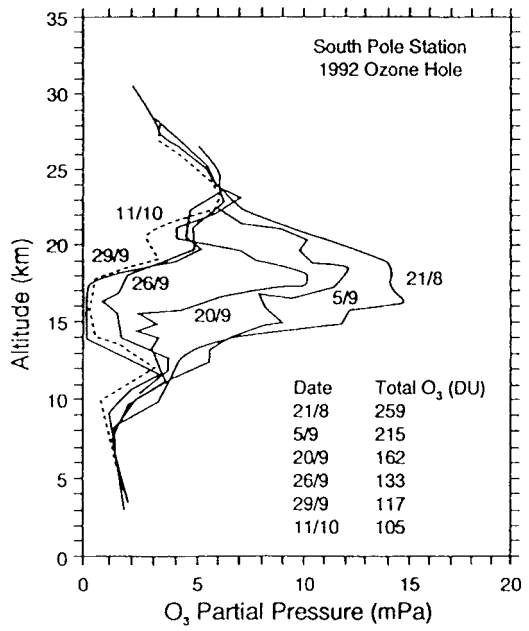

Figure 3. The evolution of the vertical distribution of ozone during the ozone hole period in Antarctica.

dissolved in them can form and freeze. These various PSCs are crucial for ozone loss to occur, since the presence of these particles allows the onset of a particular chemistry called 'heterogeneous chemistry' which transforms most of the chlorine compounds into potentially active chlorine, likely to destroy ozone. The most important reactions in the preconditioning of the polar stratosphere during winter are

$$HCl + ClONO_2 \rightarrow HNO_3 + Cl_2 \quad (7)$$

$$ClONO_2 + H_2O \rightarrow HNO_3 + HOCl \quad (8)$$

$$HCl + HOCl \rightarrow H_2O + Cl_2 \quad (9)$$

$$N_2O_5 + H_2O \rightarrow 2HNO_3. \quad (10)$$

These reactions are very fast and can only take place on the surface of polar stratospheric clouds. This is why the ozone hole was not predicted. Heterogeneous reactions were neglected in atmospheric chemistry (at least in the stratosphere) before the ozone hole was discovered. The nitric acid (HNO_3) formed in these reactions remains in the PSC particles, so that the gas phase concentrations of nitrogen oxides are reduced. This reduction, called 'denoxification', is important as it slows down the removal rate of ClO that would otherwise occur by the reaction

$$ClO + NO_2 + M \rightarrow ClONO_2 + M \quad (11)$$

where M is any air molecule.

Without reaction (6), high levels of active chlorine (multiplied by a factor of about 1000) are maintained. The destruction of ozone requires the return of sunlight over the pole. First, HOCl and Cl_2 are photodissociated:

$$Cl_2 + \text{radiation} \rightarrow Cl + Cl \quad (12)$$

$$HOCl + \text{radiation} \rightarrow Cl + OH. \quad (13)$$

Then, ozone destruction takes place through catalytic cycles which allow the re-formation of the destroying compounds. Thus, active chlorine constituents which are about 1000 time less abundant than ozone can destroy nearly all the ozone molecules in the lower stratosphere. Two main cycles are considered to be responsible for the ozone destruction:

(I)
$$ClO + ClO + M \rightarrow Cl_2O_2 + M$$
$$Cl_2O_2 + \text{radiation} \rightarrow Cl + ClO_2$$
$$ClO_2 + M \rightarrow Cl + O_2 + M$$
$$2(Cl + O_3) \rightarrow 2(ClO + O_2)$$

net: $2O_3 \rightarrow 3O_2$.

(II)
$$ClO + BrO \rightarrow Br + Cl + O_2$$
$$Cl + O_3 \rightarrow ClO + O_2$$
$$Br + O_3 \rightarrow BrO + O_2$$

net: $2O_3 \rightarrow 3O_2$.

The dimer (Cl_2O_2) of the chlorine monoxide radical involved in cycle I is thermally unstable, and the cycle is most effective at low temperatures. It is thought to be responsible for most (70%) of the ozone loss in Antarctica. In the warmer Arctic a large proportion of the loss may be driven by cycle II. These cycles lead to a very rapid ozone decrease which reach more than 1% per day at some altitude levels. This destruction is interrupted at the end of the spring when the general stratospheric warming breaks the polar vortex and the isolation of the polar airmasses. The ozone hole is then diluted in the southern hemisphere leading to a net global ozone loss.

What is happening in the Arctic?

Significant reduction in ozone content in the stratosphere above the Arctic has been observed during the late winter and early spring in five of the last eight years (1990, 1993, 1995, 1996 and 1997). However, these reductions, which can reach 25%, did not last as long and occurred over a much smaller area than the Antarctic ozone hole. The difference between the two polar regions is due to the different weather patterns: Antarctica is a very large land mass surrounded by oceans. These symmetrical conditions produce very low stratospheric temperature within the meteorologically isolated polar vortex region. The conditions that maintain elevated levels of chemically active chlorine and bromine persist into September and October when sunlight returns over the region to initiate ozone depletion. In the Arctic, large-scale weather systems disturb this main flow, making it less stable than over Antarctica. These disturbances prevent the temperature from being as cold as in the Antarctic stratosphere and fewer polar stratospheric clouds are formed. Nevertheless, chemically active chlorine and bromine compounds are also formed from reaction on the surface of the clouds. But the cold conditions rarely persist into March when sufficient sunlight is available to trigger substantial ozone depletion. Several American and European scientific campaigns have been organized since the beginning of the 1990s in order to evaluate ozone depletion in the Arctic and evaluate its possible impact on the surrounding mid-latitude regions. Such campaigns generally involve measurements from numerous ground-based stations, large stratospheric balloons, aircraft, dedicated satellite platforms and numerical simulations of the atmosphere in order to interpret the experimental results. The last major campaign, called THESEO, was organized in winter 1998–9. It was the third major European campaign to study the effects of CFCs and other ozone-depleting substances on the stratosphere.

Evolution of the ozone layer at mid-latitude

The last evaluation of the stratospheric ozone trends in mid-latitude regions show that between 25 and 60°N, ozone abundance over the last years averaged about 4% below 1979 values. The winter/spring and summer/fall ozone losses are of the order of 5.5% and 2.8% respectively. As in the polar regions, the ozone depletion occurs mainly in the lower stratosphere. It is due to the dilution after the break up of the polar vortex at the end of spring, of the polar airmasses in which ozone was destroyed and to heterogeneous reactions which take place on the surface of the stratospheric aerosol layer which exists at all latitudes around 18 km. In the latter case, the processes are similar to the ones which occur at high latitudes, but the global surface of the stratospheric particles is much less than the PSC one.

Regulations for protecting the ozone layer

In 1987, the recognition of the potential for chlorine and bromine compounds to destroy stratospheric ozone led to the 'Montreal Protocol on Substances that Deplete the Ozone Layer' which aimed at reducing the global production of ozone-depleting substances. Subsequently, global observations of significant ozone depletion have prompted amendments to strengthen the treaty. The 1990 London Amendments call for a ban of the most damaging compounds by 2000. The 1992 Copenhagen Amendments changed the date of the ban to 1996. Only some exceptions for the production of halocarbons were tolerated for essential uses, such as for medical sprays, before safe substitutes were found. Further restrictions on ozone depleting substances such as methyl bromide and strengthening measures to ensure compliance with the Montreal Protocol have been agreed upon in Vienna (1995) and Montreal (1997). Full compliance should lead to a recovery of the ozone layer by the middle of the twenty-first century. However, other environmental changes such as climate changes might impact the exact time of the recovery.

Bibliography

As a requirement of the Montreal Protocol, extensive reports on the latest findings concerning the ozone hole layer are produced regularly by the scientific community. The latest reports are the following:

World Meteorological Organization 1998 Global ozone research and monitoring project, assessment of trends in the vertical distribution of ozone *Report* 43 (Geneva: WMO)

World Meteorological Organization 1999 Global ozone research and monitoring project, scientific assessment of ozone depletion (Geneva: WMO) at press

Padova/Asiago Observatories

The Asiago Highlands, about 90 km north-west of Padova, at an elevation of about 1000 m, host, in two sites, the main complex of optical telescopes operating in Italy. The telescopes belong to two independent institutions, based in Padova: the Astronomical Observatory (OAP) and the Astronomy Department of the local University.

The OAP, a research institute, was founded in 1767 by the Venetian Republic and located in a tower built by the tyrant Ezzelino da Romano in 1242, and restructured by the architect Domenico Cerato.

Research in the eighteenth and nineteenth centuries dealt primarily with meteorology, geodesy, compilation of stellar catalogs, and determination of orbits of solar system bodies. The construction by the Padova University of the 122 cm reflector, then the largest telescope in Europe, completed in 1942, fostered the development of modern astrophysical research in Padova/Asiago. Three more telescopes were subsequently built by OAP: a Schmidt 50/40 (in 1958), a Schmidt 92/67 (in 1965) and the 182 cm 'Copernicus' reflector (in 1973). At present they are all located at the top of Cima Ekar (elevation 1350 m). A large collection of plates and spectra was secured over several decades of observations: about 10 000 direct photographs and more than 18 000 spectra taken with the 122 cm reflector; 14 500 and 18 000 wide field plates and films with the two Schmidt telescopes.

Research groups (both observational and theoretical) cover a broad range of subjects: solar system, stellar astrophysics, external galaxies, active galactic nuclei, cosmology, and the history of astronomy. The Observatory played, and is still playing, a primary role in major technological projects: construction and commissioning of the 'Galileo' telescope at La Palma (Canary Islands) and of its instruments (optical imager, high-resolution spectrograph, adaptive optics), realization of the camera for the VST and of the LBT prime focus imager, ESO VLT–LGS program; development of innovative methods for handling very large databases. It also has a significant involvment in several space projects (Rosetta, Planck Surveyor, Gaia). Also very important are the educational activities exploiting the Web—in 1998 OAP was awarded the 'New Media Prize' for the best educational site for children.

Padova is one of two Italian universities having a degree (Laurea) in astronomy (since 1968). Since 1983 it has also run PhD courses in astronomy.

The Observatory staff is: 38 astronomers (5 senior, 14 associates, 19 researchers), 38 technicians, and 28 employees for administration and general services.

The Department staff is: 16 professors (6 full, 10 associate), 8 researchers, 25 PhD students and post-doctorates; 21 employees.

Palimpsest

A bright circular feature on an icy surface with very little vertical relief. The term is used to describe features on the outer three Galilean satellites of Jupiter; it originally meant a piece of parchment prepared for reuse by erasing what had been written on it. Palimpsests are interpreted as impact features whose original morphology has been smoothed out. The impacts are supposed to have occurred when the crust was thin, and subsurface 'slush' rapidly extruded out to fill the crater; alternatively, the raised rim and depressed floor of the crater were able to 'relax' towards the mean surface layer since the lack of rigidity of the underlying material meant that it could not support surface relief. Palimpsests are typically 100 km in diameter. They are found on Callisto at the centers of the large impact features Asgrad and Valhalla; and on Europa (e.g., the 148 km diameter Tyre Macula), where they have almost no discernible surface relief, and on Ganymede (e.g., the 348 km diameter Memphis Facula).

Palitzsch, Johann Georg (1723–88)

German farmer-astronomer in Dresden who recovered Halley's Comet at its predicted reappearance in 1758. During the 1761 transit of Venus across the Sun, he observed a black band linking Venus to the edge of the Sun at the beginning and end of the transit (the 'tear-drop effect') and correctly interpreted this as an effect of Venus' atmosphere.

Pallas

The second asteroid to be discovered, by Wilhelm Olbers in 1802, and so designated (2) Pallas. It is also the second largest asteroid, irregular in shape with an average diameter of 525 km. It orbits the Sun in the main asteroid belt at a mean distance of 2.77 AU (415 million km) in a period of 4.61 years; the orbital inclination is 35°, high for a main-belt asteroid, and the eccentricity 0.23. Pallas rotates in 7.81 h. It is a B-type asteroid, with a reflectance spectrum similar to that of carbonaceous chondrites, but rather brighter, with an albedo of 0.16.

Palomar Observatory

The observatory is located on Mount Palomar, between Los Angeles and San Diego. It is owned and operated by the California Institute of Technology, a privately endowed educational and research institution located in Pasadena, and is used to support the scientific research programs of Caltech's faculty and students.

The principal instrument at Palomar is the 5 m Hale Telescope, which from 1948 to 1976 was the largest optical telescope in the world. Palomar also houses the 1.2 m Oschin Telescope, the 46 cm Schmidt telescope, and a 1.5 m reflecting telescope (operated jointly by Caltech and the Carnegie Institute of Washington). By agreement, Caltech shares use of the Hale Telescope with astronomers from Cornell University and the Jet Propulsion Laboratory.

Through the efforts of George Ellery Hale, the International Education Board (one of the Rockefeller Foundations) awarded a grant to Caltech for the construction of a 5 m telescope in 1928. Mount Palomar was selected as the optimum site for the new instrument in 1934.

The 5 m Pyrex glass disk was cast on 2 December 1934, and after a cooling period of eight months, the 20 ton disk was shipped by rail to Pasadena for the long process of grinding and polishing that would transform it to the precise shape and size required for astronomical observations.

Construction of the building (including the 1000 ton rotating dome) and the telescope structure (the moving parts weigh about 530 tons) began in the mid 1930s and was nearly complete by 1941 when the United States entered the Second World War. But the war delayed polishing of the mirror, and it was not until 18 November 1947 that the finished mirror, now weighing only 14.5 tons, began its two-day trip to Mount Palomar where it was installed in the telescope for a period of testing and adjustment.

Scientific research at Palomar Observatory has been undertaken since 1948. The Hale Telescope has been used on virtually every clear night to study objects ranging from nearby asteroids and comets, to the stars that comprise the Milky Way, distant galaxies and quasars.

The 5 m telescope has recently been upgraded. The telescope is fitted with CCD cameras which are 100 times more sensitive than the photographic plates used when the telescope first went into service. A new adaptive optics system corrects for the effects of air turbulence by using a mirror placed between the telescope and camera and which is adjusted up to 500 times a second. An infrared camera, the Palomar High Angular Resolution Observer (PHARO), has also been installed.

Although electronic detectors have replaced photography at the 5 m telescope, the 1.2 m Oschin Telescope, which is designed for wide-field viewing, still uses glass photographic plates to record images. Its Schmidt camera carried out the famous National Geographic–Palomar Sky Survey in the early 1950s, producing an atlas of the entire sky north of declination -33°. Each 6° square segment of the sky was photographed on both blue- and red-sensitive plates, a total of 879 pairs of plates.

A second sky survey was carried out in the early 1980s, and a third multi-year-long program to obtain complete photographic coverage of the northern sky is now under way. Unfortunately, light pollution is an increasing problem because of the rapid urbanization of southern California.

Parabola

A conic section obtained by cutting a right circular cone by a plane parallel to the side of the cone. Such a curve is open (i.e. it does not form a closed shape such as an ellipse or circle), with eccentricity = 1, and stretches to an infinite distance with the two arms tending to become parallel. The parabola forms the boundary between closed ellipses and open hyperbolas.

Parallaxes

The trigonometric parallax (π) of a star is the angle subtended by 1 astronomical unit (AU) at the star's distance (d) from the Sun (see figure 1). As the Earth annually orbits the Sun, the observer's changing position causes an annual shift in the star's measured position, tracing a small ellipse on the sky that reflects the size and orientation of the Earth's orbit as it might be viewed from the star. The size of this 'parallactic ellipse' is inversely proportional to the distance. For convenience, the astronomer's unit of distance, the parsec (pc), is defined as the distance at which a star's parallax would be one second of arc (arcsec), the unit in which parallaxes are traditionally measured. This gives the simple relation $d = \pi^{-1}$.

The measurement of trigonometric parallaxes is fundamental to our knowledge of stellar distances in our Galaxy and is the first step in establishing the cosmic distance scale. However, most stars are so distant that their parallaxes are very small and difficult to measure accurately. The nearest known star, Proxima Centauri (α Cen C), has a parallax of 0.77 arcsec. A typical naked-eye star's parallax is about 0.01 arcsec. Most of the 118 000 parallaxes in the Hipparcos Catalogue are only a few milliarcseconds (mas) in size, barely larger than the errors of measurement (see HIPPARCOS AND TYCHO CATALOGUES). Indeed, the history of parallax observations has been as much a quest for increasing accuracy as for increasing numbers of stars measured. Moreover, the use of parallax data is fraught with difficulties caused by the small size of most stellar parallaxes.

Parallaxes are also vital to the measurement and calibration of stellar luminosities, because a star's distance needs to be known to convert its apparent magnitude into an absolute magnitude. Likewise, parallaxes are useful in the study of stellar kinematics, because the distance is needed to convert a star's PROPER MOTION into its velocity in the plane of the sky (transverse velocity), and in the determination of stellar masses, where the distance converts a visual binary's apparent orbit into the linear scale needed to apply Kepler's third law.

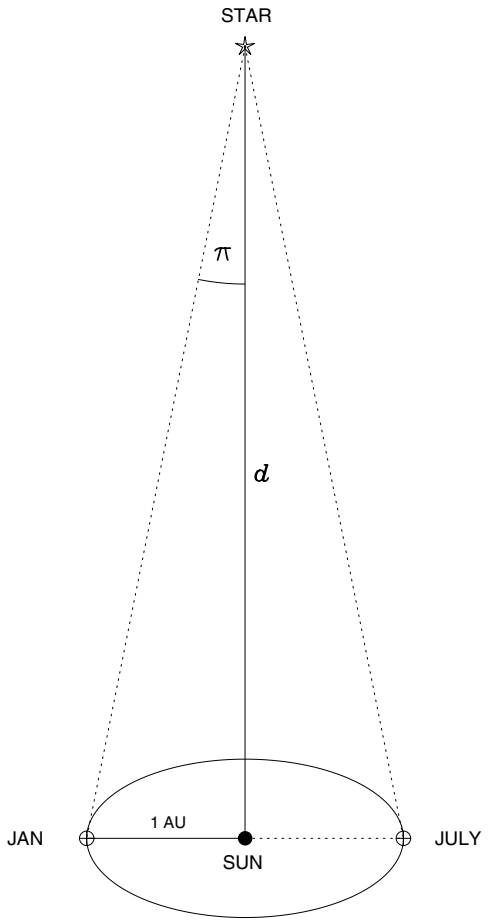

Figure 1. Parallax (π) of a star at distance (d). In this example, the star is observed at two opposite points (January and July) on the Earth's orbit, which is assumed circular with radius 1 AU, but appears as an ellipse when viewed at an angle. The distance d is not drawn to scale. Even the nearest stars are several hundred thousand AU from the Sun.

Historical background

Copernicus' 16th-century heliocentric theory of the solar system held two important implications for astrometry. First, if the stars were at finite distances, they should show annual parallactic motions. Detection of stellar parallaxes would directly confirm the COPERNICAN SYSTEM. Second, the distances to the stars themselves could be determined by measuring their parallaxes. However, more than two centuries of observational efforts, with gradually increasing accuracy, were frustrated because parallaxes remained too small to detect. Larger effects, such as proper motions (up to 10 arcsec yr^{-1}), annual aberration (20.5 arcsec), and nutation (9 arcsec) were discovered in the first half of the 18th century, but it was not until 1838 that Bessel finally measured the parallax (0.3 arcsec) of the 5th-magnitude high-proper-motion star 61 Cygni with the Königsberg heliometer. Contemporaneously, parallaxes of two bright stars, Vega and α Centauri, were measured by Struve and Henderson, with different instruments. The rest of the 19th century saw much work but little progress (see ASTROMETRY: HISTORY). The errors of visual observations were too large to measure more than a few parallaxes with any real accuracy. Parallaxes for the same stars measured by different observers and instruments often disagreed badly. The introduction of photography failed to improve matters significantly. By the end of the century, parallaxes were known for fewer than 60 stars, often with a precision not much better than 0.1 arcsec.

In the first two decades of the 20th century, SCHLESINGER revolutionized astrometry and opened the era of modern parallax determinations. Starting with the Yerkes 1 m refractor in 1903, Schlesinger perfected methods for accurate photographic observation with long-focus REFRACTING TELESCOPES. He systematized the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

observing, measuring and reduction methods to eliminate or minimize errors. By 1920, Schlesinger's techniques improved parallax precision to the 0.01 arcsec level, making it possible to measure distances for thousands of stars. This led to a world-wide program, with five major observatories (Allegheny, Cape, Greenwich, McCormick and Yale) working for nearly a half-century on an all-sky survey, complete to visual magnitude 5.5, supplemented by high-proper-motion stars as faint as 14th magnitude. Starting in 1924, Schlesinger and his successors at Yale compiled these observations into a series of catalogues. By 1960 the classic program had nearly ended; the 1963 edition of the Yale General Catalogue of Trigonometric Stellar Parallaxes (GCTSP) lists 6390 stars.

Modern observations

By the 1960s it was widely recognized that future progress in parallax observations would require another leap in accuracy, which modern technology could now provide. Vasilevskis at Lick Observatory pioneered sophisticated observational techniques, automatic plate measurements and computerized data reductions. Strand obtained a 1.5 m astrometric reflector for the US Naval Observatory. By the 1970s, parallaxes for faint, low-luminosity stars could be determined with a precision of several mas. The 1980s saw the replacement of photographic plates by electronic detectors (CCDs at USNO, the Multichannel Astrometric Photometer (MAP) at Allegheny), further reducing errors to the 1 mas level. The 1995 edition of the Yale GCTSP now lists 8112 stars. While this is only a small increase in number since 1963, the added stars represent nearly an order of magnitude increase in accuracy.

In the 1990s, astrometry was revolutionized again by the European Space Agency's HIPPARCOS satellite, which measured parallaxes and proper motions, as accurate as the best ground-based data, for 118 000 stars. Scanning the sky for just over 3 yr, Hipparcos observed 15 times as many stars as ground-based parallax observatories had accumulated over the past century. Working from a predetermined Input Catalogue, Hipparcos observed a two-part program: (1) 52 000 bright stars ($V < 7$–9, depending on galactic latitude), constituting a virtually complete magnitude-limited survey; (2) 66 000 fainter stars ($V \lesssim 12.4$) selected for astrophysical or astrometric interest. Additionally, the Tycho experiment used the satellite's star mapper to measure parallaxes of modest precision (7 mas for $V < 9$; 25 mas for $V < 11.5$) for 1.06 million stars, complete to $V \simeq 10.5$.

So, by the close of the 20th century, space astrometry has almost entirely replaced ground-based observations as the source of parallax data for bright stars. However, it is worth noting that ground-based telescopes remain the only source of parallaxes for faint stars.

Applications and critical analysis

The utility of trigonometric parallaxes to calculate stellar distances, kinematics, masses or luminosities depends critically on the size of the parallax in relation to the observational error σ_π. Parallax errors propagate into stellar distances and transverse velocities in proportion to the ratio σ_π/π, i.e.

$$\sigma_d/d = \sigma_v/v = \sigma_\pi/\pi$$

and into visual binary star masses as

$$\sigma_{\mathcal{M}}/\mathcal{M} = 3\sigma_\pi/\pi.$$

When the absolute magnitude is calculated from the apparent magnitude and parallax (in arcsec)

$$M = m + 5 + 5\log_{10}\pi$$

the parallax error propagates as

$$\sigma_M = 5\sigma(\log_{10}\pi) \simeq 2.17\sigma_\pi/\pi.$$

Because of this, only 'large' parallaxes ($\pi \gg \sigma_\pi$) are individually useful on a star-by-star basis. However, most parallaxes are 'small', i.e. $\pi \simeq \sigma_\pi$, and can only be used statistically. In either case, care must be taken to ensure that (1) the parallaxes are on an accurate absolute zero point, (2) the observational errors are accurately estimated and (3) statistical issues are properly addressed.

Absolute zero-point calibration

Ground-based parallax observations are made by repeatedly pointing the telescope at the particular field (generally $<1^\circ$ in size) containing the 'target' star(s) and a number (usually 4–10) of background 'reference' stars. The parallactic ellipse of the target star is measured relative to the reference stars, whose own motions are in phase with the target star, only (presumably) smaller. The result is a 'relative' parallax, which must be corrected to 'absolute' by adding the mean parallax of the reference stars. This correction must be determined independently. This can be done statistically, by using Galactic models to estimate the reference frame's parallax as a function of the stars' apparent magnitudes and the Galactic latitude and longitude of the field. Reference star parallaxes can also be estimated individually from photometry and spectroscopy. For the 1995 Yale GCTSP, van Altena re-calculated the corrections to absolute for all parallaxes published to that date. The size of the corrections is generally 1–5 mas, with an uncertainty of ~10%, i.e. a few tenths of 1 mas.

The Hipparcos satellite simultaneously imaged two $0.9^\circ \times 0.9^\circ$ fields of view, separated by 58° on the sky. Because the parallactic motions in the two widely separated fields were out of phase, absolute parallaxes could be determined directly from the Hipparcos observations themselves. Global tests confirm that the overall absolute zero point of the Hipparcos Catalogue is accurate to 0.1 mas. However, this does not represent the zero-point accuracy in any individual field, where small-angular-scale zero-point errors may reach the order of 1 mas. (See the discussion of cluster parallaxes below.)

Observational errors

Any parallax determination will have a finite accidental error $\pi_{\rm obs} - \pi_{\rm true}$, the size of which, σ_π, is estimated statistically from the dispersion of the positional measurements. It is usually assumed that the observing process $C(\pi_{\rm obs} \mid \pi_{\rm true})$ is represented by a normal distribution with mean $\pi_{\rm true}$ and variance σ_π^2. Great effort has been taken by the compilers of the Yale GCTSP and the Hipparcos Catalogue to detect and eliminate systematic errors and to assess the real precision of the parallaxes. This allows the user to rely on the π, σ_π values listed in these catalogues to be the best statistical estimates of the true quantities. For the 1995 GCTSP, van Altena comprehensively assessed the 'external' errors of each observatory, as a function of the published 'internal' errors. Before the 1997 publication of the Hipparcos Catalogue, the Hipparcos team verified that the errors were not underestimated by more than 10%.

Parallax errors can be correlated in two ways that may be important. First, the unknowns in a star's parallax solution (position, proper motion, parallax) will be correlated unless the observations are well distributed in time. This is simple to achieve with ground-based observations. However, for certain areas of the sky, Hipparcos was not able to provide equal numbers of observations on both sides of the parallactic ellipse, causing large (up to ± 0.6) correlations between parallax and ecliptic longitude. The Hipparcos Catalogue lists for each star the correlations between all the observational variables; the data should be used with caution when these values are not small ($\lesssim 0.2$).

Second, the parallaxes of two or more stars in one telescope's field of view will be correlated (i.e. not statistically independent) because they share the same reference frame. This is rarely a problem for ground-based observations, which generally have one 'target' star per field. Hipparcos presents a very different case. The satellite scanned great circles on the sky, timing each star's passage through the 0.9° field of view as a one-dimensional 'abscissa' relative to the positional zero point adopted for each 'reference great circle'. All stars on any one circle share the same zero-point error. As the scans repeated with different orientations, stars separated by $\gg 1^\circ$ were measured on different sets of scans, and their parallaxes are statistically independent. However, stars close together on the sky ($\lesssim 1^\circ$) share many scans in common, regardless of their orientation. As the same abscissa errors propagate into the parallax errors, the individual parallaxes are no longer statistically independent. The corresponding correlations, approaching $\rho = +0.6$ for small separations, must be carefully taken into account whenever Hipparcos data for small areas of the sky, such as in a cluster, are used.

'Large' parallaxes: Lutz–Kelker corrections

Perhaps the most important use of trigonometric parallaxes is the calibration of luminosities of different types of nearby stars. For 'large' parallaxes ($\pi \gg \sigma_\pi$), individual absolute magnitudes are calculated from

$$M = m + 5 + 5\log_{10}\pi.$$

However, this requires selecting stars by the size of their observed parallaxes, which introduces a statistical bias caused by the distribution of stars in space. This is because the conditional distribution of true parallax given the observed value, $C(\pi_{\rm true}|\pi_{\rm obs})$ is not the same as the (unbiased) conditional $C(\pi_{\rm obs}|\pi_{\rm true})$ representing the parallax measuring process. Rather,

$$C(\pi_{\rm true}|\pi_{\rm obs}) \sim C(\pi_{\rm obs}|\pi_{\rm true}) \times N_d(\pi_{\rm true})$$

where $N_d(\pi_{\rm true})$ is the spatial distribution of the stars in question. For nearby stars distributed uniformly in space, $N_d(\pi_{\rm true}) \sim \pi^{-4}$. The sense of the bias is that $\pi_{\rm true}$ is most likely less than $\pi_{\rm obs}$, because of the larger volume of space corresponding to smaller parallax.

The impact of this volume bias on luminosity calibrations was not fully understood until 1973, when Lutz and Kelker showed how to calculate absolute magnitude corrections

$$\Delta M = \langle M_{\rm true} - M_{\rm obs}\rangle = \langle 5\log_{10}(\pi_{\rm true}/\pi_{\rm obs})\rangle$$

with the averages taken over the conditional distribution $C(\pi_{\rm true}|\pi_{\rm obs})$. These 'Lutz–Kelker corrections' reach $\Delta M = -0.4$ mag for the limiting value $\sigma_\pi/\pi = 0.175$.

A serious objection to Lutz and Kelker's simple formulation is that, in practice, stars selected for parallax observation are not uniformly distributed in space. Common observational criteria (apparent magnitude, proper motion) purposely select nearby stars in preference to more distant stars. So, the space distribution of parallax stars is generally much less steep than π^{-4}, and the appropriate Lutz–Kelker corrections are correspondingly smaller. In 1979, Hanson showed how to use the power-law distribution of the proper motions of the sample of stars in question to estimate the exponent n in the generalized distribution $N_{\rm d}(\pi) \sim \pi^{-n}$ and how to calculate absolute magnitude corrections as a function of n and σ_π/π. For a typical case, $n = 2$ and $\sigma_\pi/\pi = 0.15$, $\Delta M = -0.1$ mag.

Even with the large number of mas-precision parallaxes provided by Hipparcos, many stellar luminosity calibration problems necessitate working with data of modest relative precision ($0.1 \lesssim \sigma_\pi/\pi \lesssim 0.2$) in order to obtain a large enough sample size. For this reason, Lutz–Kelker corrections remain a vital step in the careful statistical treatment of the data.

An outstanding example is the use of Hipparcos parallaxes of nearby field subdwarfs to calibrate the metal-poor main sequence which is fitted to Galactic GLOBULAR CLUSTERS to derive their distances and ages. Most studies have restricted $\sigma_\pi/\pi < 0.15$ to keep the Lutz–Kelker corrections small, but this leaves too few (~10–30) subdwarfs to calibrate M_V versus $B - V$ empirically as a function of the metallicity [Fe/H], and almost

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

no subdwarfs comparable with the most metal-poor ([Fe/H] < -2) clusters. Hipparcos actually measured parallaxes for several hundred metal-poor subdwarfs. The calibration sample could be increased substantially by extending the precision limit to $\sigma_\pi/\pi \simeq 0.2$ or greater, and applying appropriate Lutz–Kelker corrections.

'Small' parallaxes: reduced parallaxes

Most classes of high-luminosity distance indicators (e.g. RR Lyraes, Cepheids) are sufficiently rare in space that even the nearest examples are too distant for their parallaxes to be individually useful. For example, RR Lyrae itself is the only variable of that type in the Hipparcos Catalogue with $\sigma_\pi/\pi < 0.15$. Over 200 Cepheid variables were observed by Hipparcos; most are so distant that $\sigma_\pi/\pi \simeq 1$. Many of the parallaxes are negative. Although useless individually, 'small' parallaxes for large numbers of stars do contain valuable distance information, which can be extracted statistically, as long as the absolute zero point is reliable and the parallaxes are independent.

The proper tool for this work is the classic method of reduced parallaxes, first introduced by Charlier as early as 1916, and improved by Malmquist in the 1930s and again by Roman in 1952. The 'reduced parallax' P is defined by

$$P = \pi \times 10^{0.2(m+5)} = 10^{0.2M}$$

which is just a rearrangement of the usual formula relating parallax and absolute magnitude. The procedure is simple. For a group of stars presumed to have the same absolute magnitude M, the parallaxes are 'reduced' to a common apparent magnitude, thus scaling each parallax to a common distance. The reduced parallaxes P can then be averaged (with appropriate weights), and then

$$M = 5\log_{10}\langle P\rangle.$$

With the advent of the Hipparcos parallaxes, the classic method of reduced parallaxes has been re-discovered and applied with considerable success. Most notable is the work of Feast's group on the CEPHEID PERIOD–LUMINOSITY RELATION. The work of Arenou and Luri shows how reduced parallaxes can be used individually to make an 'astrometric H–R diagram' and clearly outlines the statistical advantages of the method. Respecting the long history of reduced parallaxes, however, one does regret their unfortunate coinage 'astrometry-based luminosity' in place of the classic terminology.

Cluster parallaxes: small-scale errors

For a set of stars at virtually the same distance, such as in a GALACTIC OPEN CLUSTER, the parallaxes can be simply averaged to obtain the cluster's parallax, which will be accurate if the absolute zero point is reliable and the individual parallaxes are uncorrelated. With ground-based parallaxes, only a few nearby clusters, most notably the Hyades, have enough data to provide useful results. (The parallaxes of several Hyades members have also been measured with the Hubble Space Telescope.) Without parallaxes, main-sequence (MS) fitting has been the only way to estimate distances for most open clusters.

Hipparcos observed stars in more than 200 open clusters, opening the possibility to determine their distances directly, without assumptions about stellar structure or chemical composition. Several teams have analyzed Hipparcos' cluster parallaxes. The Hyades distance was determined by Perryman *et al* to better than 1% precision ($d = 46.3 \pm 0.3$ pc) using proper motions as well as parallaxes. Robichon *et al* studied 18 other clusters with $d < 500$ pc and eight or more members observed by Hipparcos. van Leeuwen independently analyzed the nearest nine of these. Because the angular size of the clusters ($\sim 1^\circ$, except for the Hyades) is roughly the size of Hipparcos' field of view, and the star density in these clusters (9–17 stars deg^{-1}) is so high, one must account carefully for the correlations between measurements on the same great circles. Both Robichon and van Leeuwen did this using van Leeuwen's 'combined abscissae method', which uses the Hipparcos intermediate data to solve for a single parallax and proper motion for each cluster. These cluster parallaxes were claimed to be accurate to $\pm\sim$0.2–0.4 mas.

Controversy arose in 1997–9 when the Hipparcos parallax analyses gave anomalous distances (compared with MS fitting) for several clusters (e.g. Pleiades, Coma Berenices). Moreover, there were unexplained discrepancies between the two groups' results. Robichon concluded that only the Pleiades is anomalous, and the other clusters are consistent with MS fitting when their metallicities are taken into account. To the contrary, van Leeuwen claimed that the Pleiades and five other young clusters are subluminous, without regard to their metallicities, in stark contrast to modern understanding of stellar structure. Furthermore, the Hipparcos Pleiades parallax derived by both groups (8.5 ± 0.2 mas) was nearly 1 mas larger than the values determined from radial-velocity gradients by Narayanan and Gould, and from Allegheny MAP parallaxes by Gatewood.

The solution lay in recognizing the size of the small-angular-scale zero-point errors in Hipparcos' parallaxes. Regardless of what method of analysis is used, if the local zero point at the position of the cluster differs from absolute zero, the cluster parallax will be wrong by that amount. Hipparcos' zero point had been tested globally before the Catalogue was published, but no tests on small ($\sim 1^\circ$) angular scales were performed—such tests would require the cluster parallaxes themselves. van Leeuwen asserted that the local errors were only $\sim$0.1 mas, as small as the global errors, but the Pleiades parallaxes cast doubt on this.

It is important to note that the Pleiades has the highest central density (17 stars deg^{-1}) of any cluster observed by Hipparcos, and thus its parallax may be most vulnerable to small-scale systematic errors. Indeed, Pinsonneault *et al* discovered that the stars in the central 1° of the Pleiades have $\pi \simeq 9$ mas, but the outer stars have $\langle\pi\rangle = 7.5$ mas. Most of the central Pleiads have high correlations ($\rho >$

+0.34) between parallax and right ascension, identifying these stars as sharing many scans in common, and having little statistical independence. The central parallax is dominated by the local error, which does not 'average out' as it could over a larger area, such as the outer Pleiades or the Hyades.

Narayanan and Gould found correlated parallax errors with amplitude up to 2 mas on scales up to 2° for both the Pleiades and the Hyades regions. The RMS size of the zero-point fluctuations is 0.5–0.6 mas. Pinsonneault *et al* suggested that the RMS size of Hipparcos' small-scale zero-point errors over the whole sky could be up to 0.4 mas. Perryman pointed out that the parallax differences in the separate Hipparcos data reductions by the FAST and NDAC consortia reach 2 mas or more averaged over $2^\circ \times 2^\circ$ fields near the ecliptic. Merging the FAST–NDAC results for the final Catalogue reduces the local systematics by a factor of 2, to $\sim$1 mas. The Pleiades and Hyades results are fully consistent with the expected uncertainties of the Hipparcos Catalogue.

When the small-angular-scale errors in the Hipparcos parallaxes are taken into account, the cluster parallaxes are quite consistent with MS-fitting distances. In hindsight, it is now apparent that Hipparcos, for all its precision, was not the ideal instrument to measure cluster distances. The accuracy of a cluster's parallax is effectively limited to the level of the small-scale zero-point errors, no matter how many stars per cluster are observed. Future parallax surveys from space, based on Hipparcos' scanning principle, may also be affected by small-scale errors, and might well use cluster parallaxes to test them.

Future prospects

The future of parallaxes lies largely in space. Ground-based observations will continue to have importance for low-luminosity stars, binaries and clusters. Most late M dwarfs, white dwarfs and brown dwarf candidates are too faint to be observed even by the ambitious satellite programs mentioned below. Binaries generally need to be followed for longer periods than the limited lifespans of satellites. Hipparcos' experience points out the need for ground-based cluster parallaxes. At present, several observatories (Allegheny and US Naval in the north, Cerro Tololo and Mt Stromlo in the south) have active parallax programs.

The success of Hipparcos in producing large numbers of precise parallaxes for bright stars has proved the potential of space astrometry and spawned several projects to reach well beyond the magnitude and precision limits of Hipparcos.

The US National Aeronautics and Space Administration (NASA) has selected the US Naval Observatory's Full-sky Astrometric Mapping Explorer (FAME) for a 2.5–5 yr mission, scheduled for launch in 2004. With an operating principle much like Hipparcos (input catalogue, two fields of view, great circle scanning) but with an advanced 24-CCD-array detector, FAME will measure astrometry (positions, proper motions, parallaxes) and four-color photometry for nearly all stars to $V = 15$, a total of 4×10^7 stars. Projected astrometric accuracy ranges from 0.05 mas at $V = 9$ to 0.50 mas at $V = 15$. Photometric accuracy will be at the milli-magnitude level.

Several other space astrometry projects are in various stages of planning. DIVA (Double Interferometer for Visual Astrometry), proposed for launch in 2003, is a small Hipparcos-like scanning satellite which will provide astrometry and broad-band photometry to $V = 15$, and spectrophotometry to $V = 13.5$. Parallax accuracy at $V = 9$ will be 0.20 mas.

GAIA is a satellite observatory proposed for the European Space Agency's Horizon 2000+ plan, with the goal to build a catalogue of positions, distances, and three-dimensional space velocities for 10^9 stars to $V \simeq 20$. Parallax accuracy will be 0.004 mas for $V = 10$, 0.14 mas for $V = 15$ and 0.30 mas for $V = 20$. Photometry and radial velocities will be measured by separate instruments on the satellite.

NASA's SPACE INTERFEROMETRY MISSION (SIM), proposed for launch in 2005, is a 10 m baseline optical Michelson interferometer, making pointed observations from an Earth-trailing solar orbit. Astrometric precision will be 0.001 mas in relative measurements over small angles ($\leq 1^\circ$). Absolute parallax accuracy will be 0.004 mas.

Microarcsecond (μas) astrometry from space will revolutionize distance measurements once again. To give just one example, the parallax of the Galactic center is 120 μas. At that distance, an RR Lyrae star of $M_V = +0.5$ could be measured to 10% precision in parallax. Provided that systematic errors can also be reduced to the μas level, the prospects for 21st-century Galactic astronomy seem virtually unlimited.

Parker, Eugene ['Gene'] Newman (1927–)

American solar-terrestrial physicist, Parker worked at the University of Chicago, studying the solar wind and the effects of magnetic fields in the heliosphere. At first this work was through the study of the effect of the Sun on comet tails, but more recently through satellite measurements *in situ* he has developed understanding of the solar corona, the solar wind, the magnetic fields of both Earth and Sun, and their interactions.

Parkes Observatory

Arguably one of the world's great and most productive research instruments, the 64 m fully steerable paraboloid, Parkes Radio Telescope, is located in rural New South Wales, 400 km west of Sydney, Australia.

Commissioned in 1961 to further the pioneering research of the CSIRO Division of Radiophysics, continual upgrades to its surface, receivers and correlators have kept it at the forefront of radio astronomy.

Operated as part of the AUSTRALIA TELESCOPE NATIONAL FACILITY, much of its time is allocated to international pulsar, galaxy and Very Long Baseline Interferometry (VLBI) programs, with occasional support for JPL planetary missions. The H I Parkes All-Sky Survey for galaxies is a current major project.

For further information see
http://www.parkes.atnf.csiro.au.

Parsec (pc)

A unit of distance commonly used by astronomers. It is the distance at which a star would have an annual parallax of exactly one second of arc; from this distance, the Earth's orbit would have an apparent radius of one second of arc. One parsec is equivalent to 3.26 light-years (3.09×10^{13} km) or 206 265 astronomical units.

The distance of a star expressed in parsecs = 1/annual parallax (in seconds of arc); thus a star whose annual parallax is 0.1 seconds of arc lies at a distance of 1/0.1 = 10 parsecs. For example, the nearest triple-star system, Alpha Centauri, has a parallax of 0.753 seconds of arc; hence, its distance from the Sun and the Earth is 1.33 parsec.

Multiples of this unit are kiloparsecs (kpc) = 1000 parsecs and megaparsec (Mpc) = 1 000 000 parsecs. In our Galaxy distances to remote stars are measured in terms of kiloparsecs. The Sun is at a distance of 8.5 kiloparsecs from the center of the Galaxy. When dealing with other galaxies or clusters of galaxies, the convenient unit is the megaparsec. The distance to the Andromeda Galaxy (M31) is about 0.7 megaparsecs. Remoter galaxies and quasars have distances in the order of 3000 megaparsecs, or 9 000 000 000 to 10 000 000 000 light-years.

Parsons, Charles (1854–1931)

Youngest son of the third Earl of Rosse, brother to the fourth. Inventor of the steam turbine. Interested in telescope building through his father's activities with the Birr telescope, took over the machine engineering business of THOMAS and HOWARD GRUBB in 1925, and formed Sir Howard Grubb-Parsons Ltd in Newcastle, which made large telescopes starting with the 74 in reflector for the David Dunlap Observatory in Toronto. The firm took over Cooke, TROUGHTON and Simms Ltd. The firm was wound up after completing the 4.2 m William Herschel Telescope on La Palma in 1985.

Particle Acceleration in Magnetic Fields

Tenuous PLASMAS in astrophysical settings often contain particle populations which are not in thermodynamic equilibrium. Such non-thermal populations frequently possess power-law distributions. They are either observed directly or inferred from radiative properties. In low-density astrophysical plasmas the particles do not scatter against other particles, but scatter collisionlessly against magnetic field turbulence (see also PARTICLE ASTROPHYSICS; ASTROPHYSICAL BOUNDS ON PARTICLE PROPERTIES). Thus the particles are forced to equilibrate with the collective body of particles held together by the nearly frozen-in magnetic field. When the scattering centers, i.e. magnetic field turbulence, are moving toward each other, charged particles trapped in between are accelerated like tennis balls bouncing off two approaching walls. This is the basic concept of magnetic field acceleration first proposed by FERMI in 1949. Two very distinct cases can be separated: in the first case scattering is due to the magnetic field turbulence upstream and downstream of fast magnetosonic shocks, i.e. shocks which have an upstream plasma velocity larger than the fast magnetosonic velocity. The process of acceleration of particles by scattering back and forth across a shock in the presence of magnetic turbulence in the background plasma is called first-order Fermi acceleration or the diffusive acceleration mechanism. Since the phase velocity of the waves is small in comparison with the upstream flow speed the scattering centers move essentially with the flow, and a particle scattered back and forth across the shock senses the difference in the upstream and downstream flow speeds. In the second case the scattering centers are low-frequency plasma waves traveling in the plasma frame in opposite directions. In the plasma frame, a particle makes either a head-on or an overtaking collision with a scattering center, leading to either energy gain or energy loss respectively. Due to the large relative velocity between particle and wave the frequency of head-on collisions is greater than the frequency of trailing collisions, which leads to a net energy gain. This is the second-order Fermi acceleration process. Other acceleration mechanisms relay on the possibility of strong magnetic field-aligned electrostatic potential drops.

Diffusive shock acceleration

The transport of energetic particles in fluctuating magnetic fields is effectively described by the equation

$$\frac{\partial f}{\partial t} = \nabla\cdot(\bar{\kappa}\cdot\nabla f) - (\boldsymbol{V}+\boldsymbol{V}_D)\cdot\nabla f + \nabla\cdot\boldsymbol{V}\frac{p}{3}\frac{\partial f}{\partial p} + \frac{1}{p^2}\frac{\partial}{\partial p}\left(p^2\langle D_{pp}\rangle\frac{\partial f}{\partial p}\right) + Q \qquad (1)$$

where $f(\boldsymbol{r}, p, t)$ is the particle omnidirectional distribution function, $p = m\gamma v$ is momentum magnitude, $\boldsymbol{V}(\boldsymbol{r}, t)$ is the bulk velocity of the background plasma and $Q(\boldsymbol{r}, p, t)$ is a source term (to describe for example ion injection at a shock). The control of the magnetic field on the spatial transport and transport in momentum space is described by the symmetric part of the spatial diffusion tensor, $\bar{\kappa}$, the drift velocity, $\boldsymbol{V}_D$, and the diffusion coefficient in momentum space, $\langle D_{pp}\rangle$. Equation (1) is based on the assumption that $v \gg V$ and the spatial scale length, L, is sufficiently larger than the scattering mean-free path. The first term on the right-hand side describes spatial diffusion of the particles. The second term describes the effect of spatial convection and energetic particle drift, and the third term is usually called the adiabatic deceleration term. This term is a momentum convection term and describes adiabatic deceleration as well as first-order Fermi acceleration in the case of converging bulk flow as, for instance, at a shock where $\nabla\cdot\boldsymbol{V} > 0$. The drift term $\boldsymbol{V}_D\cdot\nabla f$ describes transport due to curvature, gradient and magnetization drifts in the 'average' (usually viewed as an ensemble average) magnetic field. The diffusion tensor is often assumed to be axisymmetric about the unit vector $\boldsymbol{b} = \boldsymbol{B}/B$ and therefore has the form $\bar{\kappa} = \kappa_\perp\delta_{ij} + (\kappa_\parallel - \kappa_\perp)b_i b_j$ where δ_{ij} is the Kronecker symbol. $\kappa_\parallel$ ($\kappa_\perp$) describes spatial diffusion parallel (perpendicular) to $\boldsymbol{b}$ due to magnetic field fluctuations. The parallel diffusion coefficient $\kappa_\parallel$ and the diffusion coefficient in momentum space $\langle D_{pp}\rangle$ are determined by pitch angle averages

$$\kappa_\parallel = \frac{v^2}{8}\int_{-1}^{1}\mathrm{d}\mu\frac{(1-\mu^2)}{D_{\mu\mu}} \qquad (2)$$

and

$$\langle D_{pp}\rangle = \frac{1}{2}\int_{-1}^{1}\mathrm{d}\mu\left(D_{pp} - \frac{D_{\mu p}^2}{D_{\mu\mu}}\right) \qquad (3)$$

where $D_{\mu\mu}$, D_{pp}, and $D_{\mu p}$ are the three Fokker–Planck coefficients, and μ is the cosine of the pitch angle α, $\mu = \cos\alpha = v_\parallel/v$ ($v_\parallel$ = velocity parallel to the magnetic field).

Associated with the solution to the distribution function f is a streaming flux $\boldsymbol{S}$

$$\boldsymbol{S} = -\kappa_\parallel\nabla f - \frac{1}{3}\boldsymbol{V}p\frac{\partial f}{\partial p} \qquad (4)$$

and an associated anisotropy magnitude $\delta = 3|\boldsymbol{S}|/(vf)$. In the case of a planar shock with the shock at $x = 0$ the steady-state solution to equation (1) can be obtained by solving it in the upstream and downstream regions and relating the solutions across the shock by the jump condition that the streaming flux $\boldsymbol{S}$ is continuous. With x in the direction of the shock normal the jump condition reads

$$\left[\kappa_{xx}\frac{\partial f}{\partial x} + \frac{v_x}{3}\frac{\partial f}{\partial \ln p}\right]_1^2 = \tilde{Q}. \qquad (5)$$

The sub- and superscripts 1 and 2 denote upstream and downstream states, $\tilde{Q}$ is that part of the source which is concentrated at the shock and κ_{xx}, the diffusion coefficient normal to the shock surface, is given by the angle Θ

Copyright © Nature Publishing Group 2001

between the magnetic field and the x direction as $\kappa_{xx} = \kappa_\parallel \cos^2\Theta + \kappa_\perp \sin^2\Theta$. The spectrum produced at a planar shock is a power-law spectrum in momentum, determined only by the shock compression ratio, $R = V_1/V_2 = \rho_2/\rho_1$, where ρ is the density:

$$f(p) \propto p^{-3R/(R-1)}. \tag{6}$$

This spectrum falls off upstream with e-folding distance $L = \kappa_{xx}/V_1$. The important quantity that determines the time scale for acceleration is the diffusion coefficient in the normal direction. In the case of quasi-parallel shocks this is the diffusion coefficient parallel to the magnetic field, whereas in the case of quasi-perpendicular shocks cross-field diffusion eventually determines the normal diffusion coefficient. From a time-dependent solution to equation (1) it can be shown that the steady state is reached in a characteristic time $\tau \approx 4\kappa_{xx}/V_1^2$. Other linear modifications arise due to the fact that shocks are not necessarily planar, i.e. the radius of curvature of the shock front is no longer small compared with the diffusion length scale $L = \kappa_{xx}/V_1$. This is the case for blast waves from a point explosion or for shocks terminating stellar winds.

The convection–diffusion equation (1) can be generalized to include, in addition to the term that describes energy changes due to the divergence of the flow, a term that describes energy changes due to a shear in the flow. In the case when the plasma velocity $\boldsymbol{V}$ varies over spatial scales that are large compared with the scattering mean free path, this term has the form

$$\frac{\Gamma}{p^2}\frac{\partial}{\partial p}\left(\tau p^4 \frac{\partial f}{\partial p}\right) \tag{7}$$

with Γ the viscous momentum transfer and τ the scattering time. Γ is determined by the velocity shear $\partial V_i/\partial V_j$. For a simple shear flow $\boldsymbol{V} = V_y(x)\boldsymbol{e}_y$ the coefficient of momentum transfer reduces to $\Gamma = (\partial V_y/\partial x)^2/15$. The transfer of energy to the energetic particles leads in turn to a viscosity of the ambient plasma.

The spatial diffusion coefficients

The diffusion–convection equation (1) is derived by pitch-angle averaging of a Fokker–Planck equation. The Fokker–Planck equation is obtained by applying the quasilinear approximation to the behavior of energetic particles in a uniform magnetic field with superposed small-amplitude plasma turbulence. The effect of the turbulence is determined by calculating first-order corrections to the particle's orbit in the uniform magnetic field and ensemble averaging over the statistical properties of the plasma turbulence. The ensemble-averaged first-order particle correction to the equation of motion in momentum and pitch angle space determines the three Fokker–Planck coefficients D_{pp}, $D_{\mu p}$ and $D_{\mu\mu}$. The particles interact resonantly with the magnetic field turbulence, i.e. a particle is scattered only if the Doppler shifted wave frequency equals the particle's gyrofrequency Ω times an integer n:

$$\omega - k_\parallel v_\parallel = n\Omega \tag{8}$$

where $v_\parallel = v\mu$ and $k_\parallel$ are the parallel velocity component and the parallel wavenumber respectively. The gyrofrequency is given by $\Omega = qB/mc\gamma$, where q = charge, m = mass and γ is the relativistic factor of the particle. The resulting Fokker–Planck coefficients depend strongly on the type of turbulence present. Most analytical investigations have been done for the so-called slab model, where the plasma turbulence is assumed to consist of waves propagating parallel to the magnetic field. Furthermore, these waves are usually assumed to be Alfvén waves. The dispersion relation then reads $\omega = k_\parallel V_A$, with V_A the Alfvén speed. In this case quasi-linear theory yields the pitch-angle diffusion coefficient

$$D_{\mu\mu} = \frac{\pi q^2}{2m^2c^2|\mu|v} P\left(\frac{\Omega}{\mu v}\right). \tag{9}$$

$P(k)$ is the wave power at wavenumber k:

$$P(k) = \frac{1}{2\pi}\int \mathrm{d}s \langle \delta\boldsymbol{B}(s_0)\cdot\delta\boldsymbol{B}(s_0+s)\rangle \,\mathrm{e}^{-iks}. \tag{10}$$

If $P \propto k^{-\delta}$ this gives for the spatial diffusion coefficient in the non-relativistic regime an energy dependence $\kappa_\parallel \propto E^{(3-\delta)/2}$. If fast magnetosonic waves are present equation (9) has to be changed accordingly. Very low frequency fast magnetosonic waves have a dispersion relation given by $\omega = kV_A$. For oblique propagation the wave magnetic field has both a compressive (along $\boldsymbol{b}$) and a linearly polarized transverse component. Unlike the case of slab turbulence, the compressive component of oblique fast-mode waves allows energetic particles to resonate with the waves also through the $n = 0$ (Landau) resonance. However, this resonance is unimportant for the diffusion coefficient but, as will be shown below, is the dominant factor for the momentum diffusion coefficient. Summarizing, in order to determine the parallel spatial diffusion coefficient the following parameters have to be known: the total intensities in the Alfvén and fast-mode waves, the power-law shape, the distribution of the fast mode wave power in $\boldsymbol{k}$ space and the minimum cut-off frequency of the wave power. Depending on these parameters, the energy and mass/charge dependence of the parallel spatial diffusion coefficient may vary considerably.

Resonant scattering which causes pitch angle diffusion causes particles to shift the field line about which they gyrate and thus contributes to $\kappa_\perp$. In addition, a field line randomly walks about the average field $\boldsymbol{B}$, which causes perpendicular transport of a particle that follows the field line. There is no generally accepted theory for $\kappa_\perp$. For large-amplitude fluctuations it is often assumed that $\kappa_\perp \approx \kappa_\parallel$. Another model assumes that scattering of particles by the magnetic field turbulence occurs as in hard sphere scattering. With a parallel scattering time $\tau = 3\kappa_\parallel/v^2$, the cross-field diffusion coefficient is given in this case by

$$\kappa_\perp = \kappa_\parallel \frac{1}{1+\Omega^2\tau^2}. \tag{11}$$

The contribution to $\kappa_\perp$ from field line random walk is proportional to the power $P(0)$ of the magnetic field at zero wavenumber.

Nonlinear modifications to shock acceleration

In general, the reaction of the shock-accelerated particles on the background plasma cannot be ignored. Two such kinds of reaction have to be considered. The streaming of the shock accelerated particles through the upstream plasma will excite waves through an ion/ion beam instability. This then leads to enhanced scattering with the particles themselves providing the scattering centers needed for diffusive shock acceleration. A more serious modification is concerned with the fact that for a power-law downstream distribution of energetic particles the pressure of these particles diverges for strong shocks and the reaction on the flow must be taken into account. Wave generation by the streaming of energetic particles can be dealt with in the framework of quasilinear theory. The diffusion–convection equation is supplemented by an equation for the wave energy density E_W. The time dependence $\partial E_W/\partial t$ is given by the convection of the waves with the flow and the wave growth rate γ_W, which is proportional to particle streaming. The spatial diffusion coefficient in the diffusion–convection equation according to quasilinear theory is proportional to E_W^{-1}. These two equations simultaneously determine f and E_W.

The problem of the reaction of the energetic particle pressure on the flow is essentially one in fluid dynamics. The background plasma is usually described by the Euler equations (conservation of mass flux, momentum flux and energy flux), and the reaction of the energetic particles is incorporated by an additional pressure term in the momentum equation due to energetic particles. An equation for the energetic particle pressure $P_c = (4\pi/3)\int \mathrm{d}pp^3vf(p)$ can be obtained by taking a suitable moment of the diffusion–convection equation with respect to momentum p. In practice, however, two supplemental assumptions are introduced instead. These are that the pressure and the energy flux of energetic particles are both continuous across the shock transition:

$$[P_c]_2^1 = [\gamma_c V P_c - \tilde{\kappa}\partial P_c/\partial x]_2^1 = 0 \qquad (12)$$

where γ_c is the ratio of specific heats for the energetic particles (which is 4/3 for relativistic, and 5/3 for non-relativistic particles). $\tilde{\kappa}$ is the suitable momentum averaged spatial diffusion coefficient. For low Mach number shocks the relativistic particle pressure has the effect of decreasing the effective specific heat ratio of the gas so that the shock compression ratio is not limited to four, but can increase up to seven. For stronger shocks the entire transition itself can be mediated by the presence of the energetic particles. Besides this two-fluid approach the mediation of shocks by energetic particles has been investigated through Monte Carlo simulations.

The momentum diffusion coefficient and second-order Fermi acceleration

The momentum diffusion coefficient can be computed from the Fokker–Planck coefficients according to equation (3). In the case of equal intensity of forward and backward traveling waves (vanishing cross helicity) equation (3) reduces to the much simpler equation

$$\langle D_{pp}\rangle = \int_0^1 D_{pp}\,\mathrm{d}\mu. \qquad (13)$$

In the case of slab-Alfvén waves D_{pp} has only a contribution D_{pp}^A from gyroresonance: the particles gain or lose speed when they are resonantly pitch-angle scattered. The gain or loss in speed is equal to the Alfvén speed. The Fokker–Planck coefficient D_{pp} is additive; if magnetosonic turbulence is present, additional terms D_{pp}^T and D_{pp}^G have to be added to D_{pp}^A. Here D_{pp}^G is the Fokker–Planck coefficient due to gyroresonant interaction (integer n in equation (8)), and D_{pp}^T is the Fokker–Planck coefficient for the $n = 0$ resonance, i.e. $\omega - k_\parallel v_\parallel = 0$. The latter condition means that interaction between the wave and the particle occurs when the particle is moving at about the parallel wave phase speed. This interaction is called transit-time damping and is due to the magnetic mirror force in the wave compressions. Introducing the parallel wavelength $\lambda_\parallel = 2\pi/k_\parallel$ and the wave period $T = 2\pi/\omega$, the resonance condition reads $\lambda_\parallel/v_\parallel = T$. This implies that a particle will interact with the wave when the particle transit time across the wave compression is about equal to the wave period. Transit-time damping can only occur for particles with a velocity exceeding the Alfvén velocity. In the case of a mixture of isotropically distributed fast magnetosonic turbulence and slab Alfvén waves of similar power, the contribution from the gyroresonances due to both Alfvén waves and magnetosonic waves to the Fokker–Planck coefficient D_{pp} is less than the contribution from the $n = 0$ resonance of the magnetosonic waves. If fast magnetosonic turbulence is present, energetic particle acceleration is mainly due to transit-time damping.

Other acceleration mechanisms

In addition to the above mechanisms of accelerating particles by magnetic waves and shocks, collisionless plasmas (see COLLISIONLESS PROCESSES IN ASTROPHYSICAL PLASMAS) are capable of dumping energy into small groups of particles by means of generating strong field-aligned electric potential drops, so-called electrostatic double layers. Large-scale potential drops can be produced by the action of the magnetic mirror force $\boldsymbol{F}_{m\parallel} = -M\nabla_\parallel B(s)$ on the particle distributions in a magnetic trapping configuration (e.g. the dipole magnetic field of a neutron star). Here $M = P_{c\perp}/NB$ is the magnetic moment of the particles of mass m, perpendicular pressure $P_{c\perp}$ and density N, and s is the coordinate along $\boldsymbol{b}$. Since ions and electrons mirror on the field line at different locations s, a field-aligned electric potential is produced that may accelerate particles.

Other important ways of producing strong parallel quasistatic electric fields require the presence of large-amplitude microturbulence which backscatters the electrons causing anomalous collisions, friction and ohmic electric fields. The energy for excitation of microturbulence is taken either from electric currents flowing along

or perpendicular to the magnetic field, density or temperature gradients, or from electron beams. Once the current density $|\boldsymbol{j}| \geq j_c = eN|\boldsymbol{v}_D|$ exceeds a critical threshold j_c (here e is electron charge, N density and v_D the current-drift speed), high-frequency electric fluctuations near some typical plasma resonance frequencies are driven unstable until they grow to large amplitudes. For very strong currents $v_D > \sqrt{k_B T_e/2m_e}$ exceeding the electron thermal velocity, this frequency is the Buneman frequency $\omega_B = 0.03\omega_{pe}$, with ω_{pe} the plasma frequency. At weaker currents $v_D > c_{ia}$, with c_{ia} the ion sound speed, the ion acoustic wave $\omega = kc_{ia} < \omega_{pe}/43$ is excited. Electron beams generate Langmuir waves near $\omega = \omega_{pe}$ and Bernstein waves near $\omega = n\Omega_e$ ($n = 1, 2, \ldots$ and $\Omega_e = eB/m_e$ the electron cyclotron frequency). They also drive electron acoustic waves at frequencies between the ion and electron plasma frequencies. Gradients and transverse currents excite waves near the lower-hybrid frequency $\omega = \sqrt{\Omega_i \Omega_e} = 43\Omega_e$. In the region of such turbulence (extension L along $\boldsymbol{b}$) the total resulting potential drop can be estimated from

$$U = j_\parallel L \eta_{\rm an} \approx \frac{eN\nu_{\rm an}}{\omega_{pe}^2} L v_D. \tag{14}$$

Here $\nu_{\rm an}$ is the anomalous collision frequency. The maximum available energy to which an electron may be lifted is just $K_{\rm max} = eU$. For a monochromatic electron flux $F = N_{\rm acc} v_0$ passing the potential drop U at speed v_0 the number of electrons that can be accelerated is $\mathcal{N} = Fv_0/L$. This yields for the energy that can actually be reached the expression

$$K_{\rm acc} \approx \frac{eN\nu_{\rm an}}{\omega_{pe}^2} \frac{v_D L^2}{F v_0}. \tag{15}$$

When the amplitude of the microturbulence reaches large values, typically of the order of $E_W/Nk_BT \approx 10^{-4}$, the quasilinear effects causing anomalous resistivities are superceded by nonlinear effects. Particles become trapped in the wave potential and are accelerated and released in energetic bunches. These are effects well known from nonlinear processes encountered in chaos theory. In addition the interaction between the wave and the various groups of particles leads to the emergence of small-scale structures of the order of the Debye length, electron skin depth and particle gyroradii which trap the waves locally. Interaction of particles with these so-called solitons, solitary waves, cavitons, phase space holes or BGK modes causes microscopic stationary potential drops to develop across the solitary structures. Because in well developed turbulence myriads of such microscopic drops exist along and transverse to a field line their total potential drop may add up to very large values. Any small groups of particles falling across these potentials will then experience transit time acceleration in the interaction with the potential and the turbulence and will damp the turbulence. Some of them may thereby reach very high energies. Theory of this kind of particle acceleration is still under development and relies heavily on the availability of realistic numerical simulation models in many dimensions.

Particle Astrophysics

Particle astrophysics (or, equivalently, astro-particle physics), as the name implies, is an area of research which lies at the cross-roads of high-energy particle physics and astrophysics. Because most of the interest in the field is focused on high-energy phenomena, COSMOLOGY, particularly the early universe, is at the core of research activity.

The related area of nuclear astrophysics was developed as a means to understand the mechanism of solar energy production and stellar evolution. For example, nuclear processes are fundamental to our understanding of element production in stars. Particle astrophysics was developed in the 1970s and one could perhaps identify three problems that sparked the field. The first was the recognition that NEUTRINOS, if massive, could have a profound effect on the overall mass density of the universe. In the STANDARD MODEL OF PARTICLE PHYSICS, neutrinos are massless. The theory was constructed this way to account for the lack of any experimental evidence for a neutrino mass. As such, the theory was quite economical, as it predicted the minimum number of new undetected particles. By expanding the theory, neutrino masses can be accommodated, and if present, even if very slight in comparison with any known massive particle, would come to dominate the dynamics of the universe.

Another major motivating force in the development of particle astrophysics was the realization that theories which unify three of the fundamental forces in nature (electromagnetism, and the weak and strong nuclear forces), commonly called GRAND UNIFIED THEORIES or GUTs, possessed the ingredients necessary to solve a long-standing problem in cosmology relating to the asymmetry of MATTER versus ANTIMATTER. As such, these two problems made it clear that any complete description of our evolving universe would hinge on our understanding of the fundamental processes in nature, namely particle physics.

There are three known types or flavors of neutrinos. In the early universe, even massless neutrinos played a significant role in the dynamics of the rapidly expanding SPACE-TIME. If more than the three known neutrinos were present, the increased energy density would lead to an increase in the expansion rate and would alter the big bang NUCLEOSYNTHESIS (BBN) predictions of the light element abundances (of D, ^{3}He, ^{4}He and ^{7}Li). The concordance of these predictions with the observational determination of the abundances places a strong constraint on the expansion rate at the time of BBN (about 2 minutes after the big bang) and hence on the particle content of the universe at that time. The establishment of a limit on the number of neutrino flavors also played a key role in the development of the particle-astrophysics connection. The limit on the number of neutrino flavors has been generalized to constraints on a multitude of particle properties including limits on particle masses and lifetimes, and even limits on the variation of the fundamental constants of nature.

As the field developed, particle astrophysics has grown to include a wide variety of topics beyond neutrino masses and the matter asymmetry. The cosmological significance of stable particle masses provided an alternative means of solving the long-standing problem of DARK MATTER. Indeed, the theoretical constraints on theories with dark matter candidates and the experimental effort towards the detection of these candidates is one of the major thrusts in particle astrophysics today.

The study of grand unification in a cosmological context has also spread and diversified the domain of particle astrophysics. In addition to its potential for resolving the origin of the matter-antimatter asymmetry, grand unified theories predict the existence of very massive magnetic monopoles. Like electrons which have a unit of electric charge, these particles would carry a single unit of magnetic charge. However, the predicted number of these cosmological relics is clearly ruled out by experiment. Attempts at solving the monopole problem led to one of the major changes in what is referred to as the standard COSMOLOGICAL MODEL by introducing the notion of INFLATION, a period of extremely rapid expansion in the very early universe.

As a symmetry of nature, grand unification is not realized at the energies available to laboratory experiments. The breakdown of the symmetry and its effects (including the production of magnetic monopoles) has been an active area of research. Indeed, inflation was first thought of as a direct result of this symmetry breakdown. Although the early models of inflation were not successful, the study of other exotic phenomena, such as the production of topological defects which include cosmic strings, domain walls and textures, thrived. As theories of unification were pushed to include gravity, even the number of spatial dimensions was no longer held sacred. In STRING THEORY, the universe is a ten-dimensional space-time and in extensions of string theory, called M-theory, the universe is eleven-dimensional.

Although the description of all phenomena considered to fall within the domain of particle astrophysics is clearly beyond the scope of this article, probing a few of the topics described above will serve to define the nature of the field.

As noted above, although the standard model of electroweak interactions precludes the presence of neutrino masses, simple extensions of the theory can easily account for such masses. In the standard model, neutrinos and electrons form a weak left-handed doublet of the $SU(2)_L$ gauge group. This means that there are gauge interactions, mediated by a spin-1 particle, which are capable of interconverting (left-handed) electrons and neutrinos. In addition, the theory includes an $SU(2)_L$ singlet - a right-handed electron. Through its interaction with the Higgs boson, the left- and right-handed electrons mix to form a single, massive state. By adding a right-handed neutrino to the model, a neutrino mass can also be generated. However, we know experimentally that neutrino masses must be very small. To obtain a small

mass, it is common to introduce a right-handed neutrino with a very large so-called Majorana (right-right) mass, M, in addition to the usual (left-right) Dirac mass, $m_{\rm D}$. Because of the left-right mixing, the physical neutrinos have masses which are different from the input masses, M and $m_{\rm D}$. To determine the physical masses one can write down a simple 'mass matrix' for neutrinos, which in a $(\nu_{\rm L}, \nu_{\rm R})$ basis can be of the form

$$\begin{pmatrix} 0 & m_{\rm D} \\ m_{\rm D} & M \end{pmatrix}. \quad (1)$$

Diagonalization of this matrix determines the physical neutrino masses, giving one massive state $\nu_1' \simeq \nu_{\rm R}$ with mass $m_{\nu_2} \simeq M$ and a lighter state, $\nu_1 \simeq \nu_L + {\rm O}(m_{\rm D}/M)\nu_{\rm R}$ with mass $m_{\nu_1} \simeq m_{\rm D}^2/M$. For $M \gg m_{\rm D}$, ν_1 can be made acceptably light. If all three flavors of neutrinos received mass in this way, the light states could mix (quantum mechanically) or oscillate.

Neutrino oscillations occur when the physical masses and input masses are not identical as described above. For example, nuclear processes in the Sun may produce an electron neutrino which if massive may not be a propagating state. Rather than a $\nu_{\rm e}$, it is one of the three light states $\nu_{\rm i}$ which travels to Earth from the Sun. But $\nu_{\rm i}$ contains some mixture of the three flavors of neutrinos $\nu_{\rm e}$, ν_μ and ν_τ. Depending on the degree of mixing, the distance between production and detection, and the energy of the neutrino, a ν_μ or ν_τ may be detected instead of $\nu_{\rm e}$. Neutrino experiments designed to detect $\nu_{\rm e}$s from the Sun have for decades recorded a deficit in the flux of electron neutrinos from the Sun. A similar problem is seen when detecting neutrinos produced in cosmic-ray showers in the atmosphere (see COSMIC RAYS: EXTENSIVE AIR SHOWERS). In a cosmic-ray collision with a nucleus in the atmosphere, many pions are produced. Pions decay primarily into muons which subsequently decay to electrons. Simple counting predicts that the ratio of muon to electron neutrinos is 2:1. However, observations indicate that this ratio is only about 60% of what is expected. Again, the explanation could be neutrino oscillations. In fact, it is widely believed that these experiments provide the first positive indication of a neutrino mass. Indeed, neutrino astrophysics is one of the strongest and most experimentally based components of particle astrophysics.

A light neutrino (with mostly left-handed interactions) would have been produced cosmologically and remained in equilibrium down to a temperature of about 3 MeV (the temperature scale at which the rate of weak interactions falls below the expansion rate of the universe). The relic number density of neutrinos is related to the neutrino temperature, $n_\nu \sim T_\nu^3$, and the mass density of relic neutrinos is simply $\rho_\nu = m_\nu n_\nu$. The neutrino temperature is predicted to be somewhat below the photon or microwave background temperature due to the annihilation of electron-positron pairs shortly after neutrino decoupling, $T_\nu = (4/11)^{1/3} T_\gamma$. Therefore the total mass density in neutrinos can be compared with the critical density necessary to close the universe ($\rho_{\rm c} = 1.05 \times 10^4 h^2$ eV cm^{-3} where h is the scaled Hubble parameter, $h = H/(100$ km Mpc^{-1} s$^{-1})$) and depends on the mass of the neutrino. The fraction of critical density in neutrinos is

$$\Omega_\nu = \rho_\nu/\rho_{\rm c} = 0.011 m_\nu({\rm eV}) h^{-2}. \quad (2)$$

The cosmological limit of $\Omega h^2 < 0.3$ (assuming that the age of the universe is greater than 12 Gyr) then places a constraint on the mass of the neutrino. In fact, it places a limit on the sum of all light neutrino masses

$$\sum_\nu m_\nu < 28 \text{ eV}. \quad (3)$$

The tiny mass scale should be compared with the electron mass $m_{\rm e} \simeq 0.511$ MeV, and the proton $m_{\rm p} \simeq 938$ MeV.

The connection between particle astrophysics and dark matter extends far beyond the case of light neutrinos. Very massive neutrinos (in the GeV mass range) were also considered as dark matter candidates. Neutrino interactions with matter (e.g. electrons) drop out of equilibrium when the average energy in the radiation background is about 3 MeV. At lower energies, the number densities and cross sections of neutrinos are too small to ensure scatterings with electrons in an expanding and cooling universe. Therefore, the relic density of much heavier neutrinos is determined by annihilations of ν and $\bar{\nu}$ pairs. At temperature scales below the neutrino mass ($kT \sim m_\nu c^2$ or m_ν in units where $c = 1$), neutrino annihilation is energetically preferred to neutrino production, and the density of neutrinos decreases. When the density becomes very low, the annihilations also stop (or freeze-out) and the relic density (relative to photons) becomes fixed. Because the efficiency of the neutrino annihilation scales with the neutrino mass, the cosmological limit $\Omega h^2 < 0.3$, places a *lower* bound on the mass of a heavy neutrino of about 4-7 GeV.

Experimental results based on the production of Z^0 gauge bosons at CERN and SLAC have shown that there are only three neutrinos ($\nu_{\rm e}$, ν_μ and ν_τ) with a mass less than m_Z. Therefore, the mass of a possible fourth heavy neutrino must exceed $m_Z/2 \simeq 45$ GeV. However, for such a heavy neutrino, the relic density is far too small for it to constitute a significant amount of dark matter, thereby excluding a heavy ($m_\nu > 1$ MeV) neutrino as dark matter.

The study of heavy neutrinos was nonetheless very fruitful, as many of the same relic density calculations also apply to other heavy dark matter candidates. For example, the well studied extension of the standard model of electroweak and strong interactions, known as SUPERSYMMETRY, predicts the existence of a new stable massive particle, the neutralino, which could account for the dark matter of the universe. Supersymmetry is a symmetry which relates particles of different spin. For example, all particles of spin-1, like the photon, must have a fermionic partner of spin-1/2 (for the photon, the partner is called the photino). For fermions, like the electron, a

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

spin-0 partner must exist (in this case, called the selectron). Supersymmetry predicts new interactions in addition to new particle types. In fact, some of these interactions could be responsible for the extremely rapid decay of the proton, which is clearly not observed. Therefore a new quantum number called R-parity is assigned to all particles. R-parity is related to baryon number, lepton number (see below for a description of these) and spin. As such, all observed particles are assigned an R-parity of +1, and all of the supersymmetric partners have R-parity -1. The lightest supersymmetric particle (commonly referred to as the LSP) is therefore stable as there are no lighter $R = -1$ particles to decay into. Supersymmetry is a theory which is currently under intensive experimental and theoretical investigation in both particle physics and particle astrophysics. Major efforts are under way to specifically search for the dark matter candidate that is predicted by supersymmetric theories and as such is a main focus in particle astrophysics today.

Indeed, the methods for experimental searches for dark matter can be placed into three categories: (a) accelerator searches, (b) indirect and (c) direct searches. Accelerator searches for dark matter are in principle the most direct, since one can hope to produce and detect the dark matter particle (or an associated particle) and establish its identity. However, these searches are typically designed to search for a very specific candidate with theoretically predicted interactions. The so-called direct and indirect dark matter searches are more general and do not depend on the specific properties of the candidate. Indirect dark matter searches typically key on some other particle rather than the dark matter candidate itself. Weakly interacting dark matter in our Galaxy (and solar system) continuously flows through the Sun and the Earth. For example, as a dark matter particle passes through the Sun, it will occasionally scatter and lose enough energy to become trapped in the Sun. As the number of these particles builds up, they begin to annihilate in the Sun and provide a source for high-energy neutrinos. Neutrino detectors (the same ones as used to measure neutrino oscillations) search for a flux of high energy neutrinos from the core of the Sun as well as the center of the Earth. Direct searches are based on laboratory detectors which are designed to detect the passage of dark matter particles. These are typically ultra-cold detectors which attempt to measure slight changes in the temperature of the detector induced by the interaction of the dark matter candidate and the material in the detector.

As can be inferred from the discussion above, the number of (light) neutrino flavors has been limited to three by experiment. However, particle astrophysics had provided a limit to this quantity ($N_\nu < 4$) years prior to the accelerator experimental results. Next to the prediction and discovery of the the 3 K microwave background, the prediction of the light element abundances of D, ^{3}He, ^{4}He and ^{7}Li is the most important test of big bang cosmology. The production of the light elements, and in particular ^{4}He, depends on a competition between the weak interaction rates which interconvert neutrons and protons and the rate of expansion of the universe. Because the standard models of cosmology, nucleosynthesis and particle physics (with three neutrino flavors) are so successful, most deviations from any of the standard models spoil the agreement between the theoretical predictions of the light element abundances and their observational determinations. Hence, BBN can limit the number of neutrino flavors. Other departures from the standard electroweak theory can also be constrained by BBN.

Nuclear processes in the early universe are very sensitive to the rate at which the universe expands and cools. The expansion rate of the universe (quantified by the Hubble parameter) is determined by the energy density of the universe. At early times (when curvature and the cosmological constant can be neglected) the Hubble expansion rate is given by

$$H^2 = \frac{8\pi G_{\rm N}}{3}\rho \qquad (4)$$

where the energy density in radiation is given in terms of the black body temperature and the total number of relativistic particle species present, $\rho \sim NT^4$. In the standard model, at the time of nucleosynthesis ($kT \sim 1$ MeV), $N = 2 + \frac{7}{2} + \frac{7}{4}N_\nu$, corresponding to the contributions of photons, electrons and neutrinos respectively. For $N_\nu = 3$, big bang nucleosynthesis predicts the correct abundances of the light elements. Due to the uncertainties in the observational abundances of the light elements, the limit from nucleosynthesis is $\sim$4, that is, the agreement between theory and observation becomes unacceptable when N_ν exceeds 4.

The limit to N_ν has proven to be one of the most valuable in the particle astrophysics connection. The limit in fact can be extended to any new particle degree of freedom present in the early universe at the time of big bang nucleosynthesis. Therefore, many new extensions of the standard model of particle physics can be, and have been, constrained by cosmology.

A key factor in the growth of particle astrophysics was the development of a wide class of constraints on theories of particle physics from cosmology and astrophysics. In addition to the BBN limits described above, our understanding of stellar processes has also provided valuable constraints. For example, certain theories predict new, massless or nearly massless particles. If these particles could be produced in the Sun, they would affect the rate of energy production and upset the agreement between observations and standard stellar models. In some cases, much stronger constraints are obtained by energetic arguments concerning RED GIANT STARS, which are relatively short lived. A new source of energy production could grossly affect the lifetime of these stars and make them in effect unobservable. The observation of neutrinos from the SUPERNOVA 1987A also provided a great opportunity for particle astrophysics to place constraints on many

phenomena beyond the standard model. In addition, this event, along with the new age of neutrino detectors (detecting neutrinos from the Sun and neutrinos produced in cosmic-ray collisions in the atmosphere), has opened a new door (NEUTRINO ASTRONOMY) which has grown to become a major focus of particle astrophysics.

In the late 1970s, the success of gauge theories in explaining the standard model of electroweak interactions led to ambitious efforts towards the unification of the strong and weak nuclear forces with electromagnetism, or Grand Unification. In the standard model, proton stability is guaranteed by the conservation of a quantum number called baryon number. If conserved, the net baryon number, like electric charge, must not change in any physical process. To date, all experimental results are consistent with the exact conservation of baryon number. Particles which are built out of three constituent quarks, like neutrons and protons, are ascribed a baryon number of 1 (quarks have baryon number 1/3). Electrons and neutrinos in contrast, being elementary and not comprised of quarks, have no baryon number. Although pions and other similar particles called mesons are built from quarks, because they are described by a quark-antiquark pair they also have no baryon number. The neutron, being heavier than the proton, can decay (into a proton, electron and anti-neutrino). However, the proton is the lightest state with baryon number $B = 1$, and is stable if baryon number is conserved.

One of the remarkable predictions of grand unified theories (GUTs) is the non-conservation of baryon number. The standard model interactions are mediated by particles called gauge bosons. There are 12 standard model gauge bosons: the photon, mediating electromagnetic interactions; the $W^{\pm}$ and Z^0, mediating the weak nuclear force, and eight gluons, mediating the strong nuclear force. GUTs not only place these 12 particles in a common multiplet, but predict the existence of additional gauge bosons and hence new interactions. The gauge sector of the smallest grand unified theory has 24 gauge bosons. The 12 new particles (three 'colors' of Xs and their antiparticles $\bar{X}$, and three 'colors' of Ys and their antiparticles $\bar{Y}$) mediate interactions between quarks and the class of particle which include the electron and neutrino called leptons. For example, an X gauge boson can take two quarks and turn them into an anti-quark and a positron (the antiparticle of the electron). In doing so, the X takes an initial state of baryon number +2/3, and converts it to a final state with baryon number $-1/3$, thus violating baryon number by one unit. In fact this process would allow the proton to decay into a positron and a pion.

Life, the universe and everything as we know it depend on the relative stability of the proton. Stars, planets and people could not exist if the proton lifetime were too short. The neutron lifetime or half-life, determined by the weak nuclear force and the mass of the $W^{\pm}$ gauge boson which is about 80 GeV (or about 80 times the mass of the proton), is just over 10 minutes. That means that a collection of free neutrons would be reduced by half after about 10 minutes. After 20 minutes, only 1/4 would remain, and so on. The lifetime of the decaying particle scales as $1/M^4$, where M is the mass of the gauge boson mediating the interaction.

The mass of the new GUT gauge bosons is determined by the unification energy scale, which in turn is determined by the point where the three standard model coupling constants meet after an energy-dependent renormalization. These constants determine the strength of the interactions. For example, the electromagnetic coupling constant, e, fixes the quantity known as the fine-structure constant $\alpha = e^2/4\pi$. The value of these constants must be adjusted at high energies according to the predictions of quantum field theory and as verified with high precision by experiment. At a very high energy scale, the constants take the same (unified) value. Though the exact energy scale is not known, it is typically about 10^{15-16} GeV. The masses of the X and Y gauge bosons are similarly large. The lifetime of the proton then scales as M_X^{-4} and is at least 10^{32} years. This extremely long lifetime should be compared with the current age of the universe of about 1.4×10^{10} years. Thus, although protons are allowed to decay, they do so very rarely. The search for proton decay has been under investigation since the late 1970s. To date, no decays have been observed.

Grand unified theories have had a profound impact on cosmology and were in part responsible for the development of particle astrophysics. GUTs provided the missing ingredients to the long-standing problem of a matter-antimatter asymmetry in the universe.

All particles exist as particle-antiparticle pairs (though a few particles like the photon and Z^0 are their own antiparticles). Antiparticles are produced either in high-energy accelerator experiments or naturally, when high-energy cosmic rays collide with nuclei in the Earth's atmosphere. However, apart from the secondary production of antimatter, there is no evidence of antimatter elsewhere in the universe. We know that the Earth and the solar system are composed solely of matter. If cosmic rays are of Galactic origin (as is widely accepted), then the lack of evidence of primary (not produced in a collision) antimatter in cosmic rays indicates that the Galaxy as a whole is also composed of matter. If nearby galaxies were composed of antimatter, the radiation produced by the annihilations of gaseous matter and antimatter along the boundary of these regions would be easily detected.

The question posed for cosmology and particle astrophysics is two-fold: (a) Why is there an apparent asymmetry between matter and antimatter in the universe? (b) Why is the asymmetry, commonly referred to as the baryon asymmetry (due to the asymmetry of neutrons and protons, though it is expected that there is a similar asymmetry in leptons - or electrons and neutrinos), small compared with the number density of photons in the universe? In fact, it is common to define a parameter measuring the baryon asymmetry

$$\eta = \frac{n_B - n_{\bar{B}}}{n_\gamma} \approx \frac{n_B}{n_\gamma} \approx (2-5) \times 10^{-10}. \qquad (5)$$

This quantity is estimated by comparing the observed density of matter, as determined for example by the visual and x-ray-output of galaxies and clusters of galaxies, with the density of photons determined by the measured temperature of the microwave background. This ratio can also be fixed by the observed abundances of the light elements, as η is the one free parameter of BBN theory.

In 1967, Sakharov derived three essential ingredients to solve at least the first problem. Namely the necessary conditions to generate an asymmetry of matter over antimatter. They are: (a) baryon number violating interactions; (b) a violation of two other symmetries of nature called C and CP - for charge symmetry and a combination of charge and parity; (c) a departure from thermal equilibrium. The necessity for the first condition is rather obvious. Without baryon number violating interactions, it would not be possible to change the total baryon number of the universe. As described above, grand unified theories provide baryon number violating interactions automatically. The second condition is more subtle. C, P and T (for time reversal invariance) are three fundamental symmetries of nature. In fact, all of particle theory is built on the exact conservation of the full combination of CPT (that is when all three operations are performed (charge conjugation, parity or $x \rightarrow -x$ and time reversal or $t \rightarrow -t$) simultaneously). However, individually they are known to be violated in certain interactions. Parity violation is explicitly demonstrated by the weak interactions, and was first observed in the decay of ^{60}Co in 1957. CP violation was observed in the decay properties of K^0 and $\bar{K}^0$ mesons in 1964. GUTs also contain CP violation, although the simplest GUT does not contain enough to produce the observed asymmetry of matter. Thus cosmology again places strong constraints on the building of particle theories. The violation of C and CP is necessary in order for the reactions to preferentially produce baryons rather than anti-baryons. Without this violation, any baryon number produced by a baryon number violating interaction would be exactly canceled by the corresponding reaction (under the charge symmetry), producing a net negative baryon number. Finally, the departure from thermal equilibrium is necessary so that reverse processes to those which produce a net baryon number are not operative. If they were, they would simply erase any baryon number produced. The departure from thermal equilibrium is a common feature of a rapidly expanding universe. If the expansion rate of the universe is fast compared with a specific interaction rate, that process will not be in equilibrium. In the late 1970s and early 1980s, it was shown that GUTs and standard big bang cosmology have all that it takes to explain the existence of the matter-antimatter asymmetry. The precise value of η has become a (GUT) model-dependent question. Although there are now many specific mechanisms proposed to produce the asymmetry, the exact mechanism is still an open question in particle astrophysics.

Along with the cosmological success of grand unification, a serious problem was discovered. Since a grand unified symmetry is not realized in nature today (or else we would find massless X and Y gauge bosons), it must be broken. In the process of breaking such a (grand) symmetry, it was discovered that new very massive particles called magnetic monopoles must exist. These particles, as their name implies, carry a single unit of magnetic charge much like the electron carrying a unit of electric charge. This would, in effect, appear like a magnet with only a north or south pole, but not both. Needless to say, such a particle has never been found.

In a cosmological context, grand unified theories predict the abundance of magnetic monopoles and their masses. Therefore, it is possible to compute their contribution to the energy density today. The masses of the monopoles are superheavy, of order M_X. Because the existence of monopoles is associated with the breakdown of the grand unified symmetry, their abundance is determined by the correlation length of the symmetry during the phase transition during which the symmetry is lost. The longer the correlation length, the fewer the monopoles produced. The maximum correlation length possible is determined by cosmology, and is related to the size of the observable universe at the time of the phase transition. This size is in turn determined by the age of the universe and is set by the maximum distance light can travel in that time. This distance is called the cosmological (or particle) horizon, and corresponds to the maximum distance over which information can be communicated. Therefore, this distance $d_{\rm H}$ is proportional to $t_{\rm U}$, the age of the universe. Since it is expected that the grand unified symmetry is broken at a temperature scale related to M_X, and since in the early universe $t_{\rm U} \propto T^{-2}$, the size of the horizon is very small and many massive monopoles are produced. The monopole problem, as it is referred to, is the expectation that the universe is dominated by monopoles today. In fact, the naive calculation predicts that the ratio of monopoles to baryons is about $\mathcal{O}(1)$. That is, as many monopoles as protons! This is clearly not the case.

There are several other problems which occur in the standard big bang model. Although the cosmological density parameter, Ω, is uncertain, it is known that its value is close to 1. As the universe evolves, this parameter also evolves, from an initial value extremely close to 1 (in the limit that $t_{\rm U} \rightarrow 0$, $\Omega \rightarrow 1$) to values much larger than 1 if the universe is closed, and to values much smaller than 1 if the universe is open. Since the evolution of the universe is basically a gravitational phenomenon, one might expect that Ω evolves on a typical gravitational time-scale which is set by Newton's constant $G_{\rm N}$. The natural time-scale, called the Planck time, is

$$t_{\rm P} = (G_{\rm N}\hbar/c^5)^{1/2} \approx 10^{-44}\ {\rm s}.$$

However, Ω has remained near 1 for over 10^{10} years or 10^{17} s, thus outlasting its welcome by over 61 orders of magnitude.

Another problem with the standard cosmological model is related to the near perfect isotropy of the COSMIC

MICROWAVE BACKGROUND. The temperature of the microwave background was extremely accurately measured to be 2.728 K by the COBE satellite. Furthermore, it is measured to have the same temperature in all directions to an accuracy of better than 100 parts per million. In the standard cosmological model, there is no explanation for the isotropy of the background radiation. The detected background photons were last scattered when the background temperature was a few thousand degrees and the age of the universe was about 10^5 years. The horizon size at that time was considerably smaller than it is today. (Our horizon today comprises about 10^5 horizons corresponding to the time of last scattering.) Since there is no information communicated from one horizon to another, there is no intrinsic reason why different horizons would have the same temperatures at the time of last scattering. If horizons at last scattering did have different temperatures, it would be reflected as a large anisotropy in the microwave background today, as it is measured in different directions.

A solution to this problem is known as the inflationary universe. Originally formulated as a period of rapid (exponential) expansion in the very early universe, inflation was thought to have been produced during the grand unified phase transition. That is, while the large symmetry of GUTs was being broken, the universe was dominated by the (false) vacuum energy density of the the GUT, rather than by radiation. The result of the expansion and the subsequent rethermalization of the universe was a resolution of the cosmological problems discussed above. If monopoles are not reproduced at the end of inflation (if the GUT is not restored), the density of monopoles is diluted to the extent that we only expect about one magnetic monopole in the entire visible universe! The dramatic expansion of the universe has flattened the universe to such an extent that we would predict that Ω is in fact indistinguishable from 1 today. Then, so long as the universe can live long enough to enter an inflationary stage, it is perfectly natural that it would last far beyond the gravitational lifetime discussed above. Finally, since the size of our horizon was dramatically inflated, our entire visible universe and more originated from a small and causal region of the universe. In this case, one expects the isotropy of the background radiation (up to perturbations caused by quantum fluctuations during inflation). Although it is now recognized that standard GUTs cannot be responsible for inflation, there are many alternative models. The development of these models has been another main focus of particle astrophysics since the early 1980s.

Particle Physics and Astronomy Research Council

PPARC is the agency through which UK taxpayers' money flows to fund astronomy (as well as particle physics). PPARC supports the EUROPEAN SPACE AGENCY as well as the telescopes with UK involvement such as the 8 m Gemini Telescopes, UK Infra Red Telescope (UKIRT), James Clerk Maxwell Telescope (JCMT), William Herschel Telescope (WHT) and the Anglo-Australian Telescope (AAT) along with Jodrell Bank and the Joint Institute for VBLI in Europe (JIVE). The Astronomy Technology Centre in Edinburgh is a PPARC establishment and provides the technology backbone for instruments for the telescopes.

PPARC, based in Swindon, runs the peer review and allocation system for the financing of astronomy research particularly by making grants to UK universities and argues the case for funding to the Office of Science and Technology and the Science Minister. Its budget for astronomy is approaching £100M p.a.

Pauli Exclusion Principle

A principle of quantum theory, devised in 1925 by Wolfgang Pauli (1900–58), which states that no two fermions may exist in the same quantum state. The quantum state of a particle is defined by a set of numbers that describe quantities such as energy, angular momentum and spin. Fermions are particles such as quarks, protons, neutrons and electrons, that have spin $= \frac{1}{2}$ (in units of $h/2\pi$, where h is the Planck constant). The principle implies, for example, that no two electrons in a given atom can have identical quantum values of energy, angular momentum and spin. It thereby restricts the number of electrons that can exist in the various electron shells that surround the nucleus of an atom and hence determines the electronic structure and chemical properties of atoms of different chemical elements. For example, two electrons can exist in the ground state (lowest energy level) of a helium atom only if they have opposite values of spin. The permitted permutations of quantum numbers allow a maximum of two electrons to exist in the innermost shell, eight in the second, and so on.

The principle also applies to the protons and neutrons in an atomic nucleus and to the quarks that make up protons, neutrons and other kinds of hadrons. When applied to free electrons, the principle implies essentially that no two electrons can have the same position and momentum. This limits the extent to which electrons can be squeezed together and gives rise to a pressure, called electron-degeneracy pressure, which prevents further contraction of compact stars such as white dwarfs. A similar argument applies to the close-packed neutrons inside neutron stars.

Pavo

(the Peacock; abbrev. Pav, gen. Pavonis; area 378 sq. deg.) A southern constellation which lies between Telescopium and Octans, and culminates at midnight in mid-July. It was first shown on Petrus Plancius' celestial globe of *c*. 1598, though it is usually attributed to the Dutch navigators Pieter Dirkszoon Keyser (also known as Petrus Theodorus) and Frederick de Houtman, who charted that part of the southern sky in 1595–7.

A small, rather inconspicuous constellation, the brightest stars in Pavo are α Pavonis (Peacock), magnitude 1.9, and β Pavonis, magnitude 3.4. There are four other stars of magnitude 4.0 or brighter. Interesting objects include κ Pavonis, a Cepheid variable (range 3.9–4.8, period 9.09 days), NGC 6752, a fifth-magnitude globular cluster, and NGC 6744, an eighth-magnitude spiral galaxy.

Payne-Gaposchkin, Cecilia Helena [née Payne] (1900–79)

Astronomer, born in England, married Sergei Gaposchkin, first woman to become a full professor at Harvard. Worked on stellar atmospheres, and in her 1925 dissertation suggested correctly that the great range in strength, from star to star, of absorption lines in stellar spectra was due to differing amounts of ionization (differing temperatures), not differing chemical composition. She suggested that hydrogen was the most abundant element in stars. This conclusion was at first resisted but accepted by 1929, in particular by HENRY RUSSELL.

Peculiar Galaxies

A peculiar galaxy is an object that cannot be easily classified as a SPIRAL, ELLIPTICAL, or IRREGULAR GALAXY based on its optical morphology. They constitute between 5% and 10% of the known galaxy population, although most 'normal' galaxies will show peculiar features if examined carefully. Peculiar galaxies show a great diversity of form. The vast majority can be attributed to strong gravitational tides generated in the close passage of two galaxies, to the extent that the terms 'peculiar galaxy' and 'interacting galaxy' are now virtually synonymous. These objects provided the first clear evidence that a galaxy's environment can profoundly affect its evolution (see GALAXY EVOLUTION).

Many peculiar galaxies are experiencing episodes of enhanced star formation, called starbursts. They also show a greater tendency to host ACTIVE GALACTIC NUCLEI (AGN) compared with the normal galaxy population. Conversely, when one examines the most luminous objects in the universe—quasars, radio galaxies and infrared galaxies—one often finds peculiar morphologies, suggesting a direct link between interactions and extreme levels of emission. Tidally induced mergers of separate galaxies almost certainly account for a substantial fraction of the local elliptical population. This process has probably played a key role in GALAXY FORMATION.

Peculiar galaxies can be used to deduce the structure of normal galaxies and in a few cases probe large-scale mass distributions. Observational and numerical studies of these objects offer important insights into phenomena that have shaped the formation and evolution of galaxies.

Galaxies that will not fit

EDWIN HUBBLE introduced his 'tuning fork' classification scheme in 1929, in which galaxies were grouped into spiral, elliptical and irregular families based on their appearance in photographic plates. However, even at this early stage a small number of galaxies defied these broad categories. Deep exposures of NGC 4038/39 (aka 'the Antennae') and NGC 5216/18 revealed long and faint filaments of light (see figure 1). Equally perplexing was the elliptical galaxy Messier 87 (M87, figure 1), which showed a remarkable blue linear 'jet' emanating from its core. As intriguing as these objects were, they seemed to be rare exceptions and attracted little attention. Their apparent scarcity was due to difficulties in recording extended and low-surface-brightness emission with the telescopes and photographic plates then in use. This situation changed dramatically with the advent of wide-field Schmidt cameras. On completion of the National Geographic–Palomar Sky Survey in 1956, the number of peculiar galaxies grew from a mere handful to many thousands—roughly 10% of the galaxies visible in the Sky Survey plates. This new population displayed a bewildering array of morphologies: luminous bridges and tails, often extending many galaxy diameters, ellipticals with faint ripples or dust lanes, ring-shaped galaxies, even systems that appeared to be dissolving. Figure 1 shows several examples taken from the Digitized Sky Survey and gives some idea of their varied (and beautiful) forms. Many of these were included in the photographic atlases of peculiar galaxies by Vorontsov–Vel'yaminov (1956) and Arp (1963), which are still widely used reference works.

To the early investigators, these striking objects suggested gigantic explosions, galaxies in birth, galaxies in fragmentation, material ejections from nuclei, galaxies compelled by strong magnetic forces—or entirely new forces, even the creation of matter. However, the earliest explanation has proven to be the most successful, namely *peculiar galaxies are the result of strong gravitational tides generated by near collisions of ordinary galaxies.* This was originally suggested by the fact that peculiar galaxies are usually found in close pairs, and often with symmetrically placed features. This collisional interpretation had been rejected initially because galaxy encounters were thought to be exceedingly rare and because tides were considered incapable of creating long and narrow plumes like those seen in 'the Antennae'. However, it was eventually realized that galaxies exist in groups, sometimes separated by only a few disk diameters. Galaxies should therefore experience several close passages over their lifetimes (see GALAXIES: INTERACTIONS AND MERGERS). It was Alar and Juri Toomre's landmark 1972 paper that conclusively showed how gravitational tides could produce systems like the 'the Antennae' through a near collision of two spirals. A wide range of peculiar morphologies could in fact result depending on the relative masses, inclinations, orbital speed and collision geometry of the two galaxies. Gravitational tides vary with distance like R^{-3}, so they are most significant over a brief interval near closest approach. It is here that large-scale peculiarities such as plumes and bridges are abruptly 'launched' into their trajectories. The Toomres also extended the work of Holmberg by suggesting that sufficient orbital angular momentum could be lost in an encounter for two galaxies to coalesce, producing something resembling an elliptical galaxy. Simple statistical considerations implied that most ellipticals in the NGC catalog could have arisen this way. The idea that galaxies were isolated island universes had been dramatically overthrown.

Peculiar galaxies have been studied extensively over the past 30 yr, both observationally and theoretically. During this period the tidal interpretation has proven to be so successful that the terms 'peculiar galaxy' and 'interacting galaxy' are often used interchangeably.

Peculiar galaxy morphologies

There is a great diversity of form among peculiar galaxies, as even a quick examination of the Vorontsov–Vel'yaminov or Arp atlases will show. Even so, a number of clear categories can be recognized:

Interacting spirals with tails and/or bridges

'Antennae'-like systems result from close passages of similarly massive spirals. Bridges (e.g. NGC 2535/36)

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

require lower-mass companions to prevent quick capture and are thus less common. Both may extend 100–200 kpc from the host galaxies. Bridges and plumes originate in the outer disks, and are therefore often blue in color and gas rich. Some contain dwarf-galaxy-sized condensations of stars and gas that appear to be gravitationally bound.

Interacting spiral–elliptical pairs
Because their internal motions are not dominated by rotation, interacting ellipticals produce diffuse sprays of stars rather than tails and bridges. In spiral–elliptical encounters, therefore, a single tail or bridge is seen, and the spiral typically displays the most visible damage (e.g. NGC 274/5).

Shell galaxies
Roughly 40% of ellipticals show faint interleaved shells or ripples in their outer regions (e.g. Arp 230). These may be the result of weak tidal interactions or the cannibalization of another galaxy. The peculiar elliptical Centaurus A, for example, has both shells and a dust lane, suggesting the consumption of a gas-rich spiral.

Galaxies with optical jets
Remarkably linear filaments are sometimes found near peculiar spirals. Most are tidal tails and bridges that only appear linear owing to edge-brightening and projection effects (e.g. NGC 4676). The much rarer optical synchrotron jets are manifestations of AGN. M87 and 3C 273 are the best known examples.

cD and 'dumb-bell' galaxies
The centers of rich galaxy clusters are often occupied by giant ellipticals called cD galaxies. These frequently possess multiple nuclei, most likely from the cannibalization of another cluster galaxy. An extreme form of this class are 'dumb-bell' galaxies, which are binary ellipticals embedded in a common stellar envelope (e.g. NGC 750). These are expected to coalesce after a few orbits (i.e. $\sim 5 \times 10^8$ yr).

Merger remnants
Both the Vorontsov–Vel'yaminov and Arp atlases include objects now believed to represent the late stages in the merger of two galaxies (e.g. Arp 220). At this point they are roughly elliptical in appearance, although their vestigial tidal tails, large gas masses and double nuclei—generally visible only at radio and infrared wavelengths—betray their true origin.

Polar-ring galaxies
Roughly 0.5% of known S0 galaxies possess rings orbiting a plane perpendicular to the disk. NGC 4650A (figure 2) is the prototype polar-ring galaxy. The rings are often rich in gas and young stars and are believed to represent material captured during an interaction that has settled in semistable polar orbits. Spiral–spiral mergers, in which one is transformed into an S0, have also been proposed as a formation mechanism.

Ring galaxies
Ring galaxies such as the Cartwheel (figure 2) are created by the passage of a companion through a spiral's disk near the nucleus. This interaction crowds the disk's orbits into a large ring ($D_{ring} \sim$ 10–35 kpc) that propagates outward at speeds of ~50–100 km s^{-1}. Observations show that ~90% of the spiral's gas supply is concentrated in the ring, along with essentially all star formation activity.

The expected lifetimes of these peculiarities vary greatly. The multiple nuclei of cD and dumb-bell galaxies evolve in a deep and rapidly changing gravitational potential, and so are believed to be very transient, perhaps needing less than $\sim 10^8$ yr to merge. Tidal tails, bridges and sprays experience a much shallower potential, and should persist much longer, perhaps several billion years.

Most spirals show slightly distorted arms or minor asymmetries in their disks. These can be attributed to weak interactions with companions. Many otherwise 'normal' galaxies show peculiar morphologies at low light levels. Particularly dramatic examples have been discovered by David Malin using special techniques (see DETECTORS: PHOTOGRAPHY) to explore emission as faint as 0.5% of the night-sky glow (see figure 3). These structures may represent long-lived remnants of ancient interactions. There is in fact a wide range of morphological oddities among the general galaxy population. What we have been calling peculiar galaxies throughout this article actually represent the extreme end of a continuum.

Star formation in peculiar galaxies

It had been long noted that peculiar galaxies tended to be very blue in color, and often with unusually luminous star-forming complexes. Analysis of the UV excess Byurakan Survey galaxies, for example, showed that 40% possessed double nuclei or obvious tidal features. By the 1970s sufficient observational data had accumulated to examine possible links between unusual morphologies and enhanced STAR FORMATION activity. The most influential of these early investigations was that of Larson and Tinsley (1978), who compared the optical UBV colors of a normal galaxy sample taken from the Hubble atlas with peculiar galaxies from the Arp atlas. Figure 4, taken from that paper, shows that the Arp atlas galaxies are on average significantly bluer than the normal galaxy sample (i.e. smaller U-B for a given B-V) with a much wider spread of values. This could be simply understood if the peculiar galaxy sample had recently experienced brief episodes (~10^7–10^8 yr duration) of elevated star formation activity called a starburst. The large color dispersion primarily reflects differences in the starburst's age and strength, and/or dust obscuration. Research over the last two decades has established a clear connection between peculiar morphology and the occurrence of starburst activity. Theoretical studies show that tidal interactions can be very effective in triggering starbursts by driving strong spiral or ring density waves or by transporting gas to the inner nucleus. Observations show that star

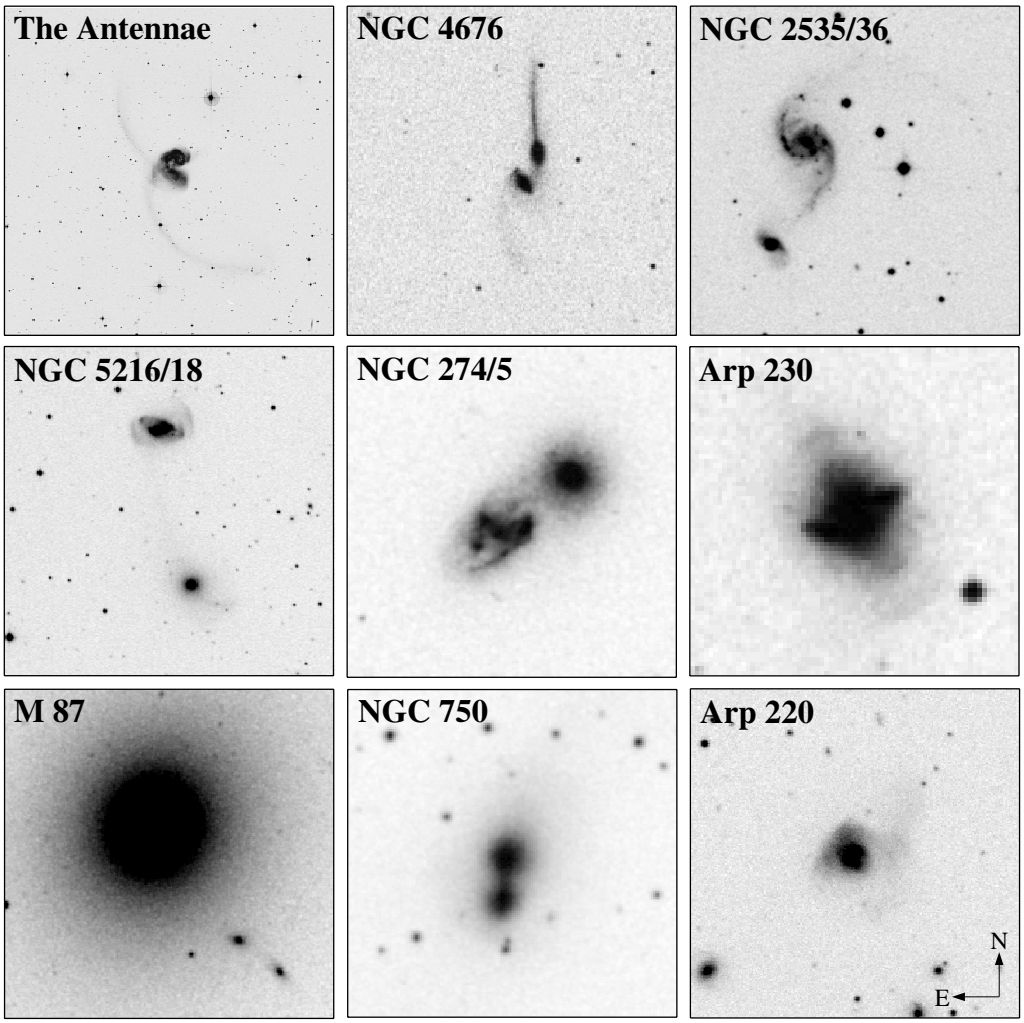

Figure 1. A montage of peculiar galaxies reproduced from the Digitized Sky Survey. They are presented in negative to make faint emission easier to see.

formation is increased only by modest factors of 2–3 over normal galaxies when averaged over the entire peculiar galaxy population. However, there is a wide range in star formation enhancement among individual peculiar galaxies, from essentially zero to several orders of magnitude. The induced star formation may be global in extent (e.g. the Cartwheel's ring). However, the most intense starbursts occur within the galaxy's inner kiloparsec. These nuclear starbursts tend to be found in the most strongly interacting systems. Excellent examples are the luminous infrared galaxies (LIRGs, e.g. Arp 220). LIRGs emit most of their total luminosity at infrared wavelengths ($\lambda > 5\,\mu$m), in at least half of the cases owing to dust heated by young massive stars. Astonishing star formation rates (SFR$\sim(10^2$–$10^3)M_\odot$ yr^{-1}) and gas masses ($M_{gas} \sim (10^{10}$–$10^{11})M_\odot$, i.e. a substantial fraction of the *total* gas mass) characterize their inner nuclear regions. LIRGs show a strong tendency to possess unusual optical morphologies. In the most luminous examples, essentially all are peculiar.

It should be emphasized that not all STARBURST GALAXIES appear highly peculiar. Also, not all peculiar galaxies are experiencing starbursts. This may reflect time delays between interaction and peak star formation, weak and quickly damped tidal perturbations, details of the collision or a lack of sufficient gas to fuel a starburst in the first place. Nevertheless, the frequency of starburst activity is much higher in peculiar galaxies. And, as the intensity of the starburst increases, so does the likelihood that the galaxy will possess a highly disturbed optical morphology.

Peculiar galaxies and active galactic nuclei

The first securely identified optical counterparts of powerful extragalactic radio sources (Cygnus A and Centaurus A) were strikingly peculiar. This fact suggested a direct connection between galaxy collisions and radio emission. However, subsequent observations found luminous radio emission to be far more likely to be

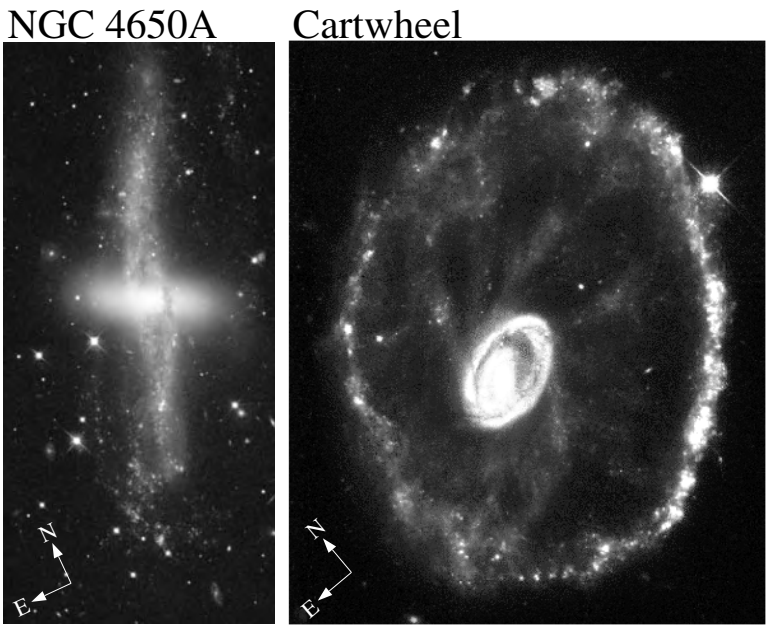

Figure 2. Two examples of peculiar rings: NGC 4650A (polar-ring galaxy) and the Cartwheel (ring galaxy). Both images were taken with the Hubble Space Telescope.

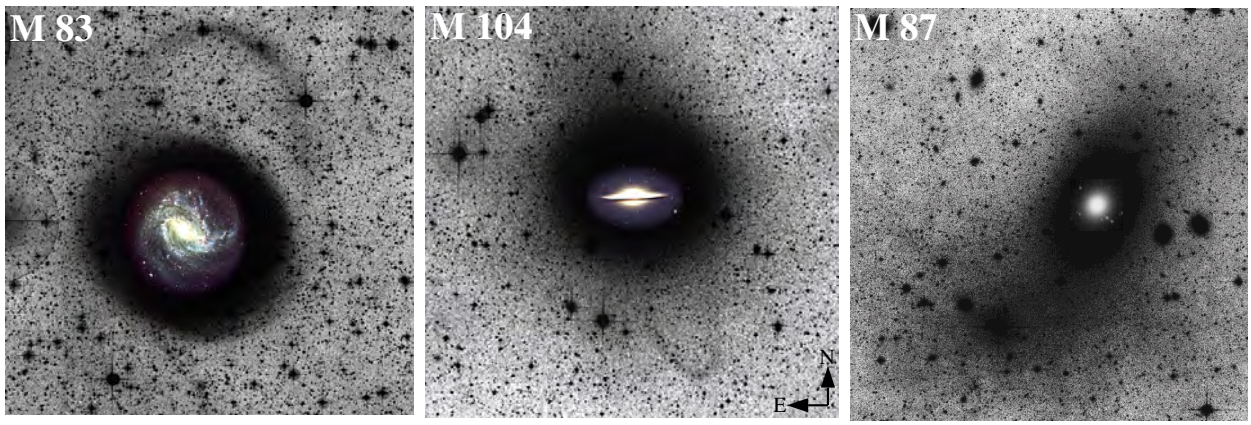

Figure 3. Enhanced photographs of nearby 'normal' galaxies by David Malin. The spiral galaxies M83 and M104 both show faint loops of starlight, while the elliptical galaxy M87 is embedded in an asymmetric spray of stars. More typical exposures have been inserted into the over-exposed centers to give an idea of their relative scales.

associated with the nuclei of rather ordinary looking ellipticals. The issue was reopened in the 1970s with the discovery that nuclear starbursts were common in peculiar galaxies. Theoretical results also suggested that interactions could efficiently transport gas to small radii and fuel an AGN's central engine. Recent surveys show that while the majority of galaxies with AGN in the local universe do not appear obviously peculiar, there is an increased tendency for peculiar galaxies to possess active nuclei. For example, Seyfert nuclei—the most common local type of AGN—occur more frequently in peculiar spirals than in normal spirals. The significance of this association increases with the degree of the morphological distortion. Further, one-third to one-half of the most powerful LIRGs appear to harbor heavily obscured AGN. These objects are invariably peculiar at optical wavelengths. In addition, ground-based imaging of low-redshift QUASARS shows that a significant fraction possess large-scale distortions, multiple nuclei or at least an excess of nearby peculiar companions. HST observations confirm that many quasars are morphologically peculiar. For example, of the 20 $z < 0.3$ quasars studied by Bahcall and collaborators (figure 5), more than a third are clearly interacting tidally, with half of the remainder showing faint extended structures resembling those of local merger remnants.

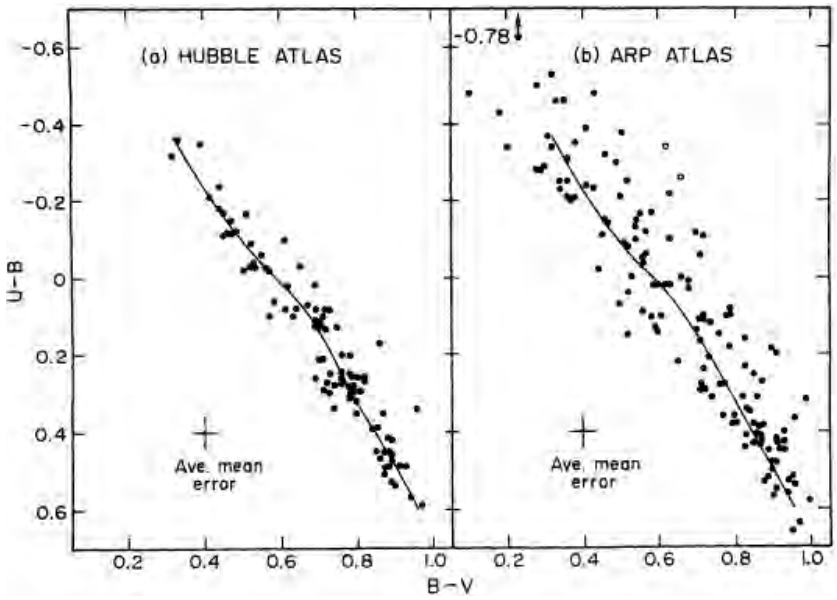

Figure 4. The UBV two-color distributions of normal (Hubble atlas) and peculiar (Arp atlas) galaxies reproduced from Larson and Tinsley (1978). The solid curve represents the mean through the Hubble atlas sample. Typical uncertainties in the colors are shown in each panel.

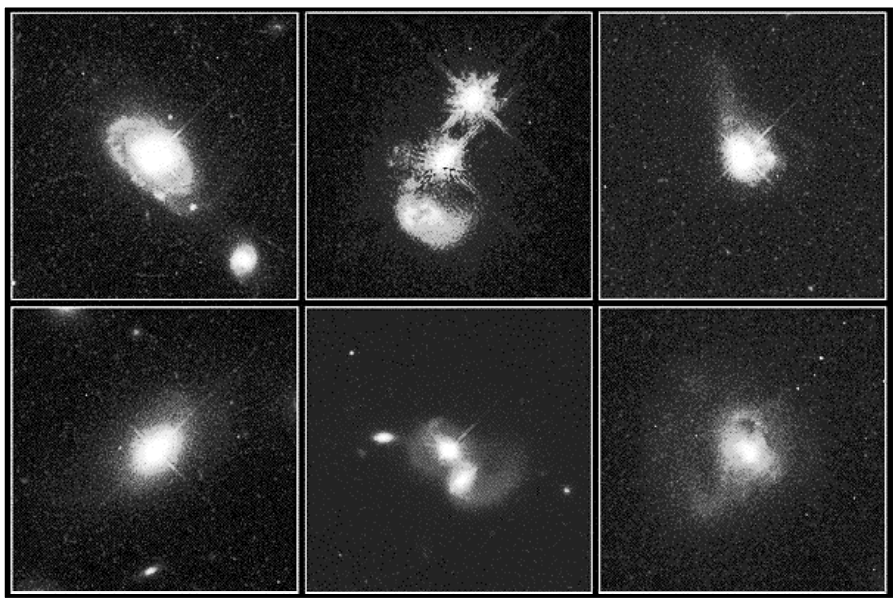

Figure 5. Optical images of low-redshift ($z < 0.3$) quasars taken with HST (Bahcall and collaborators, 1997). Note the close companions and/or obvious tidal features.

Again, most galaxies with AGN are not noticeably peculiar, and most peculiar galaxies do not possess AGN. Nevertheless, there is at least indirect evidence for a connection between galaxy interactions and at least some forms of powerful AGN.

Concluding remarks

The vast majority of peculiar galaxies represent highly perturbed ordinary galaxies. Observational and numerical studies of these systems can therefore provide insights into galactic structure. The kinematics of polar rings and tidal tails, for example, can be used to probe dark halos on scales much larger than ordinary optical or gas disks. Detailed computer simulations of interacting systems not only help

Dirac House, Temple Back, Bristol, BS1 6BE, UK

refine the input galaxy models, they also allow one to better understand how galaxies might evolve in more complex environments such as compact groups or rich clusters. Further, several lines of evidence suggest that galaxies are assembled through the coalescense of dwarf galaxy sized components at high redshift, and there is evidence that at least some nearby ellipticals have arisen through mergers. The ongoing mergers and merger remnants in the peculiar galaxy population can thus serve as templates for the study of galaxy formation and evolution. Finally, the energy released by starbursts and AGN can have a major impact on the energy balance in a galaxy's interstellar medium. Likewise, studies of peculiar galaxies such as Arp 220 show that starbursts can also supply substantial amounts of heavy elements. Both processes appear to have been much more common at higher redshifts. These few examples show that peculiar galaxies are important for what they can tell us about the structure and evolution of galaxies and for providing local examples of processes that have shaped the chemical and luminosity evolution of the universe.

Bibliography

The peculiar galaxy literature is vast. Fortunately, there are a number of excellent reviews with extensive references, e.g.

Kennicutt R, Schweizer F and Barnes J 1996 *Galaxies: Interactions and Induced Star Formation (Saas-Fee Advanced Course 26, Lecture Notes 1996)* (Swiss Society for Astrophysics and Astronomy)

One would also benefit by reading such classic papers as

Holmberg E 1941 *Astrophys. J.* **94** 385
Larson R and Tinsley B 1978 *Astrophys. J.* **219** 46

and of course

Toomre A and Toomre J 1972 *Astrophys. J.* **178** 623

Perhaps the best introduction to this subject is simply to browse through the Vorontsov–Vel'yaminov and Arp atlases. Electronic versions exist on the web (both atlases can be found at nedwww.ipac.caltech.edu/level5/pi-galaxies.html), although the quality of Arp's atlas is such that one should try to locate a large format copy in a university science library.

Pegasus

(the Winged Horse; abbrev. Peg, gen. Pegasi; area 1121 sq. deg.) A northern constellation that extends from Cygnus, Lacerta and Andromeda almost to the celestial equator, and culminates at midnight in early September. It is named after the winged horse in Greek mythology that sprang from the body of Medusa, the Gorgon, when she was beheaded by Perseus, and later was tamed by the hero Bellerophon. Its brightest stars were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*.

A large constellation, Pegasus is easily recognized by the asterism of the Square of Pegasus, formed by the stars β Pegasi (Scheat), α Pegasi (Markab), γ Pegasi (Algenib) and α Andromedae (Alpheratz). The last, which marks the north-east corner of the Square, was originally designated δ Pegasi. The brightest stars in Pegasus are ε Pegasi (Enif), magnitude 2.4, α Pegasi, magnitude 2.5, β Pegasi, a red giant irregular variable (range 2.3-2.7), γ Pegasi, a Beta Cephei variable (range 2.8–2.9, period 0.15 day), and η Pegasi (Matar), magnitude 2.9. There are five other stars of magnitude 5.0 or brighter. Other interesting objects include the W Ursae Majoris type variable star U Pegasi (range 9.2–10.1, period 0.37 day) and M15 (NGC 7078), a sixth-magnitude globular cluster.

Peiresc, Nicolas-Claude Fabri de (1580–1637)

Polymath and astronomer, born Belgentier, Var, France, widely educated in Europe. In 1610 his patron, du Vair, acquired a telescope with which Peiresc and Joseph Gaultier were the first in France to see the satellites of Jupiter. With assistants in various locations, he recorded the positions of the satellites of Jupiter and used these observations to calculate terrestrial longitudes. Organized an international campaign to observe the lunar eclipse of 28 August 1635, and was able to correct the considerably over-estimated length of the Mediterranean. Discovered the Orion nebula, M42, the first deep sky discovery with a telescope.

Pelican Nebula (IC 5070)

An emission nebula in the constellation Cygnus, position RA $20^{h}\,50.8^{m}$, dec. $+44^{\circ}\,21'$. It measures $80'$ by $70'$, but has a low surface brightness. Its eastern border, the 'pelican' profile, is delineated by dark nebulosity which separates it from the North America Nebula (NGC 7000).

Penston, Michael Victor (1943–90)

Astronomer, born in London, a 'lover of active galaxies' (a LAG), as he described himself, he witnessed the change of NGC 4151 from one type of active Seyfert galaxy to another and determined the mass of the black hole at its center. This went towards a proof of the unified theory of active galaxies by which it is hypothesized that the various types are fundamentally the same phenomena seen at different angles and in different circumstances, and set the way for the Hubble Space Telescope's more accurate determination of the mass of black holes in different active galaxies.

Penzias, Arno Allan (1933–)

Radioscientist, born in Munich in Germany, Nobel prizewinner (1978) 'for the discovery of cosmic microwave background radiation', a refugee from Germany at the age of 6, found his way to America and experience in microwave physics. Joined Bell Laboratories, Holmdel, New Jersey, searched for and investigated line emission from the interstellar OH molecule. Was able to gain the use of a large radio telescope (the Holmdel horn) and a new ultra low-noise 7 cm travelling wave maser available for radioastronomy. With ROBERT WILSON began a series of radioastronomical observations intended to make the best use of the careful calibration and extreme sensitivity of the system, including a measurement of the radiation intensity from the Galaxy at high latitudes. Discovered the cosmic microwave background radiation. Made a millimeter-wave receiver and discovered a number of interstellar molecular species, including deuterated hydrogen cyanide.

Periapsis

The point in an elliptical orbit at which the orbiting body is farthest from the body it is orbiting. The prefix 'peri-' may be attached to various words or roots depending on the body being orbited: for example, periastron for an orbit round a star; perijove for an orbit around Jupiter.

See also: perigee, perihelion.

Periastron

The closest point in the relative orbit of one component of a binary system to the other component. The term is also used for the closest position of a planet orbiting a star other than the Sun.

See also: binary system, perihelion.

Perihelion

The point in the elliptical orbit of a planet or other object around the Sun at which it is closest to the Sun. The Earth, for example, reaches perihelion in January, when it is about 147 million km from the Sun. This is the Earth's *perihelion distance*. The heliographic longitude of a body's perihelion point steadily moves around the Sun in the direction of the object's orbital motion as the major axis of the ellipse precesses. This *advance of perihelion* is largely a result of gravitational perturbations by the planets on one another, but there is a small component caused by the curvature of spacetime in the vicinity of the Sun. The latter factor is most pronounced for Mercury, and provided an early test for the general theory of relativity.

Compare: aphelion.

Perseids

The best-known meteor shower and one of the most prolific, occurring in late July and August. In medieval times the shower was known as the Tears of Saint Lawrence, who was martyred on 10 August 258, close to the time of maximum Perseid activity. The radiant begins in the constellation Cassiopeia and moves through northern Perseus. The high inclination (113°) of the parent comet, 109P/Swift–Tuttle, keeps the Perseid meteor stream largely free from planetary perturbations, and its activity has remained fairly constant for many centuries. Zenithal hourly rates rose during the 1980s and 1990s, either side of the parent comet's return in 1992.

Perseus

(abbrev. Per, gen. Persei; area 615 sq. deg.) A northern constellation which lies between Andromeda and Auriga, and culminates at midnight in early November. It is named after the hero in Greek mythology who beheaded the Gorgon Medusa and rescued Andromeda from being sacrificed to the sea monster Cetus. Its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A conspicuous constellation, the brightest stars in Perseus are α Persei (Mirfak or Algenib), magnitude 1.8, β Persei (Algol, the 'Demon Star'), the prototype eclipsing binary (range 2.1–3.4, period 2.86 days), ζ Persei, magnitude 2.8, and γ and ε Persei, both magnitude 2.9. There are 11 other stars of magnitude 4.0 or brighter.

The Milky Way passes through Perseus and the constellation contains a number of open star clusters, including the Double Cluster (NGC 869 and 884, or h and χ Persei), the two components of which are each about 45′ across, contain a few hundred stars, and are just visible to the unaided eye as a faint misty patch midway between γ Persei and δ Cassiopeiae, M34 (NGC 1039), which contains about 80 stars fainter than eighth magnitude, and Melotte 20, a loose assemblage surrounding α Persei. Other interesting objects include M76 (NGC 650-51), the Little Dumbbell Nebula, a tenth-magnitude planetary nebula, NGC 1023, a tenth-magnitude spiral galaxy, and NGC 1275 (Perseus A), a twelfth-magnitude elliptical galaxy that is the brightest member of the Perseus cluster of galaxies and a strong radio source.

The Perseid meteor shower appears to radiate from a point about 4° north of γ Persei.

PG 1159 Stars

The PG 1159 stars form a small group of about 30 objects. They are named after the prototype PG 1159-035 (=GW Vir), which was discovered in the Palomar-Green survey. They are hot post-asymptotic giant branch (post-AGB) stars and their location in the HR diagram coincides with the hottest central stars of PLANETARY NEBULAE (CSPN) and the hottest WHITE DWARFS (WD). The most peculiar characteristic is their chemical surface composition. They are hydrogen deficient and the most abundant elements are He, C and O with typical abundances of 33%, 50% and 17% respectively. This suggests that their immediate progenitors are CSPN with Wolf–Rayet type spectra, whose analyses yield similar abundance patterns. It is thought that most of the PG 1159 stars evolve into non-DA WDs, i.e. helium-rich objects from which the heavy elements were removed from the surface layer by gravitational settling. The origin of the PG 1159 surface chemistry is under debate. The most popular picture describes these stars as the result of a late He-shell flash, i.e. the re-ignition of helium fusion in a CSPN or even in a cooling, contracting WD. This event causes the star to return onto the AGB and to retrace its post-AGB evolution for a second time (born-again AGB star scenario). As a consequence, envelope convection causes ingestion and burning of surface hydrogen and, possibly in conjunction with mass loss, carbon and oxygen as helium burning products are mixed into surface layers.

The mere existence of PG 1159 stars represents a challenge to post-AGB STELLAR EVOLUTION theory. Details of the born-again scenario are being worked out, in order to prove or disprove it. An alternative scenario proposes that close binary evolution causes stripping of the envelope during the RED GIANT phase. Since some PG 1159 stars are associated with a planetary nebula, it is hoped that analyses of the planetary nebulae will give further hints as to the stellar history. Some PG 1159 stars are variable and these multi-periodic g-mode pulsators are defining the GW Vir (or DOV) instability strip in the HR diagram. The pulsational properties are used to probe the interior structure of these stars. Hence spectroscopic analyses with model atmospheres in combination with asteroseismology using pulsating stellar models help to constrain theoretical evolutionary calculations for PG 1159 stars.

The hydrogen-deficient post-AGB sequence [WC] → PG 1159

Hot post-AGB stars ($T_{\rm eff} > 20\,000$ K) can be grouped into either H-deficient or H-'normal' objects. The evolution of the latter group is in principle understood, so research focuses on the problems with H-deficient objects. Spectroscopic analyses have firmly established an evolutionary sequence formed by the Wolf–Rayet CSPN and the PG 1159 stars. This is suggested by their location in the g–$T_{\rm eff}$ plane (figure 1) as well as the similarity of their chemical abundance patterns. The Wolf–Rayet CSPN, dominated by He, C and O emission lines, are subdivided into late and early spectral types, [WCL] and [WCE] (brackets are used to discriminate these CSPN from the massive WOLF–RAYET stars). The link between the [WCE] and PG 1159 stars is marked by a few [WC]–PG 1159 transition objects which show a mixed emission/absorption line spectrum. The PG 1159 stars display essentially absorption line spectra. Their spectroscopic hallmark is a broad absorption trough formed by He II and C IV lines (figure 2). While [WC] stars have been known for a long time, the PG 1159 stars have been established as a spectral class more recently (Wesemael *et al* 1985). We know 31 PG 1159 stars and about every other one is a CSPN. Note that the so-called 'OVI' classification of CSPN is no longer used because objects having very different spectra were subsumed under it. All former 'OVI' stars are now [WCE] stars of different subclasses according to an appropriate classification scheme. An exception is the well known CSPN NGC 246, also a former 'OVI' object, which is now classified as PG 1159.

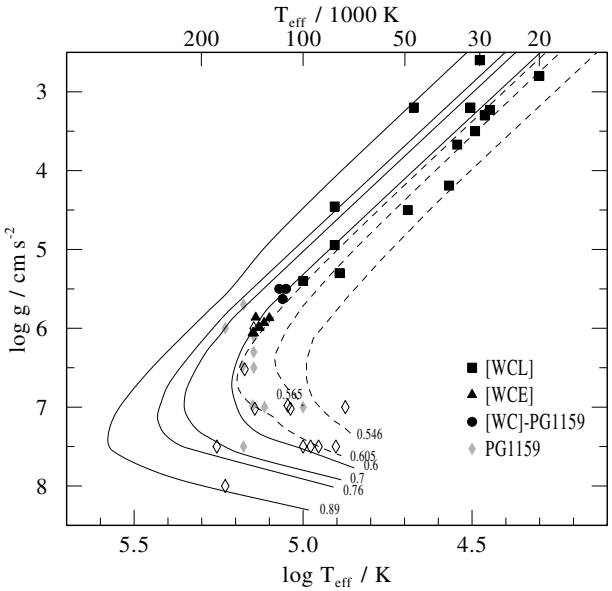

Figure 1. Hydrogen-deficient post-AGB stars in the effective temperature versus surface gravity plane. We identify Wolf–Rayet central stars of late and early spectral subtype ([WCE] and [WCL]), PG 1159 stars as well as [WC]–PG 1159 transition objects. Open symbols denote stars not associated with a planetary nebula. Evolutionary tracks (labels: mass in $M_{\odot}$) are only shown for a rough comparison, because they predict normal, H-rich surface abundances.

An overview of knowledge of PG 1159 stars with detailed references is found in Werner *et al* (1999). For detailed spectroscopic results on the [WC] stars we refer to a review by Hamann (1997).

Origin of H-deficient post-AGB stars

The typical chemical composition of PG 1159 atmospheres is displayed by the prototype PG 1159-035 itself. It was

Dirac House, Temple Back, Bristol, BS1 6BE, UK

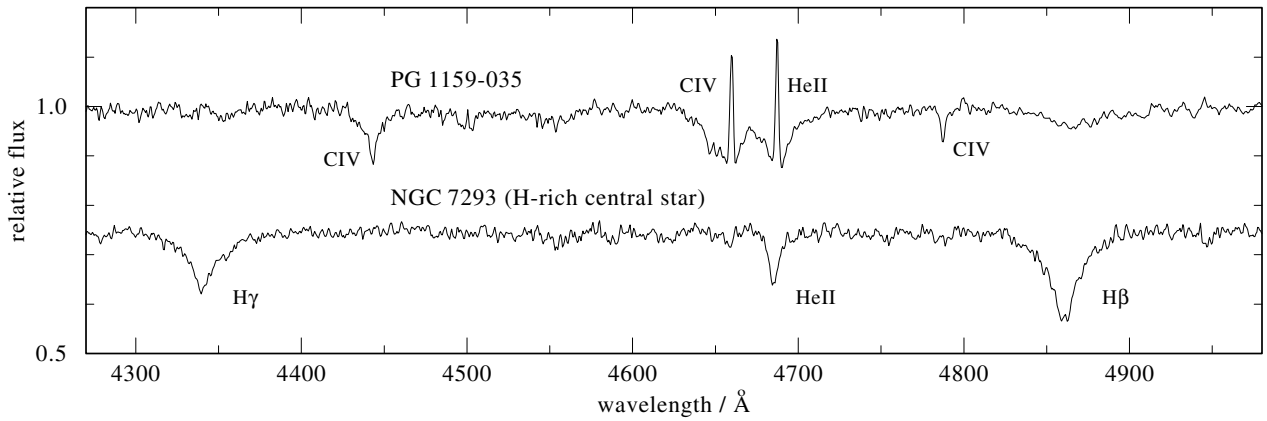

Figure 2. Optical spectrum of PG 1159-035 as compared to a central star with a usual hydrogen-rich composition. The characteristic PG 1159 spectrum lacks hydrogen lines and shows a prominent He II/C IV absorption line trough near 4670 Å, accompanied by central emission reversals in the line cores in the case of the prototype.

found to be He:C:O=33:50:17 (mass fractions) while hydrogen is not detectable. A comparison of this abundance pattern with the interior structure of post-AGB stellar models suggests that the PG 1159 stars must have lost their entire H-rich envelope ($\approx 10^{-4} M_{\odot}$) and also most of their He-rich intershell layer ($\approx 10^{-2} M_{\odot}$) because the high C and O abundances are found only at its bottom. With the first reliable non-LTE model atmosphere analyses of PG 1159 stars available it was suggested that the H deficiency is a consequence of a late He-shell flash. Originally, Iben (1984) introduced this scenario in order to explain the discovery of H-deficient zones in the inner parts of the PNe Abell 30 and Abell 78 (whose nuclei are today classified as [WC]–PG 1159 transition objects). In this scenario He-shell burning re-ignites when the post-AGB star is already on the WD cooling track. As a consequence, the star moves back to the AGB ('born-again' AGB star). The star suffers another superwind phase and during its second descent from the AGB the star loses its remaining hydrogen envelope by a fast wind. FG SAGITTAE and SAKURAI'S OBJECT (V 4334 Sgr) are thought to be such stars which are on their way back to the AGB (Asplund 1999).

There are several problems with this scenario, arising from several observational facts, which suggest that the H deficiency is not only formed during the second post-AGB evolution, but already during the second AGB phase. In spite of the rapid evolutionary rate, the existence of cool (i.e. young) [WC] stars requires the complete ejection of the H-rich envelope on the AGB. This is also corroborated by the fact that the ejection of H-deficient material in the planetary nebulae Abell 30 and Abell 78 occurs with low expansion velocities (<100 km s^{-1}), which means that the rather extended AGB precursor of the more compact CSPN must already have been H deficient.

The born-again scenario is faced with another problem, which is related to the expansion ages of the nebulae of [WC] stars. Their planetary nebulae should be systematically older than those of the CSPN with normal surface chemistry; however, this is not the case. This finding suggests that the H deficiency possibly occurs at the first departure from the AGB, i.e. without invoking the born-again scenario at all. What then is the origin of the H deficiency? One possibility is close binary evolution during which the stellar envelope could be stripped off by interaction with the companion star. However, for [WC] stars binarity is extremely difficult to detect directly from radial velocity or photometry. For PG 1159 stars the binary frequency does not appear to be unusually high. Bipolarity of planetary nebulae has frequently been invoked as a tracer of binarity. Here we face a puzzling fact: while the frequency of bipolar planetary nebulae around [WC] stars appears to be 'normal' (20%), the fraction of PG 1159 stars with a bipolar planetary nebula appears to be high (75%). The latter result, however, is limited by small-number statistics and inhomogeneous observational material.

A further problem represents the high photospheric oxygen abundance found in many PG 1159 and [WC] stars, which approaches almost 20% by mass. As already mentioned above, this means that not only must the hydrogen-rich envelope be removed from the star, but also the 100 times more massive helium envelope. This conflicts even more severely with the existence of the young [WCL] stars: removal of the He-rich intershell during the post-AGB evolution can be enforced in theoretical calculations by high mass-loss rates, but envelope removal is not completed until the star is very hot ($T_{\rm eff} > 100\,000$ K), because the main effect of mass loss is to increase the evolutionary rate. However, new evolution calculations show that this problem is probably much less severe. These calculations, which include a hydrodynamically based overshoot prescription, provide a very high oxygen abundance throughout the He-rich intershell, and not only at its bottom as suggested by earlier computations. Though the problem of envelope removal seems less serious now, it is still unsolved. In any case, we

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

have to face the exceptional case of H 1504+65, a PG 1159 star which is completely devoid of hydrogen and helium, i.e. its atmosphere is mainly composed of C and O by equal parts, with an admixture of neon (Werner and Wolff 1999). Obviously this naked C/O stellar core must have lost also its massive He-rich intershell.

Further evidence that the H deficiency is formed on the AGB or at least very early on the post-AGB track comes from the analysis of ISO spectroscopy of two [WCL] CSPN (BD+30°3639 and He 2-113.). C-rich dust (PAHs) in the inner part of the planetary nebula and crystalline (O-rich) silicates in the outer part suggest that the chemical composition of both stars changed to a C-rich mixture very recently, i.e. less than 1000 years ago. The H-rich nature of the C-rich dust suggests that some hydrogen was still left on the star, which is in accordance with the identification of hydrogen in the atmosphere of one of these CSPN (BD+30°3639).

The detection of residual hydrogen in some [WC] and PG 1159 stars as well as the detection of nitrogen in a few cases suggests that mixing and incomplete burning of the hydrogen envelope takes (or took) place in these stars. According to evolutionary calculations this can only occur after a very late He-shell flash (i.e. on the WD cooling track, where H-shell burning is extinct) and not on or soon after the AGB phase (where H-shell burning is still active). This is in clear contradiction with the planetary nebula observations of H-deficient gas and dust around the stars (see above).

To conclude, the true origin for H deficiency in post-AGB stars is not known. Further progress can be expected from evolutionary calculations which must include both overshoot as described above and time-dependent mixing.

Another H-deficient post-AGB sequence

A few hot H-deficient post-AGB stars cannot be classified as PG 1159 stars, because their absorption line spectra exhibit almost exclusively He lines and, if at all, only weak carbon or other metal lines. This small group of stars comprises four objects, two of which have an associated planetary nebula. These stars are classified as 'O(He)' and the prototype is the CSPN K1-27. Spectral analyses confirm that only trace amounts of metals are present in the helium-dominated atmospheres but, interestingly, two of them have a considerable fraction of hydrogen left (10% and 30%, by number). They are very hot ($T_{\rm eff}$ = 100 000–140 000 K) and have relatively low surface gravities ($\log g$ =5.5–6.5); hence, their location in the g–$T_{\rm eff}$ plane is among the PG 1159 and [WCE] stars. It is possible that the O(He) stars are the successors of those He-rich subdwarf O stars, which are on post-AGB evolutionary tracks. These, in turn, might be connected to the R CrB stars, which are He-rich giants very similar to Sakurai's object in its present state.

The variety of abundance patterns among PG 1159 stars and [WC] stars is rather diverse and the existence of O(He) stars makes an explanation for the origin of H-deficient stars even more difficult. At present it can only be speculated that, among other details, the phase in the thermal pulse cycle at the moment of AGB departure plays an important role.

Mass loss from H-deficient post-AGB stars

From the above discussions it is clear that knowledge about mass loss from [WC] and PG 1159 stars is essential for our understanding of the H-deficient post-AGB stars. Mass-loss rates from [WC] stars can be inferred from analyses of the optical emission line spectra. Good spectral resolution is required in order to eliminate the contribution from nebular emission lines to the photospheric features. As a result, high mass-loss rates are found, ranging between 10^{-5} and $10^{-6.5} M_{\odot}$ yr^{-1}, with rates decreasing along with proceeding post-AGB evolution. The mass-loss rate of two [WC]–PG 1159 transition objects amounts to $10^{-7.5} M_{\odot}$ yr^{-1}. For the PG 1159 stars one expects even smaller rates. As a consequence, the optical spectrum is formed in the hydrostatic layers of the photosphere and only the strong UV resonance lines of C IV and O VI can be used to study the properties of the weak winds. IUE, HST and ORFEUS spectra were analysed of four low-gravity PG 1159 stars, i.e. immediate successors of [WCE] stars, and one found $\dot{M} = 10^{-7}$–$10^{-8} M_{\odot}$ yr^{-1}. Comparison with theoretical studies suggests that the winds are radiation driven. For the [WC] stars the highly stratified ionization structure of metals in photospheric models lends further support to the hypothesis that the strong [WC] winds are radiation driven, too. This might explain why the supposed progenitors of the O(He) stars, the He-rich and metal poor SDO STARS, do have 'normal' mass-loss rates (only observable in the UV spectra) in contrast to the C- and O-rich [WC] stars which are found in the same part of the g–$T_{\rm eff}$ plane.

Occurrence of super-hot winds at the end of pre-white dwarf evolution

The bifurcation of post-AGB evolution into H-deficient and H-normal channels seems to continue into the WD domain, dividing the cooling sequence into non-DA and DA white dwarfs. It is natural to assume that the hottest He-rich WDs (spectral type DO) are descendants of the PG 1159 stars, however, some H-deficient post-AGB stars will become DA WDs, namely those which have retained at least some hydrogen in their envelope. The transition of post-AGB stars into the hot WD phase is encompassed by a spectacular phenomenon, which has been discovered only recently. It was found that a large fraction (50%) of the hot DO WDs shows signatures of a super-hot wind in the optical spectrum. High-ionization absorption lines of the CNO elements were identified (e.g. C VI, N VII, O VIII, and even Ne X). The high excitation potentials involved require temperatures approaching almost 10^6 K and the triangular shaped line profiles suggest their formation in a rapidly accelerating wind from the WD, reaching a terminal speed of the order of 10 000 km s^{-1}. Preliminary model calculations suggest mass-loss rates between 10^{-7} and $10^{-10} M_{\odot}$ yr^{-1}. However,

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

at present these radiative equilibrium models are crude at best, as they simply assume a very high $T_{\rm eff}$ in order to produce the high-ionization stages. Since the post-AGB age is of the order 10^5–10^6 yr, consequences of the stellar wind on evolutionary times scales and chemical surface composition are possible, if the mass-loss rates are in fact as high as estimated right now.

It is emphasized that this wind phenomenon is not restricted to DO WDs. It was also detected with one WD of spectral type DAO (H rich with traces of He) with similar high-ionization features. This is the only case discovered among DA/DAO WDs so far, and the question arises of why there is such a strong preference among DOs to show this phenomenon.

Phaethon

An Apollo asteroid discovered by Simon Green and John Davies in 1983 from data returned by the IRAS satellite; it is designated (3200) Phaethon. It follows a highly elliptical orbit and at perihelion is just 0.14 AU from the Sun, well within the orbit of Mercury. It was named after the son of the Sun-god Helios, who took the reins of the Sun-chariot and, losing control, nearly incinerated the Earth. By April 2000, only two other asteroids were known to have a smaller perihelion distance. Phaethon's aphelion distance is 2.40 AU, and its mean distance from the Sun is 1.27 AU (190 million miles); orbital period 1.43 years, inclination 22°, eccentricity 0.89 and rotation period about 4 h. The discovery of Phaethon solved the mystery of the Geminid meteor shower's 'missing' parent comet, for the orbital elements of the asteroid match those of the Geminid meteor stream.

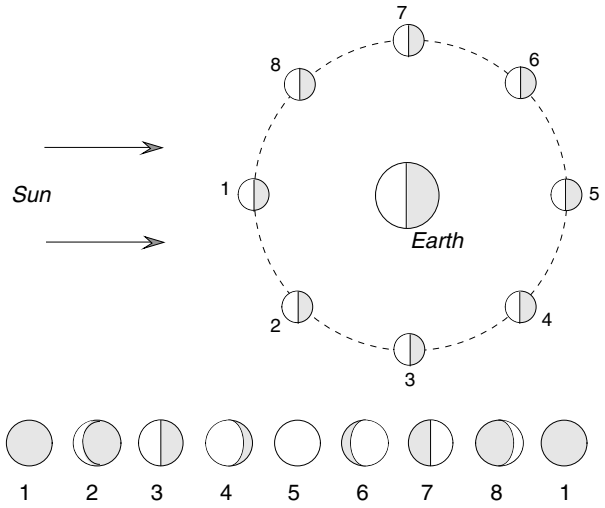

Figure 2. The Earth–Moon system as seen from space.

Phase

In the different phases of its motion, a celestial body of the solar system, as seen from the Earth, shows different apparent shapes. This comes from the relative positions of the Earth (the location of the observer), of the body (that is observed) and of the Sun (which is illuminating the body). These different successive aspects of the illuminated body that is being observed are named phases (for example: the PHASES OF THE MOON). From these first definitions, the phase angle is defined as the angle measured from the center of the illuminated observed body between the source of light (the Sun) and the observer (the Earth). It is the Sun–object–observer angle. Knowledge of the value of this angle will provide the aspect of the body, the apparent disk of which is smaller than the true apparent disk (cf figure 1).

The Moon phases

In the case of the Moon, it is easy to understand its changing appearance day after day (figure 2).

Let L_{m} and L_{s} be the longitudes of the Moon and of the Sun and φ the phase angle. The relationship between these are given in table 1 and the illumination from the Moon as a function of the phase angle is given in table 2.

Phases of the planets

Similarly to the Moon, all the bodies of the solar system, and especially the planets, are affected by the phase effect. This effect is quite different if the planet is located between the Earth and the Sun (as are Mercury and Venus) or if the planet is located outside the Earth's orbit (Mars, Jupiter, Saturn, Uranus and Neptune).

In the case of Mercury and Venus, the phases are observed just as they are for the Moon and all the aspects of the apparent disk of these planets are as for the Moon.

In the case of the other planets, the phase angle is always less than 90° (cf table 3) since these planets are never between the Earth and the Sun.

Before the use of telescopes, it was impossible to see the phases of the planets with the naked eye. This was cited as a proof to astronomers that the Earth was the center of the universe. Let us see why. If the Sun is the center of the solar system, then the distance between the Earth and Venus should have very large variations, which is not the case if the Earth is the center of the solar system. However, observation shows that VENUS keeps the same magnitude all the time, so that Venus is rotating around the Earth. Such an argument does not take into account the existence of the phase effect. GALILEO, when observing Venus through his telescope, understood easily why the magnitude of Venus was not changing much during its revolution around the Sun. The phases of Venus were compensating for the variation of distance to the Earth. Venus showed a full disk when furthest away and a thin crescent when nearest.

The phase effect

The phase effect is a tool for astronomers when observing the planets: first, the variation of the angle of incidence of the illumination of the planets by the Sun will provide information on the nature of the planets themselves. The 'flat' aspect of the Moon, independent of the phase, shows that the Moon has no atmosphere. In contrast, the relief aspect of the planet Jupiter shows that this planet has a thick atmosphere. Whether the line marking the terminator between the illuminated side and the dark side of a planet is sharp or not is an indicator of the existence of twilight due to the atmosphere on the observed planet. This shows the importance of the phase effect for astronomers. For that, astronomers have theoretical models providing the light flux received from solar system objects depending on the phase angle. Different laws of distribution of the light on the observed bodies exist including parameters depending on the characteristics of the surface of the bodies. For example, Lambert's law describes very well a planetary surface with a thick atmosphere. More recently, Hapke's law describes more precisely the granulometry of the dust and the porosity of the surface of the objects.

For example, the phase angle helps us to understand the nature of the surfaces of solar system objects: for a smooth surface, the reflectivity depends directly on the phase angle; for an irregular surface, the reflectivity changes when the phase angle becomes zero. The reflected light will increase suddenly owing to the disappearance of any shadow made by the particles of dust. This is called the opposition effect. Modeling the reflected light is very useful for the determination of the center of mass of the bodies of the solar system (in order to build dynamical models of their motion). Because of the phase effect, it is necessary to reconstruct the geometrical aspect of the planet from the apparent observed disk. Uncorrected, this can induce systematic errors in the observed astrometric positions of the body.

Phases of eclipses

In the case of phenomena such as ECLIPSES, the phases correspond to the successive configurations of the phenomenon such as partial eclipse and total eclipse. The analogy between these events led to the use of the same word.

Phases of the Moon

The various aspects that the Moon presents to observers on the Earth as the proportion of its sunlit side which is visible changes in the course of its orbit around the Earth. There are four principle phases: new moon, first quarter, full moon and last quarter. One complete cycle of phases is termed a *lunation*, and is completed in just over $29\frac{1}{2}$ days, the Moon's synodic period.

At *new moon* the Moon is between the Earth and the Sun, and is invisible as it presents its night side to the observer. If the alignment is exact a total solar eclipse will occur, but because the Moon's orbital plane is inclined to the Earth's, the solar and lunar disks do not usually coincide at new moon. The *age* of the Moon is reckoned in days from one new moon to the next. After a day or two, a sliver of the sunlit side becomes visible as a thin *crescent* (under exceptional conditions a crescent may be visible when the Moon is only about 12 hours old). From new moon until full moon the Moon is said to be *waxing*, as more of the sunlit side comes into view. A week after new moon comes *first quarter*, when the Moon is a quarter of the way around its orbit. The phase at first quarter is also termed a 'half moon'—the terminator, the line marking the boundary between night and day, bisects the Moon's disk. As the Moon continues to wax, the phase becomes *gibbous*, when most of the sunlit side is visible, a crescent-shaped portion of the disk remaining in darkness. *Full moon* occurs at just under 15 days. As at new moon, Earth, Sun and Moon are again aligned, but this time the Moon is opposite the Sun in the sky; if the alignment is close enough, a total lunar eclipse occurs. After full moon the phases then repeat in reverse, the terminator continuing its passage across the disk, through the gibbous phase to *last quarter*, when the Moon enters the last quarter of its orbit at nearly 23 days old. In this half of its orbit the Moon is said to be *waning*. After passing through a crescent phase again, and the lunation ends with another new moon.

Phobos

Two large Soviet spacecraft launched in 1988. Intended to explore Mars and drop instruments onto the surface of its moon Phobos. Contact was lost with Phobos-1 en route to Mars. Phobos-2 failed during manoeuvres in Martian orbit. Some images and other data on the planet and Phobos were returned.

Phobos and Deimos

Asaph Hall discovered the two moons of Mars, Phobos and Deimos, in August 1877. Although other observers claimed to have discovered several other moons during this opposition, a consensus was rapidly reached about the presence of two satellites only. This discovery allowed Hall to make the first determination of the mass of MARS from the observation of the satellites' orbits with a very high accuracy, differing by less than 0.1% from the currently accepted value of 0.1074 times the mass of the Earth.

Both Phobos (figure 1) and Deimos (figure 2) have a direct circular motion in the equatorial plane of Mars, at very short distances from the planet (9400 and 23 500 km). They are very dark and small (~27 and ~15 km diameter) and are difficult to observe from the ground—particularly Phobos, which rotates rapidly and is always close to the much brighter Mars. Their shape and surface morphology are known through spacecraft observations only: both objects are very irregular with surfaces saturated by impact craters, very similar to the few ASTEROIDS observed so far, although Deimos' surface is significantly smoother. These characteristics suggest that the two satellites are asteroids formed well beyond the orbit of Mars, and captured after the accretion of the planet. The capture mechanism is unknown, however. Although their low density (~1.9) is difficult to reconcile with the most favored meteoritic analogs, it is comparable to the only C-type asteroid observed so far. The surface composition has been observed only on Phobos; its spatial variations imply that, whatever its origin, Phobos is not a primitive body but instead experienced a long and complicated history. The orbital position around Mars probably favors very specific evolution processes, in particular concerning impact cratering.

Figure 1. Phobos seen by Mars Global Surveyor on 19 August 1998. The resolution is 4 meters per pixel. Individual boulders on the rim of the crater are ejecta blocks from the impact that formed Stickney, the large crater on top. The grooves are the elongated depressions near the rim of Stickney. High-resolution MOC image PIA01333 (Malin Space Science Systems, NASA).

Figure 2. Viking Orbiter image of Deimos acquired on 5 May 1977, from 1400 km. Deimos appears smooth. Higher-resolution images taken during closer approaches show that the surface is covered with craters, but many of these have been partially buried or subdued by regolith. Deimos is about 14 km from top to bottom in this image. (Viking Orbiter 413B83, NASA.)

Discovery and observations

Several astronomers, including William Herschel, had conducted unsuccessful searches for Martian satellites, and it was generally accepted that Mars had no moon when Asaph Hall systematically looked at very close distances from the planet. He eventually discovered the two satellites in the bright halo of Mars with the 66 cm refractor at the US Naval Observatory during the very close opposition of 1877—the same year Schiaparelli drew the first detailed map of Mars. Phobos and Deimos already had a literary history, however, since two satellites of Mars are mentioned by Jonathan Swift in <it>*Gulliver's Travels* (1726) and by Voltaire in *Micromégas* (1750). Swift was probably influenced by Kepler's view that, Mercury having no satellite, Earth only one, and Jupiter four (only the Galilean satellites were known at the time), Mars should have two satellites for symmetry reasons.

The first studies of the physical properties of Phobos and Deimos were conducted by E Pickering at Harvard between 1877 and 1882; however, their detailed characteristics remained unknown for nearly a century. Detailed observations of the orbital motions permitted

accurate determination of Mars' oblateness and rotation axis even before the space era. Phobos was first imaged by Mariner 7 in 1969, and appeared as a small and very irregular rock about 25 km long. Such small objects cannot be resolved by ground-based telescopes or the Hubble Space telescope at the distance of Mars, and therefore most of our current knowledge derives from spacecraft observations by Mariner 9 (1971), Viking (1977) and Phobos-2 (1989) and from a few ground-based spectroscopic observations. The Soviet Phobos mission was dedicated to the largest satellite of Mars, and represented the first attempt to land on a small body of the solar system. Unfortunately the spacecraft was lost during its approach to Phobos, after two months in Martian orbit; therefore no *in situ* observations were performed although high-quality remote sensing data were acquired, mostly from the camera and the two spectrometers.

The current Martian program is focused on sample return from Mars, and does not include specific observations of the satellites. However, several projects dedicated to Phobos have been proposed. The reason for this interest is that Phobos is the most accessible asteroid-like object and would give information about both the primitive matter from which terrestrial planets were built, and the evolution processes on small bodies of the solar system.

Orbits, orbital histories and possible origins

Deimos lies at 23 500 km from Mars's center, Phobos at only 9400 km. Phobos is so close that it is located well inside the synchronous orbit of Mars, so it rises in the west and sets in the east twice a day as seen from Mars. This also means that Phobos is slowed down by the tidal forces raised inside the volume of Mars. Phobos is therefore spiraling towards Mars, and will eventually crash to the surface; the predicted collapse time is of the order of 40 million years. Conversely, this implies that the original orbit of Phobos was very different. Both orbits currently have low eccentricity and inclination, and this puts strong constraints on the satellites' origin.

Two types of hypothesis have been proposed concerning the origin of the Martian satellites: the first type states that they formed in Martian orbit, and are remnants of the planetary formation process as are the large satellites of giant planets; in the second type of hypotheses the satellites are asteroids formed further from the Sun and captured by aerodynamic drag on either the planetary nebula or a dense primitive atmosphere. As detailed below, compositional arguments favor the second hypothesis, but the capture mechanism is difficult to explain. Dynamicists generally argue that the current orbits cannot be produced following capture of outer solar system objects; in particular the orbit of Deimos is stable on very long time scales and cannot result from a more eccentric orbit under the single influence of tidal forces. Several hints have been proposed that could accommodate the capture theory, including chaotic tumbling, collisions, gas drag on a dissipating nebula, eccentricity jumps consecutive to gravitational resonances etc. It has also been proposed that the two satellites are the two parts of a single object in synchronous orbit, split apart at the time of heavy bombardment. In the framework of the capture hypothesis, Phobos and Deimos would be the last of many objects captured by the proto-Mars, which eventually crashed on the planet and contributed to its formation (see also PLANETESIMALS).

Morphology and bulk properties

Both satellites are very irregular, as expected for such small bodies. To a first approximation they are elongated ellipsoids with dimensions given in table 1. Like most satellites in the solar system they are in synchronous rotation, with their longest axis turned toward the planet and the shortest one perpendicular to the orbital plane. Large departures from this ellipsoidal form exist however, and precise estimates of the density rely on accurate topographic models of the satellites. The currently accepted value (~1.9) is surprisingly low; it can be due to the material itself, to large porosity in a thick regolith, or to the existence of large voids inside the volume.

Phobos' shape is dominated by three large craters: Stickney (10 km diameter), Hall and Roche (5 km each). No secondary craters are identified and no central peak crater is observed, which is consistent with the small size of the satellite. On Deimos the largest identified crater is only 3 km across, and the density of large craters (>200 m) is at most half that of Phobos. However, a large saddle-like depression 10 km across, i.e. relatively much larger than Stickney on Phobos, could also result from an impact. Both surfaces are saturated with small craters and are thought to be at least 2 billion years old. All measurements demonstrate the existence of a regolith up to 200 m thick on Phobos, a consequence of the impacts. On Deimos the regolith is apparently five to ten times thinner, but it fills most of the craters.

A peculiarity of Phobos, which was long thought unique in the solar system, is the presence of several systems of parallel grooves with directions related to the main axes of the satellite. The grooves are typically 30 m

deep, 100–200 m wide and up to 20 km long. In many areas, grooves are alignments of coalescent pits that could result from outgassing mechanisms or more probably from regolith drainage into large cracks in the volume of Phobos. Most of them are centered on Stickney and are best developed in its vicinity. The main impact suffered by the satellite, which is close to the maximum that a body of this size can tolerate without disruption, is sufficient to cause these cracks to form, but tidal effects could have later played a role in the evolution of the grooves. Deimos has a much more rounded shape with large regular facets separated by bright ridges; other bright patches are visible on crater rims. The whole surface has a distinctly smoother appearance that is due to downslope movement of surface materials. This difference in morphology is unexpected, given the similarity in bulk properties of the two satellites.

The first high-resolution observations of asteroids by the Galileo and NEAR spacecraft have shown that Phobos is actually the most 'normal' body, while Deimos is markedly different. Gaspra and Ida, which are S-type asteroids with a much larger density, are the only other known solar system bodies with grooves, although theirs are less developed than those on Phobos. Mathilde, currently the only C-type asteroid observed, is very much like Phobos: its overall morphology, its density (1.5–2.0 g cm^{-3}) and its spectral properties are similar; conversely, it exhibits at least five impact craters with radius half its size, and no grooves.

Evolution mechanisms

Internal evolution of small bodies stops very early in their history because their volume-to-surface ratio is too small to allow significant heating. In these conditions the most efficient evolution process is meteoritic cratering, which is responsible for the shape and relief but also forms a regolith by accumulation of debris and can even modify the surface composition. Other significant processes include space weathering (formation of dark glasses and modification of surface chemistry by interaction with the solar wind and cosmic particles) and possibly tidal effects.

Crater formation (see CRATERS) is in general in the strength-scaling regime, where ejecta leave the immediate vicinity of the crater and well-defined rims do not form. On Phobos, only craters more than 5 km large have a significant ejecta blanket; this suggests that the bulk material has a compressive strength similar to anhydrous carbonaceous chondrites, while the regolith has properties similar to that of the Moon. In these conditions, materials can be excavated from one or two kilometers deep; due to the small gravity, ejecta are also transported very far from the impact. However, observations from the Phobos-2 spacecraft showed significant spectral variability on a kilometer scale, related in particular to ejecta blankets and deep craters. Therefore, lateral and vertical mixing are not efficient enough to homogenize the whole surface.

Cratering processes are deeply affected by the orbital situation around Mars. Because of the strong asymmetry of the effective gravitational field, ejecta suffer a different fate depending on the longitude of impact and on the speed and direction of ejection; this mechanism is clearly seen on Stickney's ejecta, which are more confined in the sub-Mars direction. In addition, the average escape velocities are much smaller than the orbital velocities (~8 m s^{-1} versus ~2 km s^{-1}), therefore most ejecta escaping the satellites remain on the same orbit around Mars and are reaccreted by low-velocity impacts in a very short time (~10^4 yr), which strongly increases the meteorite flux and regolith thickness. Dust belts may have formed along the orbits of Phobos and Deimos when impacts were very frequent; these dust belts were never observed, however, and the lifetime of such objects seems rather short. Over long periods of times, surface materials can be ejected and reaccreted over and over

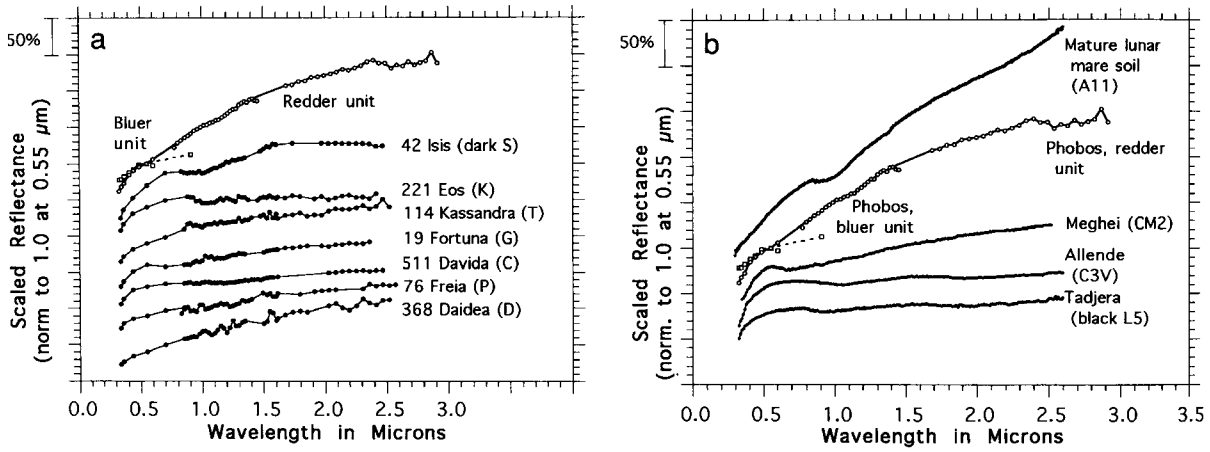

Figure 3. Comparison of the spectra of Phobos and various dark asteroids and meteorites. (From Murchie and Erard 1996 *Icarus* **123** 63–86.)

again. Shock heating would then dehydrate the surface materials and could profoundly modify the composition and spectral properties of the regolith. The regolith itself can insulate the interior, which could retain large quantities of volatiles.

The morphological peculiarities of Deimos are currently best explained by the effect of a large impact corresponding to the saddle-like scar mentioned above; seismic shaking and reaccumulation of ~200 m of debris would have concealed previous craters and possible grooves formed during the impact, thus explaining the lower density of large craters, the thinner regolith in the craters, and global downslope movements. The location in the Martian orbit permits isotropic reaccumulation of large quantities of ejecta, which is not possible for an asteroid in solar orbit, and could contribute to the particularly smooth appearance of Deimos.

Composition and internal structure

Composition is inferred from spectral observations, with a strong constraint from the density. The observed properties (figure 3) strongly suggest that the satellites are captured asteroids but do not strictly preclude formation in the inner solar system, although independent from Mars' formation. The two satellites are among the darkest bodies in the solar system, with geometric albedo half that of the Moon. Variations in brightness and photometric functions are observed, but are usually ascribed to variations in particle size rather than composition.

The Martian satellites have often been presented as homogeneous mixtures of materials similar to hydrated carbonaceous chondrites, inferred to be the primary component of C-type asteroids. This interpretation was based on the low albedo, on limited spectral coverage by Mariner 9 and Viking, and on the low density. More recent observations contradict this view, however. The major spectral properties observed by Phobos-2 are a very red continuum slope, no hydration signature, a weak and variable pyroxene/olivine absorption, and a strong fall-off in reflectance below 0.5 μm; the Hubble Space Telescope has provided consistent results for both satellites in the visible range. These properties do not fit any known meteorite spectrum; the best match is given by some dark ordinary chondrites (L and LL types), but is not incompatible with dry carbonaceous chondrites (CO and CV types). However, only the mature lunar mare soils exhibit similarly steep spectral slopes, which demonstrates that exposure to the space environment has modified the regolith extensively. Consistently, Stickney's ejecta have flatter spectra, and either are less altered or consist of a different material excavated by the impact. As for asteroids, only the driest C-type have low hydration bands like Phobos and Deimos, but the best spectral matches are given by P, D and T types. T-type asteroids are poorly understood, but there appears to be a gradual evolution in spectral properties from C to P and D. Most P and D objects are thought to be primitive, rich in organic materials and possibly in anhydrous silicates, and are located in the outer asteroid belt (2.8 to 3.8 AU); interestingly, these dry asteroids are often suspected to contain large amounts of water ice preserved since the formation of the solar system.

The low density of the Martian satellites is in fact inconsistent with that of any low-albedo METEORITES. The density of the best spectral analogs is so much higher (3.4–3.8 for black ordinary chondrites, 3.3–3.6 for dry carbonaceous chondrites) that regolith porosity alone cannot explain the discrepancy. The presence of large quantities of ice in the interior would resolve this paradox. On Phobos, an ice core with radius 7–9.5 km is required, depending on the density of the upper layer; the latter would mostly consist of space-weathered primitive material, but could also have accreted Martian material ejected during the formation of impact basins.

Another possibility often suggested to explain the low density and surface heterogeneity of Phobos is that of the 'rubble pile' of fragments. Such objects are thought to result from disruption of larger parent bodies, and to have large internal porosity and therefore low density. However, impact modeling of Stickney suggests that Phobos' grooves could have formed only in a coherent body; in addition, the satellite was apparently not fragmented in the process and the resulting cracks are not large enough to explain the unusual low density. Furthermore, a rubble pile is expected to exhibit only a small departure from sphericity, which is hardly compatible with Phobos' shape. The rheological properties of an ice core at low temperature would probably permit the formation of grooves during a large impact. Considering the absence of grooves and the more spherical shape, the rubble pile hypothesis cannot be rejected for Deimos in the framework of the large impact theory mentioned above; it is also favored for Mathilde, in spite of its close similarities with Phobos.

Conclusion

The last point above is representative of the uncertainty that persists concerning the origin and evolution of the Martian satellites: although it is more and more widely accepted that they are captured bodies formed in the outer asteroid belt, their structure and evolution are still poorly understood. The more attractive assumption is perhaps that they are D or T-type asteroids made of relatively primitive material accreted on a water ice core, with surfaces extensively modified by exposure to the space environment; specific processes related to the orbital position and the unusual proximity of the Sun have probably resulted in surface characteristics that are uncommon among asteroids of similar origin.

However, numerous intriguing questions remain, including: the origin of the bodies (do they represent primitive objects still containing large amounts of ice formed in the solar nebula; from which part of the asteroid belt do they come?), the regolith composition (are they made of a material similar to carbonaceous chondrites or a more evolved one; is there a significant

Dirac House, Temple Back, Bristol, BS21 6BE, UK

amount of Martian material accreted on the surfaces?), the internal structure, the nature and efficiency of specific evolution processes, the origin of the difference between Phobos and Deimos, and so on. The possibility of capturing distant objects around Mars is actually still problematic.

A better understanding will require further observations of the Martian satellites and more asteroids. Planetary missions now systematically consider asteroid flybys during the cruise phase (e.g. Cassini/Huygens, Rosetta), so our knowledge of these objects is rapidly improving. In the long term, sample return from Phobos may prove the only way to address open issues concerning its origin. In the meantime, global imaging spectroscopy coverage in the near-infrared would provide important information about its composition; such observations could be performed from a spacecraft dedicated to the exploration of Mars.

Phoenix

(the Phoenix; abbrev. Phe, gen. Phoenicis; area 469 sq. deg.) A southern constellation which lies between Sculptor and Tucana, and culminates at midnight in early October. It was probably first shown on Petrus Plancius' celestial globe of *c*. 1598, though it is usually attributed to the Dutch navigators Pieter Dirkszoon Keyser (also known as Petrus Theodorus) and Frederick de Houtman, who charted that part of the southern sky in 1595–7.

A rather inconspicuous constellation, the brightest stars in Phoenix are α Phoenicis (Ankaa or Nair al Zaurak), magnitude 2.4, β Phoenicis (combined magnitude 3.3), a very close binary with a yellow (G8) primary, magnitude 4.0, and a slightly fainter secondary, magnitude 4.2, separation 0.7″, and γ Phoenicis, magnitude 3.4. There are four other stars brighter than fourth magnitude, including ζ Phoenicis, a multiple system with bluish-white/white (B6 and A7) components, magnitudes 3.9v and 8.0, separation 6.5″, the former of which is an eclipsing binary (range 3.9–4.4, period 1.67 days). Other interesting objects include NGC 625, an eleventh-magnitude galaxy.

Photodissociation Regions

Photodissociation regions, or photon-dominated regions (PDRs), are dense ($\sim 10^3$–10^7 cm^{-3}) regions in the interstellar medium (ISM) where the hydrogen gas is neutral, and is either atomic or molecular (see H I and H II regions), and where externally incident far-ultraviolet (FUV: 6–13.6 eV) radiation controls the chemical structure and dominates the thermal properties of the gas. This definition excludes the diffuse and translucent clouds which are less dense and generally more transparent to FUV radiation, although some authors refer to the latter objects as 'low-density' PDRs. PDRs are ubiquitous in the ISM and are present in the surface layers of dense molecular clouds, reflection nebulae, planetary nebulae, neutral stellar winds and circumstellar disks.

PDRs are widespread sources of optical, infrared and millimeter atomic and molecular line emission, as well as thermal infrared dust continuum emission. PDR emission is particularly bright in gas exposed to enhanced FUV radiation fields, such as exist in massive-star-forming regions in the Milky Way. PDRs are prominent in starburst galaxy nuclei and active galactic nuclei.

Famous and well-studied Galactic PDRs are located in the A and B clouds and Bright-Bar region in the Orion molecular cloud complex, the star-forming regions M17 and S140, molecular clouds in the Galactic center, the reflection nebulae NGC 2023, NGC 7023 and IC 63, and the planetary nebulae NGC 7027 and BD+30°3639. PDR emission has been observed in numerous galaxies including the well-studied starburst galaxies M82 and NGC 253.

Chemical structure

The chemical processes which occur in PDRs are similar to those which occur in the diffuse and translucent clouds (see INTERSTELLAR MOLECULAR CLOUDS). Molecules are destroyed by photodissociation (XY+$h\nu$ $\rightarrow$ X + Y), and atoms with ionization potentials less than that of atomic hydrogen (13.6 eV) are photoionized (X+$h\nu$ $\rightarrow$ X + e) by the FUV radiation. Molecules form via sequences of two-body gas-phase processes including radiative association (X+Y $\rightarrow$ XY + $h\nu$), ion–molecule exchange (X^+ + YZ $\rightarrow$ XY^+ + Z), charge-transfer (X^+ + YZ $\rightarrow$ X + YZ^+) and neutral-neutral (X+YZ $\rightarrow$ XY + Z) chemical reactions. Molecular ions are removed by dissociative recombination (XY^+ + e $\rightarrow$ X + Y). Endothermic neutral–neutral reactions play a more important role in PDRs compared with diffuse or translucent clouds owing to the generally higher gas temperatures that prevail in PDRs.

Formation of molecules on grain surfaces and their ejection into the gas phase may also play an important role, particularly in the production of hydrogenated species. Molecular hydrogen (H_2) is not formed efficiently by two-body reactions, and catalytic formation on grain surfaces dominates its production in PDRs (and elsewhere in the ISM).

The typical structure of a uniform-density (model) PDR is illustrated schematically in figure 1. This particular model is for a cloud with a total hydrogen density equal to 10^4 cm^{-3} exposed to an incident FUV field which is 2×10^3 times more intense than the mean interstellar FUV field. The relative abundances of H, H_2, C^+, C, CO, S^+, S, SO and SO_2 are shown as functions of increasing visual extinction, A_V, into the cloud.

A thin ionization front (IF) lies at the outer boundary of the PDR. Lyman continuum photons are absorbed in the IF, and longer-wavelength FUV radiation penetrates into the PDR. At the outer edge of the PDR molecules (in particular H_2 and CO) are rapidly photodissociated, and atomic carbon is photoionized. The incident FUV radiation is attenuated by a combination of dust grain continuum absorption and molecular line absorptions. The gas becomes progressively more molecular as the destructive effects of the FUV field diminish with increasing cloud depth.

Figure 1 illustrates some important chemical layers which occur in PDRs. The first is the H–H_2 'dissociation front' across which the hydrogen gas becomes molecular. H_2 is photodissociated in a two-step process. FUV photons are first absorbed in electronic excitations in lines of the Lyman and Werner band systems. This is then followed by spontaneous radiative decays to the ground-state continuum, which lead to dissociation. The dominant H_2 absorption lines generally become very optically thick in PDRs, and once this occurs the hydrogen molecules are said to 'self-shield' against the destructive FUV radiation.

A second important transition is the C^+–C–CO layer across which the gas-phase carbon is incorporated into CO molecules. Atomic carbon becomes abundant in this transition layer. At large cloud depths the excess oxygen either remains atomic or is incoporated into O_2. A third transition illustrated in figure 1 is the S^+–S–SO,SO_2 layer across which sulfur is incorporated into molecules.

The locations of the various transition layers depend primarily on the hydrogen particle density and the intensity of the incident FUV field. Other cloud parameters include the elemental abundances, the grain absorption and scattering properties, and the cloud geometry.

The observations are generally consistent with the structure illustrated in figure 1. However, in inhomogeneous clumpy clouds the behavior can become more complicated, owing to enhanced penetration and internal scattering of the FUV radiation and the presence of unresolved dense clumps within the observational beams. For example, photodissociation of CO molecules by scattered radiation in clumpy media probably accounts for the extended atomic carbon emission observed in star-forming molecular clouds.

The ionization fraction is an important parameter of interstellar clouds. Near the outer edges of PDRs the positive charge is carried mainly by C^+ ions, and beyond the C^+–C–CO transition photoionization of silicon and sulfur provides the free electrons. In clouds which are

sufficiently thick to absorb all of the incident FUV radiation an inner boundary to the PDR exists beyond which other processes (e.g. cosmic-ray ionization) dominate the thermal and chemical properties of the gas. In the interior shielded regions the positive charge is carried mainly by abundant molecular ions (e.g. H_3^+ and HCO^+) and metal ions.

PDR emission lines

The gas temerature in PDRs is fixed by the balance between FUV heating and atomic and molecular emission line cooling. Observations and theoretical computations show that the gas temperatures in the outer parts of PDRs range from a few 100 K in lower density clouds to more than 1000 K in very dense clouds. The gas temperature decreases with increasing cloud depth. Generally the gas temperature is significantly higher than the dust temperature in PDRs.

The FUV radiation energy is effectively transferred to the gas via photoelectric emission from small dust grains and by the photoionization of 'large molecules' or polycyclic aromatic hydrocarbons (PAHs). Evidence for the presence of PAHs in PDRs is provided by observations of broad emission features at 3.3, 6.2, 7.7, 8.6 and 11.3 μm, although the exact identifications of these features remain uncertain. Dense PDRs are also heated by collisional de-excitation of H_2 molecules which have been vibrationally excited by the FUV-pumping process (see below).

PDRs are cooled by atomic and ionic fine-structure emission lines and molecular rotational transitions. Important fine-structure emission lines include the [C II] 158 μm, [O I] 63 and 146 μm, [Si II] 35 μm, and [C I] 370 and 609 μm transitions. Their relative intensities serve as diagnostics of the conditions in PDRs. The [C II] and [O I] emission lines are particularly useful diagnostics, and can emit up to $\sim$ 1% of the absorbed FUV luminosity (most of the FUV energy is reradiated as thermal far-infrared dust emission).

Figure 2 shows model computations of the [C II] 158 μm and [O I] 63 μm emission line strengths as functions of the incident FUV intensities for a range of assumed cloud densities. A selection of observed line strengths from several astronomical sources is also displayed in figure 2. The emission line intensities saturate at large values of the FUV intensity owing to the effects of dust absorption. The critical densities of the [C II] 158 μm and [O I] 63 μm transitions (for collisions with neutral hydrogen) are 3×10^3 and 3×10^5 cm^{-3} respectively, so that the [O I]/[C II] emission line ratio becomes large in high-density PDRs. The [C II] line generally remains optically thin and can be used as a tracer of the cloud mass. The [O I] line becomes optically thick in PDRs.

PDRs are prominent sources of H_2 and CO emission lines. Because H_2 is a light molecule with a small moment of inertia its rotational energy levels are widely spaced, and elevated temperatures are required for efficient excitation. This occurs in PDRs, and mid-infrared H_2 emission lines, such as the fundamental $J = 2$–0 28.2 μm line (and other transitions including the 17.0, 12.3, 9.7 and 8.0 μm lines) are readily excited and have have been observed (from

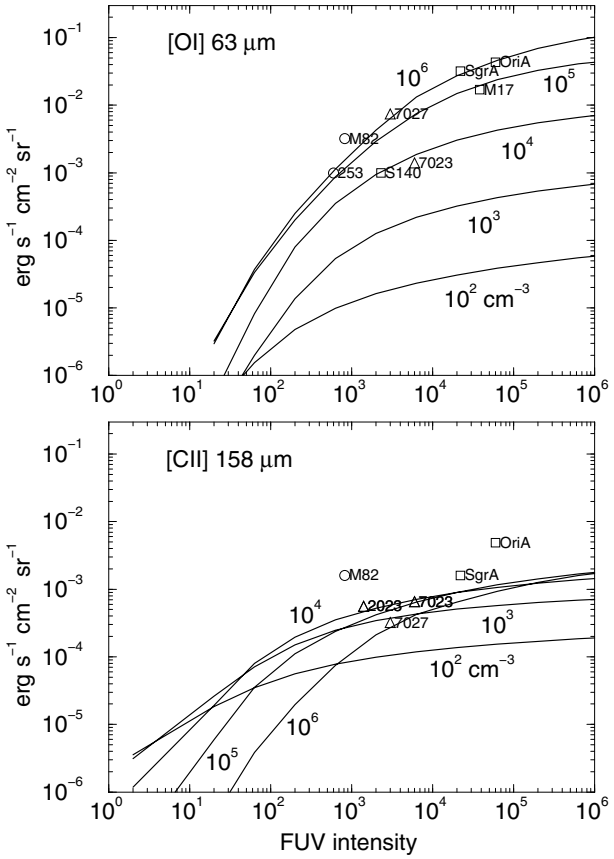

Figure 2. [C II] 158 μm and [O I] 63 μm fine-structure emission line intensities as functions of the incident FUV intensity for hydrogen particle densities in the range 10^2–10^7 cm^{-3}. Square symbols indicate PDRs adjacent to H II regions, triangles are reflection and planetary nebulae and circles are starburst galaxy nuclei.

space) in several Galactic PDRs. Mid-IR H_2 emissions have also been observed in several STARBURST GALAXIES, and may arise in PDRs. Near-infrared vibrational H_2 emissions, including the commonly observed $v = 1$–0 S(1) 2.12 μm line can also be collisionally excited in hot ($T > 1000$ K) and dense ($>10^4$ cm^{-3}) PDRs. The relative intensities of the collisionally excited H_2 emission lines are useful probes of the gas temperatures in the outer atomic hydrogen gas layer and the H–H_2 dissociation front.

H_2 is also excited directly by the FUV photons in PDRs via an important process called FUV pumping in which the Lyman and Werner band FUV line absorptions are followed by decays to discrete excited vibrational levels of the ground electronic state. The transitions to the excited vibrational levels initiate a cascade of slow radiative transitions at optical and near-infrared wavelengths. Figure 3 displays a model computation of the FUV-pumped fluorescent vibrational emission line spectrum produced in a PDR with a hydrogen density equal to 10^3 cm^{-3} exposed to an FUV field with an intensity of 10^3. Fluorescent H_2 emissions have been observed in

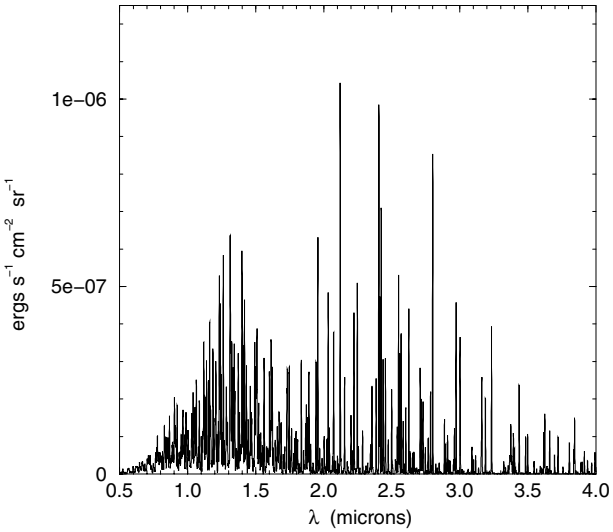

Figure 3. The FUV-pumped fluorescent H_2 emission line spectrum in the range 0.5–4 μm.

numerous PDRs (e.g. the REFLECTION NEBULA NGC 2023 and the PLANETARY NEBULA NGC 7027). The fluorescent emission line intensities are useful diagnostics of the hydrogen gas density, the FUV field intensity, the grain-surface H_2 formation efficiency, the dust grain scattering properties and the PDR lifetimes.

The intensity ratio of the 2.12 μm 1–0 S(1) and the 2.25 μm 2–1 S(1) lines may be used to discriminate between collisional and fluorescent H_2 excitation in PDRs. The 1–0/2–1 line intensity ratio is small ($\sim$2) when FUV pumping dominates the excitation and becomes large ($>$10) when collisions dominate the excitation and the level distributions approach local thermodynamic equilibrium. For example, observations of H_2 line emissions from the planetary nebula BD+30°3639 show that the 1–0/2–1 line ratio is large in the hot outer part of the PDR which is closest to the central star. Collisional excitation becomes less effective with increasing distance from the star, and the FUV pumping by the stellar photons then dominates the molecular excitation, and the 1–0/2–1 intensity ratio becomes small.

PDRs are prominent sources of CO rotational emission lines, including the fundamental millimeter wave CO $J = 1$–0 rotational transition at 115 GHz which is the standard tracer of interstellar molecular clouds. This important emission line generally forms in the inner cooler parts of the PDRs. PDRs are also sources of submillimeter and far-infrared mid-J (e.g. CO $J = 7$–6) and high-J (e.g. CO $J = 14$–13) emission lines. The high-J CO emissions trace warm and high-density gas, which is usually confined to isolated clumps within molecular clouds. These high-pressure clumps may be self-gravitating and collapsing objects.

Despite the destructive effects of the FUV radiation fields some molecules are formed preferentially in PDRs.

Important examples are the radicals OH and CN and the molecular ion CO^+. In warm PDRs OH and CO^+ are produced by the endothermic hydrogen abstraction reaction $O+H_2 \rightarrow OH + H$, followed by the ion–molecule exchange $OH + C^+ \rightarrow CO^+ + H$. This simple sequence may explain the large abundances of CO^+ ions that have been observed in the planetary nebula NGC 7027 and molecular cloud interfaces in M17 and the Orion Bar. Another interesting molecular diagnostic of PDRs is the CN/HCN abundance ratio which, because of the photodissociation of HCN, is expected to be larger in PDRs compared with shielded regions. Indeed, observations of HCN and CN molecules in the reflection nebulae NGC 2023 and NGC 7023 show that the CN/HCN density ratios are enhanced near the sources of FUV radiation and decrease by large factors with increasing distance from the illuminating stars.

FUV regulated star formation

The ionization fraction in PDRs (see above) may control the rate of low-mass star-formation in the Galaxy. In this scenario the STAR-FORMATION rate is fixed by the rate at which magnetic fields are removed from the clouds via ambipolar diffusion. The diffusion rates are inversely proportional to the ionization fractions which are fixed by the visual extinctions through the clouds. A feedback loop becomes possible in which energy injection by newly formed stars leads to cloud expansion, greater penetration of the background interstellar radiation and therefore larger ionization fractions, so that the star-formation rate decreases. As the energy injection rates decrease the clouds collapse, become better shielded against the FUV radiation and become less ionized, thereby leading to an increased star-formation rate. Theoretical computations suggest that an equilibrium occurs for clouds with total visual extinctions $A_V \sim 7.5$, generally consistent with the typical observed opacities of molecular clouds.

Photon

An elementary particle that is equivalent to a discrete packet, or 'quantum', of electromagnetic energy.

In accordance with the wave–particle duality, light, or any other form of electromagnetic radiation, behaves in some respect like a wave motion and in others as a stream of photons. The energy (E) of a photon is directly proportional to the frequency (f), and inversely proportional to the wavelength (λ), of the radiation. It is given by $E = hf = hc/\lambda$, where c denotes the speed of light and h is the Planck constant. Gamma-ray photons, which correspond to the shortest wavelengths of electromagnetic radiation, have the highest energies, and radio photons, which correspond to the longest wavelengths, have the lowest.

The photon is the force-carrying particle (gauge boson) that conveys the electromagnetic force between charged particles. It has zero mass, zero charge, and spin = 1 (in units of $h/2\pi$).

Physics of Molecules

Many varieties of molecule have been detected in the Milky Way and in other galaxies. The processes by which these molecules are formed and destroyed are now broadly understood (see INTERSTELLAR CHEMISTRY). These molecules are important components of galaxies in two ways. Firstly, radiation emitted by molecules enables us to trace the presence of diffuse gas, to infer its physical properties and to estimate the propensity for further STAR FORMATION in that galaxy. Secondly, the emitted radiation removes energy from the emitting regions, allowing them to cool. This cooling is an essential part of the process of the gravitational collapse of gas clouds in the initial stages of star formation.

Molecules are found in many environments in space, but most readily in the denser, cooler parts of the Galaxy and other galaxies. Molecules were discovered first in interstellar clouds and are also abundant in cool circumstellar envelopes around evolved stars. They have also been detected in planetary nebulae, in the ejecta of novae and supernovae, and in the atmospheres of relatively cool stars. Molecules have even been detected in the Sun: SUNSPOTS contain water molecules (admittedly, very short-lived). In general, molecules are likely to be present in astronomical situations where the gas temperatures are less than about 4000 K and the gas number densities are above about 10^6 H atoms/m^3 (assuming that other elements are also present with the usual cosmic abundances).

Molecules were even important in the early universe where hydrogen molecules were an important cooling agent for pre-galactic gas clouds, allowing them to collapse under gravity to form PROTOGALAXIES.

Physical processes

Physical processes are here defined to be those in which the molecules interact with their environment but remain fundamentally unchanged. In a chemical process, by contrast, an exchange of atoms occurs, and new species are created.

The main physical processes to which astronomical molecules are subjected are the following:

- absorption and emission of electromagnetic radiation;
- collisions with fast particles (COSMIC RAYS) and with other atoms and molecules on the gas;
- sticking to and desorption from the surfaces of dust grains.

Since these processes generally involve the excitation of energy levels in molecules, we shall first give a brief summary of molecular energy level structure, emphasizing in particular how it differs from that of atoms.

Energy level structure in molecules

Molecules have degrees of freedom unavailable to atoms: molecules may vibrate and rotate. Of course, molecules may also be excited electronically. Molecular electronic excitation energies are different from those of the individual atoms in the molecule. However, in the limit of large separations between the atoms (when the interaction energy between them becomes small) the molecular electronic energy levels approach those of the atoms. Hence, molecular electronic energy levels are normally of the same order of magnitude as atomic energy levels, and are separated typically by energies of a few electron volts. Energies associated with vibrational transitions are generally one to two orders of magnitude smaller than this, and transitions between rotational levels have energies that are generally again much smaller than those of vibrational transitions.

The essential features of molecular vibration and rotation are evident in the smallest molecules, i.e. diatomics, so the discussion here is introduced in terms of diatomic molecules. In the simplest approximation, the vibrations of diatomic molecules can be treated as simple harmonic oscillations. Classically, a harmonic oscillator may have any energy, but for molecules quantum mechanics restricts the permitted energies, E_v, to the discrete values

$$E_v = \hbar\omega(v + \tfrac{1}{2})$$

where $\hbar$ is the reduced Planck's constant, ω is an angular frequency measured in radians per second, related to the force constant in the oscillator, and v is the vibrational quantum number that may take integer values or zero. The energies permitted by quantum mechanics for the harmonic oscillator are, therefore, $\frac{1}{2}\hbar\omega, \frac{3}{2}\hbar\omega, \frac{5}{2}\hbar\omega, \ldots$. There is no restriction on transitions between these permitted energy levels, in this approximation.

The rotation of a molecule can be considered in a simple approximation to be that of a rigid rotator. Quantum mechanics confines the permitted energy levels of a molecular rigid rotator, E_r to the set of discrete values

$$E_r = B_r J(J+1)$$

where B_r is related to the moment of inertia, I, of the molecule

$$B_r = \hbar^2/2I$$

and J is the rotational quantum number and is confined to integer values or zero. Thus, the permitted energy levels are $0, 2B_r, 6B_r, 12B_r, \ldots$ in this approximation and transitions between the levels are restricted by selection rules. Hence, massive molecules with large moments of inertia have relatively closely spaced energy levels, and the associated wavelengths of absorption or emission are relatively long, and vice versa.

The total energy of a diatomic molecule is in the simplest approximation the sum of electronic, vibrational and rotational energies:

$$E_{\rm tot}(n, v, J) = E_e(n) + E_v(v) + E_r(J)$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

where E_e is the electronic energy which depends on one or several quantum numbers, n. In general, transitions may occur between states of different n, v, and J, subject, of course, to any selection rules. For example, interstellar molecular hydrogen was first detected by absorption in its electronic transition from the ground electronic state, $v = 0$ vibrational level, and $J = 0$ and 1 rotational levels to the first accessible excited electronic state in a variety of vibrational and rotational levels.

Vibration–rotation transitions may also be important. For example, molecular hydrogen is readily detected in warm astronomical regions by its emission at wavelengths near 2 μm arising from transitions in level $v = 1$ to level $v = 0$ in the ground electronic state. In both v levels, several J levels are involved. Finally, pure rotation transitions may occur, and are the means by which most interstellar molecules have been detected. For example, carbon monoxide, CO, is an important tracer of cold gas through its emission from $J = 1$ to $J = 0$, occurring at a wavelength of 2.6 mm. The energy difference corresponding to this is equivalent to about 5 K$\times k$ (k is Boltzmann's constant), and so the $J = 1$ level is readily excited in collisions in gas at a temperature as low as about 10 K (which is often the case for interstellar CO).

Of course, many cosmic molecules are much more complex than diatomics. For polyatomics, the vibrational spectra can be regarded as a superposition of harmonic oscillations for each of the normal modes of the system, so the diatomic description can be very easily extended. However, polyatomics have a considerably more complex rotational energy level structure than diatomics. When there is an axis of symmetry in the molecule (a so-called symmetric top) then one more rotational quantum number, K, in addition to J, is required to define the energy state and a simple extension can be given:

$$E_r = B_r J(J+1) + (A_r - B_r)K^2$$

where A_r is related to the moment of inertia about an axis which is not the axis of symmetry. Figure 1 illustrates the rotational energy level structure that arises for a molecule of this type. However, when the molecule does not have an axis of symmetry (an asymmetric rotator) then no simple formula can be given.

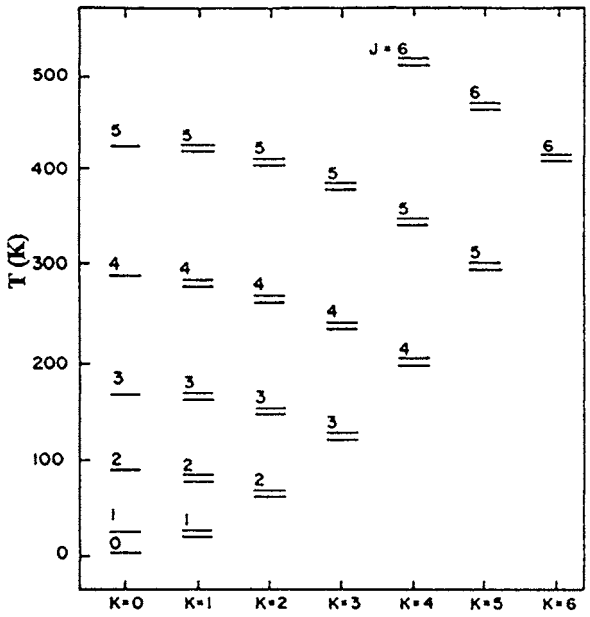

Figure 1. A partial energy level diagram for the rotational energy levels of a molecule with an axis of symmetry (a symmetric top); the levels illustrated are for the ammonia molecule NH_3. The quantum number J is indicated for each level; the quantum number K is indicated on the abscissa. In the case of ammonia, each level with $K > 0$ is doubled because there are two equivalent positions for the N atom, one of each side of the plane defined by the three H atoms. Perturbations in the molecule (not discussed here) ensure that these two levels have slightly differing energy.

Excitation of molecules

Radiative excitation

Stellar radiation may raise molecules to high states of excitation from which relaxation will occur, though not necessarily back to the initial state. In the mainly neutral regions of space where molecules are found, stellar radiation is truncated at wavelengths of 91.2 nm corresponding to the ionization potential of hydrogen (13.6 eV). All radiation shortward of this value is confined within the Strömgren sphere of ionized hydrogen (H II REGION) around the star. Within the Strömgren sphere, any molecules that form are very rapidly destroyed through processes of direct photodissociation and direct photoionization. For example, in the case of molecular hydrogen in its ground vibrational state, the following processes occur:

$$\begin{aligned} H_2 + h\nu &\rightarrow 2H \quad (h\nu > 14.7\ \text{eV}) \\ H_2 + h\nu &\rightarrow H_2^+ + e \quad (h\nu > 15.4\ \text{eV}) \\ H_2^+ + h\nu &\rightarrow H + H^+ \quad (h\nu > 2.65\ \text{eV}) \end{aligned}$$

for photons ($h\nu$) of appropriate energy. Here, 'direct' processes signify transitions to states which are either repulsive (so that the molecule falls apart), or states in which the excess energy in the excited molecule is sufficient to dissociate or ionize the molecule (see also EXCITATION AND IONIZATION).

In molecular clouds which are predominantly neutral and where the stellar radiation is restricted to wavelengths greater than 91.2 nm (photon energies less than 13.6 eV), many of these direct processes are inaccessible. However, electronic excitation of H_2, and many other molecular species, is still possible, and this enables the detection of H_2 and provides a means of both populating vibrational energy levels and of destroying molecules. For H_2, absorption of starlight at wavelengths around 100 nm raises this molecule from the ground electronic state, X, and ground vibrational state $v'' = 0$ to an excited electronic

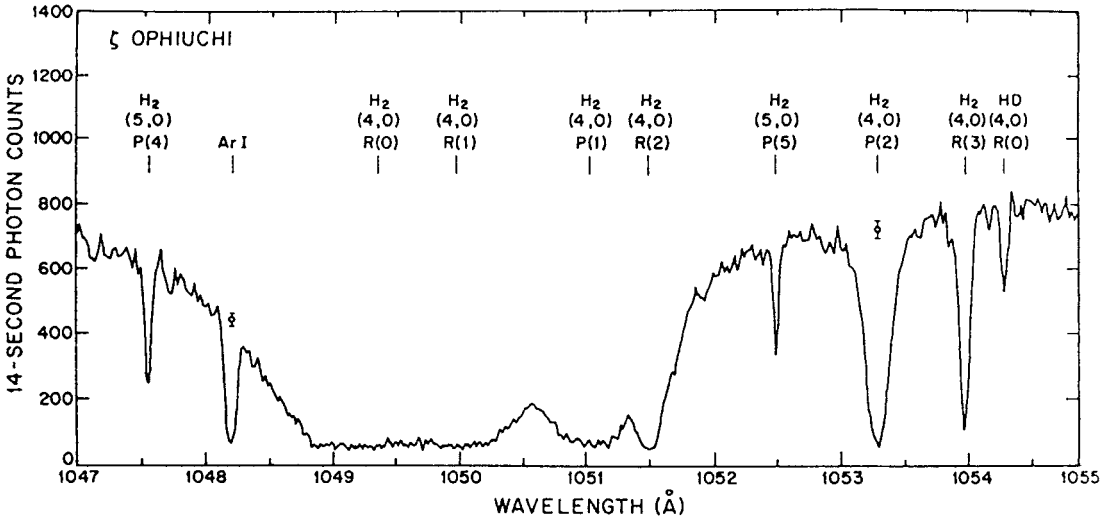

Figure 3. The ultraviolet absorption spectrum of H_2 (the wavelength scale is in angströms, Å; 1 Å is 0.1 nm). The radiation from a bright star ζ Ophiuchi is absorbed by foreground H_2 in a diffuse interstellar cloud. The lines of H_2 arise in the ground electronic state and ground vibrational level. For example, the absorption at a wavelength of 1054 Å is from X, $v = 0$, to the upper electronic state, B, in the $v = 4$ vibrational level. The transitions also involve a change of rotational levels; in the notation used in the figure, $R(0)$ refers to an increase in J from 0 to 1, while $P(1)$ implies a reduction in J from 1 to 0. Some of the lines are saturated. (From Spitzer and Jenkins 1975.)

state, B or C, in a variety of vibrational and rotational states

$$H_2(X;\, v'' = 0;\, J'') \rightarrow H_2(B \text{ or } C;\, v';\, J')$$

where the v' and J' quantum numbers refer to the upper electronic state, B or C (see figure 2). The absorption of ultraviolet radiation from a background star enables the detection of H_2 in foreground diffuse interstellar clouds (figure 3). This excitation is very rapidly (on a timescale of about 10^{-8} s) followed by radiative relaxation into the ground electronic state, X, and into a range of vibrational and rotational levels of X:

$$H_2(B \text{ or } C;\, v';\, J') \rightarrow H_2(X;\, v'' > 0;\, J'') + h\nu.$$

The distribution over the v'' levels can be calculated, and for excitation by radiation around wavelengths of 100 nm peaks around $v'' = 6$. Then, further relaxation occurs through vibration–rotation transitions within the ground electronic state of the molecule; for example, the vibrational quantum number may change by one

$$H_2(X;\, v'';\, J'') \rightarrow H_2(X;\, v'' - 1,\, J'' \pm 2).$$

Therefore, electronic excitation of a molecule can lead to the population of a range of vibration–rotation states in the ground electronic state, and radiative relaxation from those levels then occurs through infrared and radio wavelength transitions.

In the important case of H_2, the relaxation from the upper electronic state may end in the vibrational continuum of the ground electronic state, X, implying that the molecule falls apart. This vibrational continuum arises in the following way: the harmonic oscillator approximation breaks down for high vibrational energies, and the discrete levels become closer together (see figure 2) and eventually merge into a continuum for states above $v'' = 14$. For excitation of H_2 by radiation near 100 nm, the probability that the molecule relaxes into the vibrational continuum is about 10%. This mechanism constitutes the main destruction route for H_2 in diffuse interstellar clouds. However, one should note that the excitation occurs through absorption in spectral lines. Therefore, if H_2 formation is also occurring, then H_2 may shield itself from the dissociating radiation by absorbing all the photons within the narrow spectral lines. In diffuse clouds, a transition from mostly H atomic to mostly H_2 molecular gas occurs at depths into a cloud corresponding to an optical depth (caused by interstellar dust) at visual wavelengths of a few tenths. For molecules other than H_2, however, this indirect destruction mechanism is generally unimportant. Its special role for H_2 arises because the minima of the potential energy curves of groundstate X and of excited states B and C differ considerably; this tends to promote a relaxation into high v'' states of X.

Other simple molecules may respond radiatively in the direct or indirect modes described here. For example, H_2O molecules absorb strongly in the wavelength range 150 nm to 200 nm, and are directly dissociated. However, larger molecules have more complex responses to radiation, including internal conversion of absorbed energy into vibrational energy of many modes of the molecule. The energy is radiated away in the infrared, on relatively long time scales (on the order of seconds), in many photons.

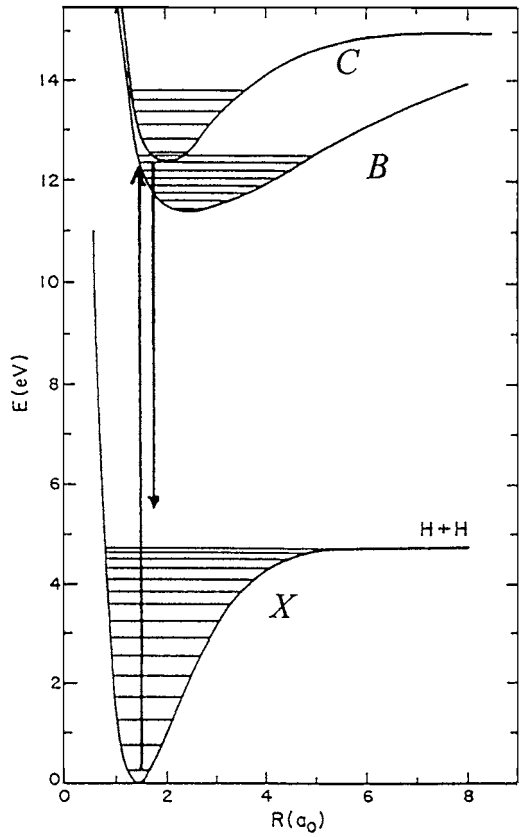

Figure 2. The potential energy curves of H_2, in several electronic states. The curves show how two H atoms interact as the distance between them, R (measured in H-atom radii), is allowed to vary. The curves are attractive at long range, and repulsive at short range. The vibrational energy levels associated with each electronic state are shown. The transition from the lowest vibration level of the ground electronic state, X, to the upper state, B, is shown; this excitation is rapidly followed by a relaxation into discrete or continuum vibrational levels of the ground electronic state.

Collisional excitation

In the collision between a molecule, M, and a collision partner, P

$$M + P \rightarrow M^* + P$$

energy may be transferred to or from the molecule, M, changing its energy state. The final state of the molecule M^*, may differ from the initial state in its electronic, vibrational or rotational energies, or in a combination of these energies. If the process is one of excitation, then the internal energy of M^* is increased at the expense of kinetic energy of the colliding pair. Conversely, in de-excitation processes, internal energy is converted into kinetic energy.

Collisional excitation of molecules into electronic states via thermal processes is generally rare in astronomical situations, because the energies required (a few eV) correspond to temperatures that are too high for molecules to survive for very long. The final state of the molecule, M^*, may then correspond to a dissociating state. Non-thermal excitation by fast particles can, however, be very important. Molecular hydrogen in collision with cosmic rays (mainly MeV protons and electrons) is directly excited electronically into the ionization continuum of the molecule

$$H_2 + \text{c.r.} \rightarrow H_2^+ + e^* + \text{c.r.}$$

and the free electron carries away some 30 eV of energy. This energy is partly lost in collision with other molecules and with atoms, e.g.

$$e^* + H_2 \rightarrow e^* + H_2^*$$

followed by

$$H_2^* \rightarrow H_2 + h\nu$$

so that at least some of the energy released in the ionization is radiated away. However, some of the electron's energy is shared in elastic collisions with atoms, e.g.

$$e^* + H \rightarrow e^* + H^*$$

and this represents a heating process for the gas which is important in situations such as molecular clouds from which starlight (the alternative energy source) has been excluded by interstellar dust. The molecular ion, H_2^+, created in the ionization of H_2 by cosmic rays, is responsible for initiating an extensive ion–molecule interstellar chemistry.

Thermal excitation and de-excitation of vibrational and rotational levels occurs in warm (around 2000 K) and cold (around 10 K) interstellar clouds (see figure 4). These processes compete with radiative relaxation, and together determine which molecular transitions are important in tracing and in cooling the gas. Emission is maximized when the collision rate is high, implying a high gas density, but not so high that radiative relaxation is quenched by collisional de-excitation. Hence, each transition of each molecule has associated with it a range of physical conditions in which it radiates most effectively, and this range is determined by equating the radiative rate (the Einstein A coefficient for spontaneous emission, $A_{\rm em}$) with the collisional excitation rate

$$n_{\rm coll} v_{\rm coll} \sigma_{\rm coll} \simeq A_{\rm em}$$

where $n_{\rm coll}$, $v_{\rm coll}$ and $\sigma_{\rm coll}$ are the number density of the colliding partner (usually H_2), and the velocity and cross section for the collisions.

For a given temperature, therefore, this equation gives the approximate number density range of collision partners for which particular transitions of particular molecules are significant radiators, the so-called critical density. For example, in molecular clouds at temperatures of about 10 K, then CO(J = 1–0) is an effective tracer of gas in which the number density of H_2 is about 10^9 H_2 molecules/m^3, whereas the 1-0 rotational emission of CS traces the gas most effectively when the density is about 100 times greater. The large differences between these

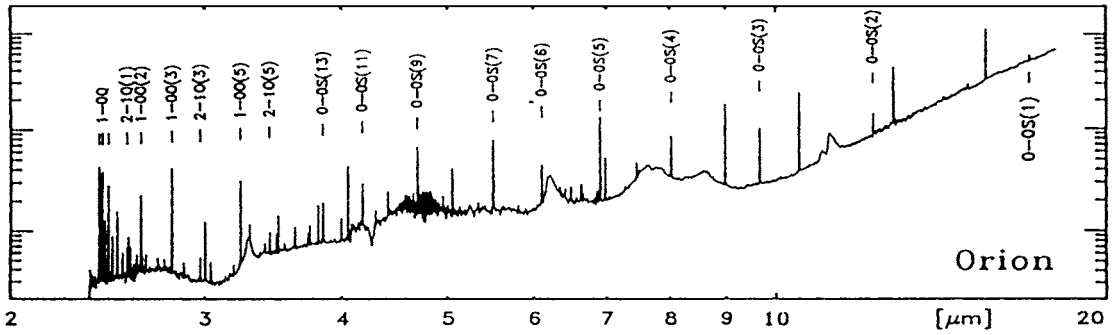

Figure 4. Vibrational emission from collisionally excited H_2 in warm interstellar gas in the Orion Molecular Cloud, detected by the Short Wavelength Spectrometer on the Infrared Space Observatory (ISO). This gas has been heated by the passage of an interstellar shock. The emission in the spectrum arises because the collisions between atoms and molecules in the gas are sufficiently energetic to populate the $v = 1$ and $v = 2$ levels and high rotational states. Relaxation to lower energy states then provides the radiation that is detected. (From Rosenthal *et al* 1999.)

values are caused mainly by the differences in the Einstein A values for the various transitions of each molecular species. In practice, the wealth of the chemistry and the richness available in molecular spectra ensure that there is a molecule and transition that is an appropriate tracer for almost any physical conditions in which molecules can exist in astronomy.

Surface physics

In interstellar molecular clouds, interstellar dust particles are generally well mixed with the gas. The particles have a range of sizes from about a nanometer to about a micrometer, and they probably have a porous open structure. They are probably composed mainly of silicates and carbons, and the total mass of interstellar dust is about 1% of the mass of interstellar gas. Both the gas and dust in molecular clouds are normally cold, with gas phase and solid temperatures typically around 10 K. At such low temperatures, there is a high probability that molecules stick to dust surfaces when they collide with them. For cold interstellar clouds with a normal gas:dust ratio then the time scale for loss of molecules from the gas phase by sticking to dust grains is rather shorter than $10^6(10^{10}\ \mathrm{m}^{-3}/n)(1/S_X)$ years, where n is the total number density of H atoms in all forms in the gas, and S_X is the sticking probability per collision of species X. Therefore, in a molecular cloud with number density $n = 10^{10}$ H atoms/m^3 and with a sticking probability of $S_X = 1$, the time scale t_0 for loss of molecules X from the gas is about one million years, i.e. the number of molecules of X would, in the absence of other processes, decay exponentially as e^{-t/t_0}. Therefore, significant depletion of gas phase molecules may occur within the typical age of a cloud (probably a few million years).

The interaction between a perfect surface of the dust grain and a closed shell molecule (i.e. one with all valencies satisfied) is a physical process involving long-range van der Waals forces. In fact, the surfaces of dust grains are likely to be defective, and stronger, shorter-range forces may also be involved. In any case, the interaction must involve a transfer of energy from the incident molecule into the grain if sticking is to occur.

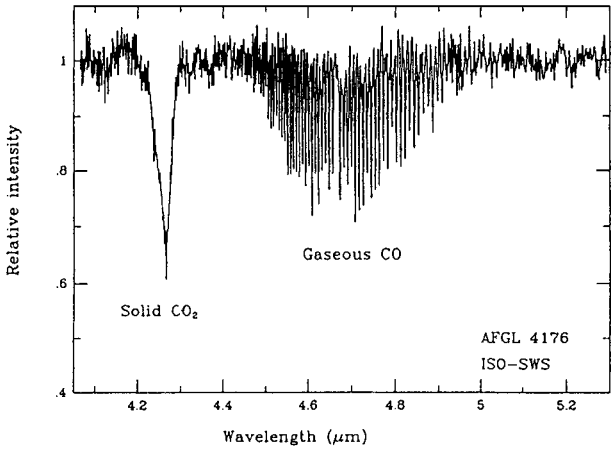

Figure 5. The normalized spectrum obtained with the Short Wavelength Spectrometer on the Infrared Space Observatory (ISO) towards massive young stellar object AFGL 4176 embedded in a dense molecular cloud. The strong broad absorption at 4.27 μm is due to solid CO_2, while the characteristic rotational structure near 4.4–4.9 μm indicates the line of sight. (From van Dishoeck *et al* 1996.)

Experimental and theoretical studies suggest that for most interstellar molecules and likely surfaces this interaction leads to energy transfer (possibly in repeated encounters) and that the sticking probability is on the order of unity. The detection of molecular ices on dust grains in molecular clouds confirms that sticking must be efficient. These ices are found to contain H_2O, CO, CO_2 and some other simple molecules, and molecules on the grains have a quite distinct spectrum from those in the gas (see figure 5). The ices are all detected by means of absorption in the infrared, corresponding to stretching vibrations; e.g. the CO molecule has a vibrational transition at a wavelength near 4.7 μm, and all rotational structure is suppressed for CO in the ice.

Observations show, however, that the fraction of any particular molecule locked up in ice on dust grains is often rather small. This suggests either that all such clouds are young, compared to t_0, or that some process is returning molecules from the solid to the gas phase. Since the former possibility seems implausible, several desorption mechanisms have been invoked. Thermal evaporation at the low temperature of interstellar dust is too slow, and the desorption mechanisms depend on non-thermal processes to create a local 'hot-spot' from which some evaporation may occur. Sources of energy for the 'hot spot' include deposition of energy by cosmic rays in the grains, photodesorption by a cosmic ray generated radiation field internal to the cloud, or chemical energy from reactions occurring at the surface of grains (see figure 6).

Piazzi, Giuseppe (1746–1826)

Born in Ponte di Valtellina, Italy, became a monk, professor of theology and professor of mathematics in Palermo, where he set up an observatory in 1789. Measured the positions of 7646 stars, discovering that the star 61 Cygni had a large proper motion. Because this suggests that the star is nearby, BESSEL chose it to investigate its parallax, making the first successful such measurement. He discovered the first minor planet, Ceres, on 1 January 1801, but was able to make only three observations before it was lost behind the Sun. Fortunately, GAUSS had developed mathematical techniques with which he could calculate the orbit and Ceres was recovered. The thousandth asteroid discovered was named Piazzia in his honour, as was the British astronomer CHARLES PIAZZI SMYTH.

Picard, Jean (1620–82)

Astronomer, born in La Flèche, France, became professor of astronomy at the Collège de France in Paris and a member of the Académie Royale des Sciences. He made instruments to make more accurate observations, including (with Auzout) the movable-wire micrometer to measure small angles, such as the diameters of the planets, and a sighting telescope for a quadrant and sector to determine star positions. He also measured the length of a degree on the meridian at Paris; the data were used by NEWTON in his calculations of the shape of the Earth. Picard measured the location of TYCHO BRAHE's observatory at Hven so that TYCHO's observations could be re-interpreted.

Pic-du-Midi Observatory (Observatoire Midi-Pyrenees) (OMP)

OMP is under the administrative supervision of both the Institute des Sciences de l'Univers (INSU) of the French National Center for Scientific Research (CNRS) and the Ministry of Research, Technology and Education. It has laboratories located at the Université Paul Sabatier in Toulouse, Bagnères, Lannemezan and at the summit of Pic du Midi de Bigorre.

The Pic du Midi Observatory is located in the Pyrenees, 2876 m above sea level—the highest observatory in France. Construction began on the site of a meteorological station in 1878. It was affiliated to the Toulouse University Observatory in 1903.

The main instrument is the 2 m Bernard Lyot Memorial Telescope, which began operation in 1980. It is named after the scientist who carried out the first experiments with a coronagraph in the 1930s. Other instruments include a 1.06 m lunar and planetary telescope, a solar telescope, four coronographs and a 60 cm telescope used by amateur astronomers.

The observatory is perhaps best known for solar and planetary observations and for the detailed lunar map produced for NASA's Apollo program in 1968. It is being developed as a cultural center for the Bigorre region in the Hautes-Pyrénées.

For further information see http://www.obs-mip.fr/omp/.

Pickering, Edward Charles (1846–1919) and Pickering, William Henry (1858–1938)

Astronomers—two brothers. Born in Boston, MA, Edward became director of the Harvard College Observatory and observed the brightnesses of 45 000 stars. He hired a number of women, including WILLIAMINA P FLEMING, ANNIE J CANNON, Antonia Maury and HENRIETTA LEAVITT, and produced the *Henry Draper Catalog*, classifying the spectra of hundreds of thousands of stars. He and HERMANN CARL VOGEL independently discovered the first spectroscopic binary stars. Edward's brother William, born in Boston, worked in Harvard's astronomy department with the new astronomical detector, dry-plate photography, becoming the first person to discover a satellite (Phoebe, Saturn's ninth moon) by photography in 1899. William established an outpost observatory for Harvard at Arequipa, Peru, and published sensationalist accounts of Martian canals, using the Arequipa telescopes, not for the stellar spectroscopy for which they had been established. For this and his inability to stay within budget his brother dismissed him from his post at Arequipa. William took up with PERCIVAL LOWELL and founded the Lowell Observatory to observe Mars. William's and Percival Lowell's careers overlapped later when William, independently of Lowell, predicted the position of a trans-Neptunian planet using the discrepancies in both the orbits of Uranus and Neptune as data, without it being found.

Pictor

(the Painter's Easel; abbrev. Pic, gen. Pictoris; area 247 sq. deg.) A southern constellation which lies between Columba and Dorado, and culminates at midnight in mid-December. It was introduced as Equuleus Pictoris (the Painter's Easel) by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2. The shortened form (which strictly translated means 'the Painter') was introduced by the American astronomer Benjamin A Gould (1824–96) in the 1870s and adopted by the IAU in 1922.

A small, inconspicuous constellation, the brightest stars in Pictor are α Pictoris, magnitude 3.2, and β Pictoris, magnitude 3.9, the first star found, in 1983, to be surrounded by a dusty disk, out of which planets may be condensing. There are no other stars brighter than fourth magnitude. Other interesting objects include ι Pictoris, a double star with two yellow (F9) components, magnitudes 5.6 and 6.4, separation 12.3″, that have the same proper motion, and Kapteyn's Star, a nearby star which has the second largest proper motion of any star.

There are no bright star clusters, nebulae or galaxies in Pictor.

See also: Beta Pictoris, Kapteyn's Star.

Pioneer Missions

Development of the first 'Pioneer' space missions began with the advent of the space age in 1957. After NASA was established by Congress in 1958, a further series of Pioneer missions were developed by NASA's Ames Research Center. The series included humanity's first probes of space outside Earth's influence, first passage through the Asteroid Belt, first flyby of Jupiter, first flyby of Saturn and first to escape the solar system. The final Pioneer mission was the United States' first intense study of Venus. Pioneers became consistently successful with numerous discoveries and long productive lives.

Pioneers 1–5 were part of the US Air Force's urgent program to get America competitive in the space age. These were the United States' first probes into space beyond altitudes of the early satellites to measure radiation and detect micrometeoroids. Pioneer 1 was launched in 1958, the year NASA was created. The program was completed in 1960.

Pioneers 6–9, launched in the years 1965 through 1969, were NASA's first spacecraft to explore space beyond any of Earth's influence. These four orbited the Sun independently from Earth, not far inside and outside Earth's orbital path at 1 astronomical unit (AU), 93 million miles, from the Sun. They measured the million-miles-per-hour wind of plasma (electrons and ions) emanating from the Sun. Pioneers 6–9 identified storms on the Sun's surface with magnetic storms from solar wind affecting communications and power grids on Earth. Pioneers 6–9 proved interplanetary space flight safe from destructive dust particles.

Pioneers 10 and 11 were launched in 1972 and 1973. Greatly more complex than earlier Pioneers, they were the first spacecraft to explore beyond Mars (1.6 AU),

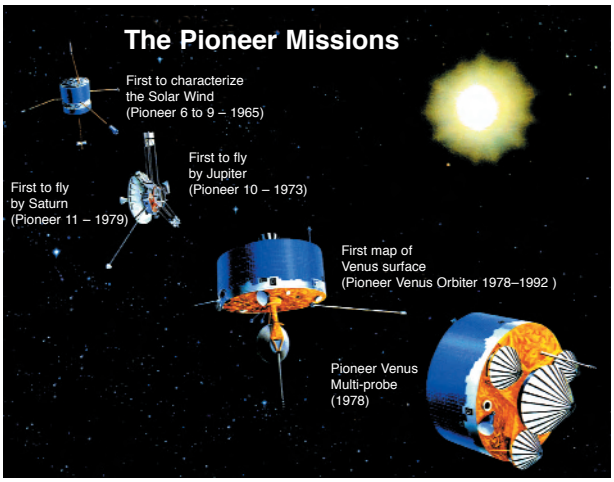

Figure 1. The Pioneer missions. From left to right: Pioneers 6 through 9, Pioneers 10 and 11, Pioneer 12 and Pioneer 13. (NASA / Ames Research Center.)

through the Asteroid Belt (2.5–4 AU), near Jupiter (5 AU) and beyond. Pioneer 11 later made a close reconnaissance with Saturn (10 AU). As the first man-made craft to escape the solar system, Pioneer 10 carried a plaque to identify where in our galaxy it originated and to introduce the creatures who made it. (Pioneer 11 carried a duplicate.) Data collection from Pioneer 10 continued through 2000.

The Pioneer Venus Orbiter and Multiprobe spacecraft, launched in 1978, were USA's first dedicated investigations of VENUS. The Orbiter mapped Venus's cloud-shrouded surface by radar, examined Venus's upper atmosphere, and explored interaction of the solar wind with Venus's atmosphere over a 14 yr period. (The Orbiter also measured rate of water loss from Halley's

comet as it passed near the Sun.) The Multiprobe deployed four probes into Venus's atmosphere describing the atmosphere down to the surface where lead and zinc would melt.

PIONEER VENUS, the last launched of NASA's 'Pioneer' series of programs, is summarized in a separate article. Below, from latest to earliest, are summary descriptions of the missions of Pioneers 10 and 11, Pioneers 6–9 and Pioneers 1–5. Forms of NASA's Pioneer spacecraft are illustrated in figure 1.

Pioneers 10 and 11

Dominating scientific objectives for Pioneers 10 and 11 were important practical questions about outer space: would exploration beyond the orbit of Mars with more sophisticated spacecraft be feasible and in what environments? Of special concern were possibilities of an impenetrable population of micrometeoroids among asteroids and of destructively intense radiation belts (charged particles trapped in a magnetic field) then theorized to be source of JUPITER's radio noise. Scientific objectives included study of the solar wind en route to Jupiter and beyond, and the maximum practical definition of Jupiter and its environment from a small spacecraft. Penetration of the boundary of the heliosphere with the interstellar medium (heliopause) was expected to occur between 5 and 10 AU. The interstellar medium was to be characterized.

The scientific instruments carried on Pioneers 10 and 11 are listed in table 1 and are indicated in figure 2.

Designed for 21 month or longer missions beginning in 1972 and 1973, Pioneer 10 was still transmitting data after 28 yr, and Pioneer 11 produced data for 21 yr. Launched in heliocentric orbits with energies to reach about 6 AU, their final planetary encounters in 1973

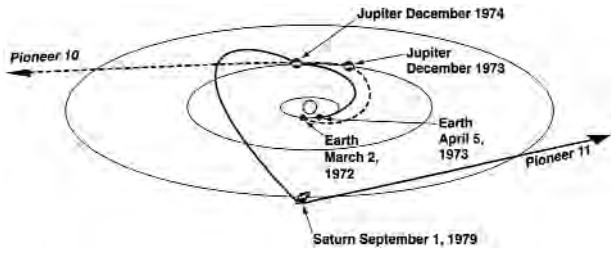

Figure 3. Pioneer 10 and 11 trajectories. (NASA / Ames Research Center.)

(Pioneer 10, Jupiter) and 1979 (Pioneer 11, Saturn) gave them sufficient velocities to escape the solar system. They recede at about 2.5 AU per year forward (Pioneer 11) and backward (Pioneer 10) along the Sun's motion among nearest stars (see figure 3).

Numerical density of dust particles was detected with an array of pressurized cells and was found to follow a diminishing gradient with solar distance unaffected by the ASTEROID BELT. (However, density was surprisingly greater in Jupiter's equatorial plane where VOYAGER later showed a faint ring.) Size distribution of particles was found as expected by the fewer particles larger than 10^{-9} g that could puncture thicker-skinned cells on Pioneer 11. An optical detector for tiny asteroids did not produce convincing observations.

At Jupiter, radiation belts were measured. Giant inflation and compression of Jupiter's shock wave in the solar wind were discovered dependent on the solar wind's energy. Intensity of trapped radiation was found to be several thousand times greater than Earth's, and the performance of some of Pioneer 10's subsystems and instruments was temporarily impaired by radiation. Jupiter's magnetic field, 19 000 times Earth's magnetic moment, was precisely modeled. Axis and rate of rotation of the nongaseous core of the planet were established for the first time. Cloud-top temperatures and an estimate of the planet's radiation heat balance were determined with the infrared scanner. Hydrogen and helium proportions in Jupiter's upper atmosphere and in space were measured. Abundance of gas and dust above the clouds were estimated with data from the Imaging Photo-Polarimeter (IPP). The first close-up 'pictures' of Jupiter, and of SATURN and its rings, came from the two-color optical imaging mode of the IPP. ('Images' were constructed from recordings of light intensity each half-milliradian of rotation of the spacecraft as it passed by Jupiter and Saturn, and the instrument's small telescope was stepped such that the planet would appear to move correspondingly in cone angle during each rotation. Clarity and scientific value of these 'images' greatly exceeded expectations.)

Exploration of Saturn by Pioneer 11 was first contemplated several months after launch of Pioneer 10. Feasibility of a Jupiter gravity assist to Saturn was

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

identified then, and the longevity of Pioneers' newly redesigned plutonium power sources was showing promise. After Pioneer 10's successful equatorial flyby of Jupiter, Pioneer 11 was targeted for a much closer steeply spiraled 'reverse' (clockwise looking south) flyby of Jupiter. The new trajectory greatly enhanced definition of Jupiter's characteristics, such as magnetic field, charged particle distribution with latitude, polar optical depth etc, admitted a much smaller radiation dose to the spacecraft (from higher average Jovian latitudes and higher speed) and induced a trajectory inclined 16° to the Sun's equatorial plane that subsequently encountered Saturn (see figure 3). A proposal for high-risk passage between Saturn and its visible rings was abandoned in 1977 for a test of Voyager's intended penetration of the ring plane just outside the A ring. Approach to Saturn was at low inclination to its ring plane, so *in situ* measurements of the environment could be made about 3/4 inward from the rings' visible outer edge. A magnetic field and radiation belt was discovered and defined at Saturn. Interaction of radiation particles with ring material was found to produce a uniquely radiation-free space under the rings. Corresponding to results obtained at Jupiter, particulars of Saturn's atmosphere, external heat balance, internal structure, mass and rotation were gleaned from Pioneer 11's encounter.

A confusing picture of solar influence in interplanetary space was initially presented by Pioneer data. Energetic interactions between magnetic field lines and charged particles led to a number of theories to explain the data from Pioneers, later combined with data from other spacecraft. Reversal in polarity of the Sun's magnetic field every 22 yr, i.e. every other 11 yr solar cycle, was discovered through Pioneer 11's data. Pioneer 10 and 11's data, together with data from Voyagers and others, have been analyzed to show a dynamic pattern of plasma embedded in outward-moving magnetic field lines beyond 70 AU. The heliopause lies very much farther out from the Sun. Low-energy helium, oxygen and nitrogen ions, increasingly encountered by both spacecraft toward extremes of their productive travels, suggest incursions from the still unexamined interstellar medium.

Densities of cosmic rays of energetic electrons and ions from interstellar space were found to increase as Pioneers 10 and 11 ranged beyond 10 AU from the Sun, but not as rapidly as expected. This implication of strength of the Sun's influence is further evidenced by modulations in cosmic ray spectra. High-speed streams of solar wind correlate with decreased local cosmic rays in lower energy ranges. These observations add to suggestions that the radius of the heliosphere varies and is perhaps much greater than 100 AU.

Precise Doppler tracking of Pioneers 10 and 11 has provided intervals of data with which to test hypotheses of long (several AU) gravity waves emanating from celestial cataclysms. None has been detected. Mysteriously, these tracking data persist in showing 10^{-10} g excess in gravitational attraction of the solar system, apparently due to unidentified mass.

On March 1, 2002, engineers and technicians at the NASA Jet Propulsion Laboratory's (JPL) Deep Space Network in Goldstone, Calif., sent a signal to Pioneer 10 which is still hurtling toward the fringes of the solar system. Twenty-two hours later, at 1:47 p.m. EST, engineers and technicians at the network's facility in Madrid, Spain, monitoring a 70 meter dish antenna, heard Pioneer's response. The signal was received on the 30th anniversary of the spacecraft's launch (2 March, 1972). NASA previously lost contact with Pioneer 10 in August 2000, but made contact again in April 2001 by switching the spacecraft to a different communications mode. Before 1 March, NASA had most recently made contact with the spacecraft on 9 July, 2001. There was another successful contact with telemetry received on 27 April 2002 with more possible in the future depending upon the overall communication system link margin, spacecraft power, and the durability of the transmitter. Scientific data were received during these contacts from the single remaining operating instrument onboard and passed on to the NASA Ames Research Center mission operations center and then relayed to the Principal Investigator, James Van Allen, at the University of Iowa.

Spacecraft

The form of the Pioneer 10 and 11 twins is an 8 ft diameter parabolic dish reflector with equipment and instruments in (and on) a box mounted behind (figure 2). Two pairs of radioactive thermoelectric generators (RTGs) and a magnetometer protrude from the equipment box on three booms, and an antenna feed is mounted on a tripod in front of the reflector. Mass was about 285 kg. The spacecraft were built by TRW Inc.

Three especially difficult technical problems were overcome in development of Pioneers 10 and 11: (1) electrical power was needed to at least 6 AU from the Sun; (2) reliable communications were required through 7 AU of the unexplored interplanetary medium; (3) magnetic cleanliness was required to permit measurement of the weak interplanetary field levels. Plutonium RTGs had been flown but required basic improvements to reach past Jupiter reliably and to gain more from the isotope's 93 yr half-life. The generators were redesigned and rigorously qualified against impacts and temperatures of accident to ensure against leakage into Earth's environment. The telemetry system was designed with convolutional encoding so that data bit errors could be corrected for a then-theoretical improvement of communications at extremely low signal power margins. The Deep Space Network, developed and operated by JPL, improved

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

designs of receivers on Earth so much during development and flights of the Pioneers that data were ultimately recorded from more than 10 times the original 7 AU system design capability. The spacecraft's material content and arrangement of its circuits were planned and tested to minimize magnetic fields. Partly because of the spacecraft's simplicity (e.g. no camera or gyroscopes), a uniquely low background was achieved with Pioneer allowing unexcelled measurement of the interplanetary and planetary magnetic fields.

Pioneers 6–9

Pioneers 6, 7, 8 and 9 were the first Pioneers developed under management of NASA's Ames Research Center. Each was of the same general design, built by TRW Inc. They carried scientific instruments to detect and measure magnetic field, electric field, plasma, cosmic rays and their anisotropy, and cosmic dust. Their orbits, at ranges from 0.8 to 1.1 AU from the Sun, provided descriptions of SOLAR WIND from varying longitudes around the Sun in Earth's orbital plane.

Pioneer 6–9's data showed strong correlations of solar wind velocities and densities with eruptions on the Sun's surface. 'Magnetic storms' which upset communications and power grids on Earth became predictable when Pioneer 6–9 spacecraft found their sources on the rotating Sun before Earth was exposed. Solar wind was found to travel past the spacecraft at about 400 km sec^{-1}. Embedded magnetic field lines appeared to move outward with solar wind. Severe solar storms could propel plasma to Earth in as little as 20 min. The Earth and its magnetic field were observed to create a huge 'bow wave' in the solar wind with a 'tail' of turbulence outward from the Sun. Variations in speed and density of solar wind result in large changes in the volume behind its shock wave shielding Earth's magnetic field.

Precise tracking of Pioneers 6–9 over their extended lives enabled NASA to substantially improve fundamental metrics of the solar system needed for guiding interplanetary trajectories. The Sun/Earth mass ratio uncertainty was reduced to 2.5×10^{-6}. Orbits of the Earth and other planets were much better defined than before. Radio transmission from Pioneer 6 began to be occulted by the Sun's corona in 1968. Effects of the corona on the radio carrier signal provided direct data on changing magnetic and electrical characteristics of the corona.

Spacecraft

Structures of Pioneer 6–9 spacecraft were simple rotating cylinders with axes aligned such that their flat 'pancake' antenna patterns always illuminated Earth (figure 1). Long-term stability of these aircraft spinning at 60 rev min^{-1} was the first such application of the principle for pointing scientific sensors and for controlling antenna pattern. Data telemetered at low rates were originally communicated from tracking stations via standard teletype format in blocks of alphabetic characters before breakdown into engineering and scientific intelligence by computers. Delta E and Delta L launch vehicles guided Pioneers 6–9 into the desired orbits around the Sun; compressed gas was pulsed to reorient spin axes normal to their orbital plane.

Designed for at least 6 months of service, Pioneers 6, 7, 8 and 9 produced much more than hoped and gained wide notice, with operating lives of 32, 19, 19 and 25 yr, respectively.

Pioneers 1–5

Pioneer 1 was launched in 1958, the year NASA was created by Congress. Intended to determine the extent of radiation belts in Earth's magnetic field above altitudes of the earliest satellites, Pioneer 1 fell short of plan at about one-third the Moon's altitude. Pioneer 2's launch failed completely. (A number for Pioneer 2 would not have been assigned by subsequent NASA policy.) Pioneers 3 and 4 discovered the VAN ALLEN (radiation) BELTS to consist of two distinct bands of charged particles trapped in Earth's magnetic field. Pioneer 4 passed close to the MOON (37 000 miles) to measure radiation in its vicinity. Although second by 1 week to pass the Moon, Pioneer 4 became humanity's first spacecraft to escape Earth's gravity. Pioneer 5 made the first measurement of the interplanetary magnetic field outside the Earth's influence and operated for the then record of 106 days. These five earliest Pioneers were launched on Thor Able (Pioneer's 1, 2 and 5) and Juno 2 (Pioneer's 3 and 4) launch vehicles. Instruments they carried were magnetometers, radiation detectors, Geiger counters and micrometeoroid detectors.

Pioneer Venus Mission

Rather contrary to its name, Pioneer was not the first, although certainly the most comprehensive mission yet, to explore VENUS, and most of our current knowledge, of the atmosphere in particular, derives from the measurements it made around 20 years ago. It also made the first detailed radar maps of Venus' surface, although these are now largely superseded by the higher-resolution data from the more recent MAGELLAN mission.

Pioneer Venus was in fact two missions, launched separately within a few months of each other. The first launch placed in orbit the first artificial satellite of Venus (the 'orbiter' mission), while the second delivered four probes, one large and three small, directly into Venus' atmosphere (the 'multiprobe' mission). The orbiter mapped the atmosphere above the clouds at infrared wavelengths, the clouds themselves in the visible and ultraviolet, and the surface using radar. Operating from a highly elliptical orbit, it also investigated the thermosphere of Venus, utilizing measurements of the drag on the spacecraft as it dipped down into the atmosphere, to altitudes as low as 150 km, and occasionally lower. Aided by the angular coverage which it obtained as a result of its spin-stabilized configuration, the orbiter also obtained the first comprehensive maps of the Venus magnetosphere.

History and scientific objectives

The Pioneer Venus program was born of a series of studies carried out in the USA in the late 1960s and early 1970s, aimed at defining the best approach to addressing the major mysteries posed by Venus. The mission in its final form began in January 1972, when NASA formed a Pioneer Venus Science Steering Group (SSG) and assigned the project to its Ames Research Center in Mountain View, California. The SSG laid out a list of the most important scientific questions to be addressed and worked with the project to devise the mission design which would provide the best answers within the imposed cost ceiling of $200 million. From this the concept of the two-launch strategy, within a single launch opportunity (originally 1976, but eventually 1978), evolved.

The multiprobe was to address questions of the nature of the clouds on Venus, their layering, microstructure, and composition, solar heating of the atmosphere as a function of depth, the atmospheric circulation and its driving forces, the bulk composition of the atmosphere, the loss of water and stability of carbon dioxide, the deep atmosphere vertical temperature structure, ionospheric turbulence, ion chemistry and exospheric temperature. The orbiter, to be in position before, and operating during, the probe descent, was to address cloud-top morphology, the cause and extent of the 4 day 'super-rotation' at the cloud tops, vertical temperature structure, gravitational moments, exospheric temperature, composition and loss of water and ionospheric temperatures and motions.

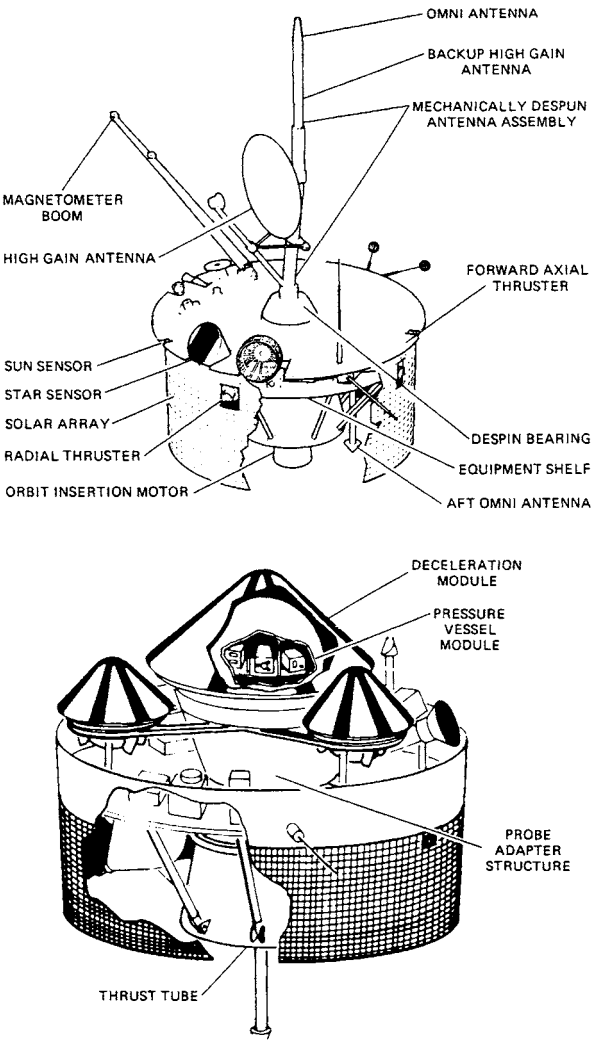

Figure 1. The Pioneer Venus orbiter (top) and multiprobe (bottom) spacecraft, showing the accommodation for the scientific instruments on the upper platform below the antenna on the orbiter, and the positioning of the cone-shaped probes on the corresponding platform of the multiprobe bus (NASA).

Mission description

Both spacecraft used the same basic body, a flat cylinder 2.5 m in diameter and 1.2 m high, built by the Hughes Aircraft Corporation (figure 1). The orbiter was spin stabilized, using a 1.09 m diameter despun dish antenna to communicate with the Earth. It also carried a solid-fuel rocket motor to decelerate the spacecraft on arrival and allow it to achieve orbit insertion. It weighed 553 kg when launched, including 55 kg of scientific instruments and 179 kg of propellant. The multiprobe weighed 875 kg, including the probes themselves at 585 kg.

The mission was launched from Cape Canaveral using two Atlas–Centaur vehicles. The orbiter was launched first, on 20 May 1978, followed by the multiprobe on 6 August. The orbiter arrived at Venus on 4 December

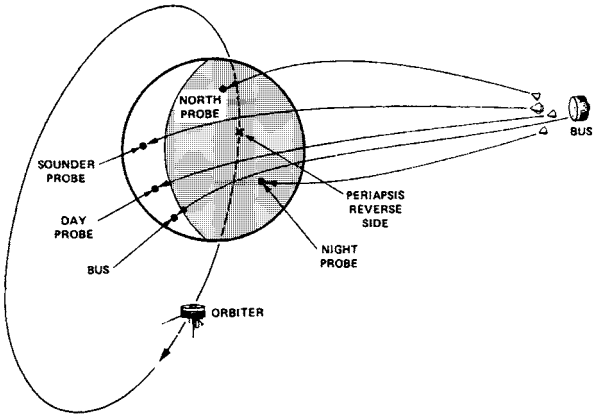

Figure 3. Geometry of the Pioneer Venus probe entries on 9 December 1978, showing the orbiter already on station (NASA).

of the same year, followed by the probes only 4 days later; the latter could follow a faster, more direct trajectory since their velocity relative to Venus on arrival was less critical. Figure 2 shows the trajectories they followed and figure 3 the geometry of their deployment at Venus. The large, or 'Sounder' probe landed near the equator, at 4.0° latitude and 304.0° longitude, the three small probes, now named 'North', 'Day' and 'Night' at 60.2°, 3.2°, −31.3°, 317.7°, and −27.4°, 56.6° respectively. In addition, the bus which had carried the probes prior to separation entered at −37.9°, 290.9°, carrying two instruments (a neutral mass spectrometer and an ion mass spectrometer) and operated down to 100 km altitude. The probe instruments functioned down to a height of about 12 km above the surface, when most of them stopped working simultaneously. An enquiry showed the cause of this to have been the failure of insulating material on one of the external sensors, which caused a short circuit. One of the probes survived its impact with the surface and continued to transmit data for a further hour.

The orbiter functioned throughout its nominal mission of 1 Venus year with the loss of only one instrument, the infrared radiometer, after 72 days of excellent performance. It went on to obtain valuable data for nearly 14 Earth years, finally entering the atmosphere and burning up during mid-1992.

Scientific payload

The total complement of scientific instruments on all six spacecraft is summarized in table 1. The instruments are grouped according to their principal scientific objective, and the code names begin with O, L, S or B to signify mounting on orbiter, large probe, each of the three small probes, or probe carrier bus, respectively. The principal investigator and institution responsible for each experiment are also shown.

Scientific achievements

The scientific results from the mission are very extensive and in some cases still being accumulated. Compilations can be found in the references given at the end of this article. The following is a brief summary.

Pioneer Venus obtained radar altimetry for about 90% of the surface of the planet and made a number of radar images (see VENUS: SURFACE). With these, volcanic and tectonic features such as rift valleys, mountains, continents and volcanoes were discovered. It was found that there is a unimodal distribution of topography on Venus, whereas Earth has a more bimodal distribution, resulting from a dearth of elevated regions of continental size. The detailed mapping confirmed the existence of great troughs or 'rift valleys', the presence of which had been expected from Earth-based radar data. No evidence was found for a Venusian analogue to the continuous ridge systems which are characteristic of the terrestrial plate tectonics system.

Over the course of its 14 yr lifetime, the Pioneer Venus orbiter obtained measurements of the gravity field that, when combined with the radar altimetry results, showed that the interior behavior of Venus is more Earthlike than Mars or the Moon. However, there is a great difference between Venus and Earth in that on Venus there is a strong positive correlation of gravity with topography at all wavelengths.

Probe and orbiter made refined measurements of the abundances of major, minor and noble gas species in the lower, mixed atmosphere and in the upper, diffusively separated atmosphere (see VENUS: ATMOSPHERE). The orbiter discovered that sulfur dioxide is an important absorber of ultraviolet radiation a wavelengths below 3200 Å, accounting in part for the well-known ultraviolet markings in the clouds. However, another absorber, still unidentified but probably a solid or liquid component of the clouds, must be present to account for absorption at longer wavelengths.

The structure of the clouds was investigated globally and vertically, producing (when taken with results from earlier Soviet probes) the first good data on cloud layering, the distribution of particles of different sizes, composition and optical properties. These quantities are now known to

vary enormously across the planet, so the Pioneer Venus large probe nephelometer (cloud sensor) and particle size spectrometer data, once taken to represent the mean global structure in a relatively horizontally homogeneous cloud, are now regarded as a snapshot of a very dynamic cloud system (see also CLOUDS IN PLANETARY ATMOSPHERES). Net flux measurements determined the sinks for solar radiation and the sources and sinks of infrared radiation in the lower atmosphere and clouds at four locations characterizing daytime, night-time, low-latitude and high-latitude conditions. Taken altogether, these provided an improved understanding of the Venusian version of the 'greenhouse effect' which, coupled with global dynamics, explains the high surface temperature. The orbiter instruments detected radio signals that are thought to originate from lightning discharges in the clouds of Venus, thereby confirming earlier observations made by VENERA probes.

One of the biggest mysteries concerning Venus is the dynamics of its atmosphere. Measurements of vertical profiles of wind velocities at four probe locations, and global wind measurements at the cloud tops and above by remote sensing, helped to clarify the vertical profile of the four-day winds observed in UV markings in the upper cloud layers, while orbiter infrared imaging discovered remarkable structure in the polar regions of the atmosphere. This included the 'polar dipole', a kind of double vortex several thousands of km across rotating around the pole. This and the polar collar, a cold wave-like disturbance surrounding the dipole, are aspects of the circulation pattern in those regions which still remain to be understood.

Direct entry-probe measurements and remote sensing of temperature profiles with the infrared radiometer produced much new data concerning the atmospheric state properties (temperature, pressure and density) globally and vertically from the surface through the clouds and into the upper atmosphere. Several remarkable features were revealed for the first time, including a reverse temperature gradient from the equator to the pole (making the atmosphere above the pole warmer than that above the equator) and global-scale wave motions. Prominent among the latter are the solar tides, i.e. the diurnal cycle of heating of the atmosphere by the Sun, which on Venus have two maxima per day in contrast to the one on Earth. Pioneer Venus also discovered that the high atmosphere well above the cloud tops is much colder at night than in the daytime, with a surprisingly abrupt boundary between them.

Pioneer Venus mapped the AIRGLOW on the dark side of Venus, determined the global characteristics of the ionosphere—its ion composition, temperature, flows, electron concentration and temperature, modification of ionospheric characteristics by input from the solar wind and the production and maintenance of a night-side ionosphere. It determined the nature of the solar-wind interaction with the planet, including temporal and spatial studies of the location of the bow shock and ionopause, and particle and energy input to the atmosphere (see VENUS: INTERACTION WITH SOLAR WIND). Finally, it confirmed that Venus has little if any intrinsic magnetic field, and set a very low upper limit on the magnetic moment of the planet.

Pisces

(the Fishes; abbrev. Psc, gen. Piscium; area 889 sq. deg.) A northern zodiacal constellation which lies between Pegasus and Cetus, and culminates at midnight in late September. Its origin dates back to Babylonian times and it is said to represent Aphrodite, the goddess of love in Greek mythology, and her son Eros, who jumped into the Euphrates to escape from the multi-headed Typhon and were turned into fish. Its brightest stars were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*.

A large but rather inconspicuous constellation, the brightest stars in Pisces are η Piscium, magnitude 3.6, γ Piscium, magnitude 3.7, α Piscium (Alrescha), a close binary with bluish-white (A0 and A3) components, magnitudes 4.2 and 5.3, separation 1.9″, and ω Piscium, magnitude 4.0. Other interesting objects include ζ Piscium, a double star consisting of white (A7) and pale yellow (F7) components, magnitudes 5.2 and 6.4, separation 23″, that share the same proper motion, each of which has a very close (separation <0.05″) companion, 19 Piscium (also called TX Piscium), one of the few so-called 'carbon stars' visible to the unaided eye (magnitude range 4.8–5.2), and M74 (NGC 628), a ninth-magnitude face-on spiral galaxy mistakenly cataloged by John Herschel as a globular cluster.

Pisces also contains the First Point of Aries, or vernal equinox (see First Point of Aries), which when named lay in the neighboring constellation of Aries but has since moved into Pisces as a result of precession.

Piscis Austrinus

(sometimes called Piscis Australis; the Southern Fish; abbrev. PsA, gen. Piscis Austrini; area 245 sq. deg.) A southern constellation which lies between Aquarius and Grus, and culminates at midnight in late August. Its origin dates back to Babylonian times, and it is usually shown on early celestial charts unnaturally drinking water from an urn carried by Aquarius. Its brightest stars were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*, though he included α Piscis Austrini (Fomalhaut) in the neighboring constellation of Aquarius.

A small but not inconspicuous constellation, Piscis Austrinus is easily recognized by virtue of α Piscis Austrini, magnitude 1.3. There are no other stars brighter than fourth magnitude. Interesting objects include β Piscis Austrini, a wide binary with bluish-white (A0) and yellow (G2?) components, magnitudes 4.3 and 7.9, separation 30″, γ Piscis Austrini, a close binary with bluish-white (A0) and pale yellow (F5) components, magnitudes 4.5 and 8.2, separation 4.1″, and NGC 7314, an eleventh-magnitude spiral galaxy.

Plage

A region of intensified emission in the solar chromosphere. Plages are revealed in monochromatic images obtained in the light of various emission lines, for example, the hydrogen-α line and the 'H' and 'K' lines of ionized calcium. The name derives from the French word for 'beach', an allusion to the fact that these features stand out like bright sandy beaches against the fainter background of the chromosphere as a whole.

Physically, plages are regions of enhanced temperature and density that float in the chromosphere. They are heated by magnetic fields, with strengths of upwards of 0.01 T, which are concentrated within solar active regions. Plages usually cover most of the area occupied by an active region, forming before sunspots appear in the region and persisting for some time after the spots have disappeared.

They are similar in nature to the faculae that are observed in the photosphere.

Planck Surveyor

European Space Agency mission to measure temperature fluctuations in the cosmic microwave background with a precision of about 2 parts in a million and an angular resolution of about 10 arcseconds. Named after Nobel Prize winning physicist Max Planck. Will carry a 1.5 m telescope and two instruments to cover frequencies between 30 and 857 GHz. Planned for launch together with FIRST in 2007.

Planck, Max (1858–1947)

Born in Kiel, Schleswig-Holstein, Germany, Nobel prizewinner for physics (1918). Calculated the radiation of a black-body by means of the introduction of the quantum theory of light. The Planck satellite launched to study the black-body spectrum of the cosmic microwave background was named for him.

Planet

A body, in an independent orbit around the Sun or another star, that is not self-luminous. The major planets of the solar system show a variety of sizes and physical states. The inner planets are of rock and metal, while the outer planets are much larger and predominantly gaseous (and liquid, under the high pressures in their interiors), with relatively small rock/metal cores. Asteroids in the main belt are mostly rocky; Pluto is icy with a rocky core, and the Kuiper Belt objects (which have been given minor planet designations) are icy. The icy comets, though, are excluded from the definition. The term *planetary body* is sometimes used to include sizeable planetary satellites and asteroids.

There is no agreed lower size limit which determines what constitutes a planet. The largest bodies orbiting the Sun are sometimes referred to as major planets to distinguish them from the minor planets, and the category 'minor planets' includes near-Earth objects only meters in size. Meteoroidal particles and dust do not count as 'planetary'. The question of an upper size limit has been highlighted with the discovery in the 1990s of *exoplanets*—planets orbiting other stars. All but a handful of them are several times the mass of Jupiter; the most massive are better described as *substellar objects*. The more massive a substellar object, the more closely its characteristics approach those of a brown dwarf. A common rule of thumb is that 10 Jupiter masses marks the division between planets/substellar objects and brown dwarfs.

Planet X

A name given to a hypothetical tenth major planet once believed to exist in the outer solar system, beyond the orbit of Neptune. The 'X', which stood for 'unknown', was also appropriate as the roman numeral for 'ten'. The label 'Planet X' was originated by Percival Lowell. From the late nineteenth century, he and others, including William H Pickering, worked out orbits for a large tenth planet which they believed responsible for gravitational perturbations of Uranus, which, even since the discovery of Neptune in 1846, did not appear to be following the orbit calculated for it. In 1930 Clyde Tombaugh discovered Pluto. Though Pluto was only 5° from Lowell's predicted position, and in a similar orbit, it soon became clear that the new planet was too small to be Lowell's Planet X. Tombaugh continued searching, and by 1943 had surveyed the entire sky, but without finding a Planet X.

From the 1940s, further predictions were made for a tenth planet whose perturbations would account for the deflection of comets from an outer reservoir into orbits that would bring them into the inner solar system. Charles Kowal's search from 1977 to 1984 turned up the 180 km Chiron, orbiting between Saturn and Uranus, briefly hailed in the media as the tenth planet. Others, including Robert Harrington and Thomas Van Flandern, returned to the problem of discrepancies in the orbits of Uranus and Neptune, and issued a variety of predictions for a tenth planet; but searches revealed nothing.

In the 1990s the need to invoke a Planet X disappeared. Voyager 2 in 1989 had established a new mass for Neptune, and Myles Standish and others demonstrated that the discrepancies in the orbital motions of Uranus and Neptune could be explained away by this and by observational errors. The discovery from 1992 onwards of the first members of what appears to be a large population of asteroidal objects beyond the orbit of Neptune seems finally to have brought the Planet X chapter to a close.

Planetarium

Usually a domed building housing a special projector that is used to simulate the night sky. The institution associated with a planetarium is devoted to popular education in astronomy. The term was originally used to describe teaching devices, known as orreries, designed to portray the orbital motions of the planets and their satellites. The first planetarium was opened at the Deutsches Museum in Munich in 1923.

Planetarium installations vary greatly. The larger planetariums have an extensive exhibition area, museum collections and a seating capacity in excess of 600. The most common projector, since the 1940s, is manufactured by Zeiss in Oberkochen, Germany. Modern Zeiss instruments are large, technically advanced combinations of lenses, lights, gears and motors. They are designed to place the planets, Sun and Moon in their correct locations among the stars for thousands of years past and future. Manufacturers in Japan and the United States compete with Zeiss, producing an array of instruments appropriate for a variety of dome sizes and for different purposes.

Planetary Atmospheres

Planetary atmospheres are the external gaseous envelopes which surround the planets. In the case of the telluric planets, they represent only a negligible fraction of their mass, but they play an essential role in the energy balance between the surfaces and the Sun. In the case of the GIANT PLANETS, which are mostly gaseous, they account for a large fraction of their total mass and constitute their major component. Planetary atmospheres show extremely diverse physical conditions, with surface pressures ranging from nanobars to hundreds of bars and surface temperatures ranging from 40 to over 700 K; they also show large differences in their chemical compositions, from the lightest, hydrogen-dominated, to the densest, dominated by carbon dioxide.

In spite of these differences, there are striking similarities in the physical and chemical processes involved: photochemistry and photodissociation take place as a consequence of solar radiation and, in some cases, magnetospheric effects; condensation takes place on almost all planets, generating cloud structures, sometimes subject to seasonal effects; volcanism is present, or has been present, on several planets and/or satellites, and sometimes drives the surface/atmosphere interaction.

From Mercury to Pluto

Among the nine planets of the SOLAR SYSTEM, all except one have an atmosphere (table 1). MERCURY, the planet closest to the Sun, is too small and too hot to retain a permanent atmosphere. The other planets are all surrounded by a gaseous envelope, but there is an incredible variety in their characteristics. Even within the group of the TERRESTRIAL PLANETS, the atmospheres of Venus, the Earth and Mars show extreme differences in their physical conditions: on Venus, the surface pressure reaches almost 100 bar and its surface pressure is 730 K, while at the surface of Mars, the mean pressure is only 6 mbar and the mean temperature ranges around 210–230 K (see VENUS: ATMOSPHERE, MARS: ATMOSPHERE). Between these two extremes, the EARTH'S ATMOSPHERE shows intermediate physical conditions. Concerning their visual aspect, there is little in common between the cratered surface of Mercury, the thick white-yellow cloud layer of Venus, presumably composed of sulfuric acid, the blue planet Earth surrounded by white clouds, and the red rocky surface of Mars. The terrestrial planets, however, exhibit more similarities in their chemical atmospheric composition, dominated by carbon dioxide and nitrogen. In the case of the Earth, carbon dioxide is indeed present too, trapped under the oceans in the form of carbonates. The main difference, for our planet, comes from the presence of large amounts of oxygen, due to the presence of life.

At further distances from the Sun, the four giant planets—JUPITER, SATURN, URANUS and NEPTUNE—also show striking differences in their visual appearance. Although they are all composed mostly of hydrogen and helium, their clouds, composed of various minor constituents, are very different. Giant planets have no 'surface'; they are mostly gaseous and their central core is not directly observable. Finally, PLUTO, the ninth planet, is a single case by itself. This small icy body, surrounded by a very tenuous atmosphere of nitrogen, shows more similarities with the satellites of the outer solar system than with any other planet.

Some satellites are also surrounded with a stable atmosphere: TITAN, Saturn's largest satellite, has a nitrogen-dominated atmosphere with a surface pressure comparable to that of the Earth. TRITON, Neptune's largest satellite, also has a nitrogen atmosphere with a surface pressure of a few nanobars, comparable to that of Pluto when the planet is close to perihelion. Finally IO, the Galilean satellite closest to Jupiter, has a very tenuous atmosphere of sulfur dioxide generated by active volcanism.

What is an atmosphere?

All planetary atmosphere are governed by the hydrostatic law, which expresses the balance between pressure and gravity. Its equation is

$$\mathrm{d}P/\mathrm{d}z = -\rho g \tag{1}$$

where P is the pressure, z the altitude, ρ is the density and g is the acceleration due to gravity. Combining this equation with the ideal gas law, one can derive the pressure distribution as a function of altitude. In an isothermal atmosphere, its equation is

$$P = P_0 \exp(-z/H) \tag{2}$$

where H is the scale height:

$$H = RT/\mu g \tag{3}$$

R is the universal gas constant and μ is the mean molecular weight. H is the height at which the pressure is reduced by a factor e; the value of H, at the surface of terrestrial planets, is about 8 km for the Earth, 14 km for Venus and 10 km for Mars; it reaches 20 and 40 km in the observable regions (at a pressure of about 0.5 bar) of Jupiter and Saturn respectively. For a given planet, the scale height is proportional to the temperature and thus slightly varies with altitude following the thermal profile. Atmospheric constituents are mixed up to high altitudes; the separation level is the homopause, at a pressure of a few microbars in the case of the Earth. Below the homopause is the homosphere, where mixing is achieved by convection in the lower part and by eddy diffusion above.

Thermal structure

The thermal structure of an atmosphere is a direct result of its interaction with the incoming solar flux. In the case of the telluric atmospheres, a small fraction of the solar radiation (especially in the UV and the near IR) is absorbed by the atmosphere itself (gas and/or

§ Rotation period of the magnetic field.

aerosols) while a larger fraction (in the visible range) is absorbed by the surface; a third part is scattered and reflected outside. Near the surface, the troposphere is heated by the infrared radiation of the surface, itself heated by the solar flux. This temperature gradient induces convection which transports the energy toward higher levels; this part of the atmosphere is called the troposphere. The tropopause, at the top of the convective cells, corresponds to a temperature minimum. Above it, in the stratosphere, the energy is transferred by radiation. In several cases, the temperature increases again with altitude, due to the absorption of the solar UV flux by atmospheric gases or aerosols. In the case of the Earth, ozone absorbs in this region while, in the giant planets, the solar flux is absorbed by methane and stratospheric aerosols. The stratosphere may be more or less complex, depending on the spectroscopic properties of the atmospheric constituents. Other heating mechanisms contribute at higher altitudes, including dissociation of radicals and propagation of gravity waves. At even higher altitudes, the solar flux is energetic enough to ionize all atoms; this region, called the ionosphere, strongly interacts with the magnetic field, when present, to produce, in particular, auroral phenomena (see AURORA).

The thermal structure described above basically applies for all planets (figures 1 and 2), except that in the case of the giant planets there is no surface to absorb the visible solar flux, which is absorbed in the troposphere. In addition, with the exception of Uranus, all giant planets exhibit an internal source of energy, comparable to the energy received from the Sun. This internal source is probably the result of specific evolutionary processes.

In the case of the telluric planets, the GREENHOUSE EFFECT can strongly affect the temperature distribution of the lower troposphere. Its mechanism is as follows: the surface, heated by the visible solar flux, mostly emits in the infrared range. This radiation can be absorbed by atmospheric gases if they present spectroscopic transitions in this spectral range: this is the case for CO_2, H_2O and CH_4 in particular. The lower atmosphere is then heated, and radiates back to the surface to heat it even more, and the process accelerates. The extreme case is Venus, which now has a surface temperature of 730 K while its equilibrium temperature, in the absence of greenhouse effect, would be 229 K! Both the Earth and Mars also present a significant greenhouse effect, which causes an increase of 33 K for the Earth and 4 K for Mars.

General circulation

Because the solar flux falls preferentially near the equator of all planets (except Uranus), latitudinal temperature and pressure gradients are created, and the heat is redistributed by thermal winds. The effect of the planet's rotation then determines the general circulation. Due to Coriolis forces, pole-ward winds are apparently deflected in the direction of the planet's rotation. A typical example is, on the Earth, the cyclonic motions (in the northern hemisphere) around low-pressure centers at mid-latitudes; similar examples exist in the southern hemisphere of Jupiter. If nonlinear terms, like centrifugal force, dominate in the momentum balance, the balance with the pressure gradient is called cyclostrophic balance. The Rossby number gives the ratio of nonlinear terms to Coriolis terms in the momentum balance:

$$R_0 = U/fL \tag{4}$$

where U is the mean zonal wind and L is a typical horizontal length scale of the weather system. f is given by

$$f = 2\omega \sin\theta \tag{5}$$

where ω is the rotation angular velocity and θ is the latitude. Geostrophy or cyclostrophy take place respectively for small or large values of R_0. The thermal wind equation is derived from a combination of the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

geostrophic balance, the hydrostatic equilibrium and the ideal gas law

$$H\frac{\mathrm{d}U}{\mathrm{d}T} = -\frac{R}{fa}\frac{\mathrm{d}T}{\mathrm{d}\theta} \qquad (6)$$

where a is the planetary radius. If the temperature decreases toward the poles (as is usually the case), the zonal winds increase with height; this is observed on terrestrial planets up to the tropopause. In the case of Jupiter the situation is different, as strong winds have been measured in the deep troposphere by the Galileo probe; the circulation in this case is also influenced by the existence of the internal heat source.

The rapidly rotating planets Mars and Earth, as well as the giant planets, are characterized by geostrophic dynamics, with low values of R_0 (0.1–0.5). In contrast, for Venus and Titan, which have very slow rotation, R_0 is in the range 10-100. Venus exhibits a strong superrotation, and it seems also to be the case for Titan.

The exploration of planetary atmospheres

How can we study planetary atmospheres? There are two distinct classes of methods. The first one, used for centuries, is ground-based telescopic observation; the second, which started in the 1970s, is *in situ* exploration from space probes.

Observations using ground-based telescopes consist first of images, which allow one to study the atmospheric cloud structures and to monitor their evolution with time, an essential tool for climatology studies. The main technique used for remote sensing is spectroscopy: spectra recorded at different wavelengths, from the ultraviolet to the millimeter range, allow us to probe different altitude levels of the planetary atmospheres (depending upon the atmospheric composition). Infrared spectra of planetary atmospheres, in particular, are essential for determining their chemical composition and their thermal profile. Another powerful method is the photometric observation of stellar occultation events: the stellar flux decreases at the time of the OCCULTATION and increases as the star emerges from the planet's atmosphere. The study of the lightcurve provides valuable information about the refractive index of the atmosphere, which allows us to determine the temperature if the mean molecular weight is known; this technique has been successfully used in the case of Uranus, Neptune and Titan.

With the space era, we now have access to direct measurement of the physical parameters and the chemical composition of planetary atmospheres. Sensors are used for direct measurements of the pressure and the temperature, and mass spectrometers provide the chemical analysis of the atmosphere. The first space probes devoted to PLANETARY EXPLORATION were flyby or orbiter spacecraft, equipped with remote sensing instruments (cameras and spectrometers): then landers were sent for *in situ* analysis of the atmosphere and the surface. Some of these missions have been especially fruitful: VIKING on Mars (launch in 1974, operation in 1976–7), VOYAGER toward the giant planets (launch in 1979, operation in 1979–89), and, more recently, GALILEO toward Jupiter (launch in 1989, operation in 1995–2000). In parallel, after the launch of Mars Pathfinder and Mars Global Surveyor, the exploration of Mars is the object of an extensive on-going space program including, in forthcoming years, the planned launch of several planetary probes.

For the terrestrial planets, most of our knowledge has

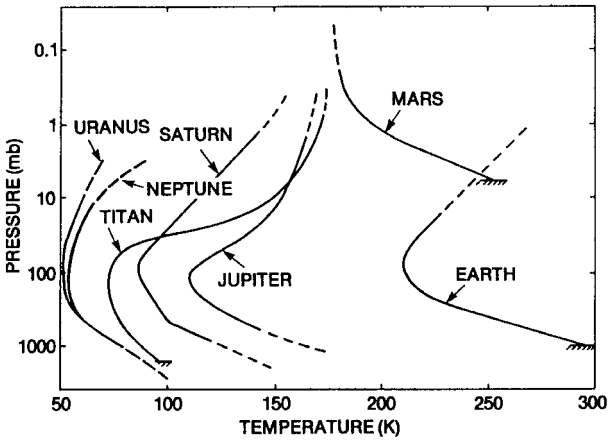

Figure 1. Vertical temperature profiles as a function of pressure for the planets (except Venus, out of scale) and Titan. The figure is taken from Samuelson (1997).

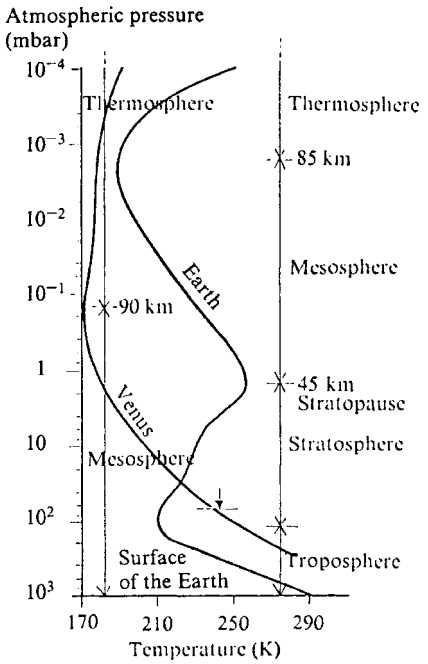

Figure 2. Temperature profiles in the atmospheres of the Earth and Venus. The pressure scale is common to both planets. The altitude scales refer to the Earth (left) and Venus (right). On Venus, the surface temperature is 730 K and the surface pressure is 94 bar. The figure is taken from Encrenaz *et al* (1995).

come from space exploration. The atmosphere of Venus was extensively explored in the 1970s and 1980s by the Venera and Pioneer Venus missions with, in addition, the Galileo flyby (1990); its surface has been mapped by the radar of the Magellan mission (1991–3). Our knowledge of Mars mostly relies on the results of the Viking mission which, with its two orbiters and landers, studied the Martian atmosphere and surface over a full Martian seasonal cycle (2 years). For both Mars and Venus, the space missions provided most of our knowledge about the atmospheric composition, the thermal profile and the properties of the clouds, as well as their spatio-temporal variation.

In the case of the giant planets, our knowledge about the chemical atmospheric composition and the cloud and thermal structure first came from ground-based observations, especially in the infrared range, until the major achievement of the Voyager mission, which followed the precursor approach of the Pioneer 10 and 11 spacecraft in the 1970s. Voyager was especially successful in revealing the thermal structure and the chemical composition of Titan's atmosphere, largely unknown before. Finally, the Galileo mission, with the first launch of a probe in the atmosphere of a giant planet, has opened a new era in the space exploration of the outer solar system, with an extended monitoring of the planetary system. The next step of this program will be the CASSINI MISSION, which includes the descent of the Huygens probe into Titan's atmosphere and the 4-year monitoring of the whole Saturnian system by the Cassini orbiter.

The origin of planetary atmospheres

In order to understand the formation of planetary atmospheres and their subsequent evolution, we need to know how the planets themselves formed. The history of the solar system is now understood in its basic concept, and generally accepted among the scientific community. Like other stars and stellar systems, the Sun and the solar system generated from a mass of interstellar gas, called the primordial nebula. The chemical composition of this gas must have been close to the composition generally found in the universe, i.e. mostly hydrogen (about 75%) and helium (25%), with all other elements (C, O, N,...) with their cosmic abundances, i.e. below 1%. Due to some instability (for example, the explosion of a nearby star), this primordial nebula starts rotating and contracting. At some point, the rotation becomes fast enough for the gas to collapse into a rotating disk. The central part will become the Sun, and the planets will form from the outside disk. We now observe some examples of such PROTOPLANETARY DISKS outside the solar system, around young nearby stars, so this formation process seems to be common in the universe.

As the temperature cools down, the matter of the disk, mostly gaseous at the time of the collapse, combines from atoms to molecules and starts to condense (minerals and silicates first, then the H_2O ice, then the other ices like CO_2, NH_3, CH_4, etc). Some molecules like CO and H_2 stay in gaseous form because of their low condensation temperatures. These are the bricks which will form the future planets, through the process of repeated collisions, leading to the formation of PLANETESIMALS. These small particles will continue to collide with each other and to stick together, giving rise to a larger and larger body. The protoplanet grows through the repeated accretion of infalling bodies, finally acquiring, for diameters larger than about 100 km, a spherical shape as a result of self-gravity.

The major differences that we see today in the composition of the various planets and their atmospheres can largely be explained, at least to first order, by an effect of the condensation sequence which takes place as the temperature decreases from the Sun to the outside edge of the protoplanetary disk. This condensation sequence may have been the following: in the vicinity of the Sun, at heliocentric distances smaller than about 2 astronomical units (AU), only the heavy elements (minerals, silicates, etc) could be found in solid form. These elements were used in the planetesimals which formed the terrestrial planets. This explains why these planets are relatively dense and small. In contrast, at large heliocentric distances (at 5 AU and beyond) most of the molecules are in solid form, especially the molecules made with the most abundant elements H, O, C and N: H_2O, CO_2, CH_4, NH_3. Molecular hydrogen H_2, however, is still in gaseous form.

As a result, the cores formed by the ACCRETION process were much larger than in the case of the terrestrial planets, since, following the cosmic abundances, the mass contained in the ices is by far larger than the mass contained in the heavier elements. Theoretical models estimate that the cores of the protoplanets formed at 5 AU and beyond may have been about 15 times the mass of the Earth. At this stage, a qualitative difference appears in the evolution of the two classes of planets. Indeed, cores of 15 terrestrial masses have a gravity which is sufficient to accrete the surrounding nebula, mostly composed of gaseous hydrogen and helium; in the case of the terrestrial planets, the gravity field is not sufficient for this accretion to take place. This scenario explains why the giant planets are so massive (Jupiter's mass is over 300 times the Earth's one), mostly gaseous, and mostly formed of hydrogen and helium.

At the heliocentric distances of Uranus and Neptune, the matter available for the core accretion must have been less abundant than close to the Sun; as a result, the time needed to accrete a core of 10–15 terrestrial masses must have been significantly longer. It is possible that in the meantime a large fraction of the light elements of the disk were blown away during the T-Tauri phase of the young Sun. In this case, Uranus and Neptune had little gas available in the surrounding nebula to be accreted around their cores. This would explain why Uranus and Neptune are smaller than Jupiter and Saturn, and why the relative mass fraction of their cores (about 60 to 80%) is much higher than for Jupiter and Saturn (3 to 15%).

In the case of the terrestrial planets, the process of formation must have been very different. It is generally

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

believed that these atmospheres have been at least partly outgassed from the interior of the planets by active volcanism. It has been suggested, in particular by Owen, that part of their atmosphere might have been brought from the exterior through the infalling flux of meteorites (see Atreya *et al* 1989); a significant part of these meteorites must have been of cometary origin, i.e. rich in volatiles (H_2O, CO_2, etc). As will be discussed below, the recent measurement of the deuterium abundance in comets provides a constraint to this hypothesis. However, because the terrestrial planets are much less massive than the giant planets, they could not retain in their atmospheres the lightest elements like H_2 and He. Only heavier molecules like CO, N_2, O_2 and CO_2 could stay within the lifetime of the solar system.

Chemical composition of planetary atmospheres

In view of their chemical composition, planetary atmospheres also fall into two distinct classes. The terrestrial planetary atmospheres are mostly composed of CO_2 and N_2, with variable amounts of H_2O, O_2 and traces of CO and O_3. In contrast, the giant planets' composition includes, apart from hydrogen and helium, CH_4 and NH_3, with traces of many other minor constituents.

In which form were carbon and nitrogen in the primordial nebula and the protoplanetary disk? Calculations of thermochemical equilibrium indicate that C is in the form of CH_4 or CO, and N is in the form of NH_3 or N_2, according to the following reversible chemical reactions

$$CH_4 + H_2O \rightleftharpoons CO + 3\,H_2$$

$$2\,NH_3 \rightleftharpoons N_2 + 3\,H_2$$

which evolve toward the formation of CH_4 and NH_3 at low temperature, and the formation of CO and N_2 at high temperature. To first order, this favors the formation of CH_4 and NH_3 in the cold and dense environment of the giant planets where thermochemical equilibrium can effectively occur (this may not be the case in dilute media, like the interstellar medium or the medium from which comets formed). In the outer solar system, this scenario, however, does not explain the origin of the atmospheres surrounding the small bodies, Titan, Triton and Pluto, all dominated by nitrogen with a small fraction of methane. As for the terrestrial planets, these atmospheres are 'secondary', i.e. probably outgassed from the cores, with some possible contribution from meteoritic impacts. The presence of both N_2 and CH_4 on Titan, Triton and Pluto is not fully understood at present. In the case of Titan, formed within the Saturnian sub-nebula, the atmosphere may have originally contained CH_4 and NH_3, ammonia being subsequently converted into N_2 by photolysis, and H_2 escaping in the process. The case of Pluto and Triton is different, as they were not formed in a dense environment, and they may have accreted like comets in a dilute medium far from equilibrium.

In the vicinity of the Sun, the reactions evolved toward CO and N_2. CO in turn reacts with H_2O according to the chemical reaction

$$CO + H_2O \rightarrow CO_2 + H_2.$$

This favors the formation of CO, CO_2, N_2 and H_2 in the terrestrial atmospheres. Hydrogen escapes, as it is too light to be trapped by the planetary gravity field, and the planets are left with an atmosphere of N_2, CO_2, CO and H_2O in various amounts. As mentioned above, the presence of a large fraction of O_2 on Earth is due to the presence of life.

The relative evolution of the telluric planets

By which processes did Venus, the Earth and Mars evolve toward their extreme present conditions, while they started from more or less similar initial conditions? The three planets indeed are in the same range of heliocentric distances, diameters and densities, yet exhibit extreme differences in their present surface temperatures and surface pressures. In addition, water has almost completely disappeared from the atmosphere of Venus and Mars, while large amounts are present in the terrestrial oceans. How was such an evolution possible? Several authors, including Pollack, Hunten and Donahue (see Atreya *et al* 1989), have tried to rebuild the history of the three planets on the basis of the data available now: physical parameters, chemical composition, abundances of rare gases, isotopic ratios, etc. Although the question is still not completely solved, it is generally believed that two factors were especially important: the difference in heliocentric distance and the variation in the planetary mass.

Although not more than a factor 2, the change in heliocentric distance implies a significant variation of the equilibrium temperature at the corresponding orbit. This temperature change is such that a key atmospheric element, water, tends to take different states on the three planets: mostly gaseous in the Venusian atmosphere, liquid at the Earth's surface and solid on Mars. We know that water was very abundant in the early stages of Venus' history, through the measurement of the deuterium-to-hydrogen ratio, derived from the HDO/H_2O ratio. The abundances of HDO and H_2O have been measured from their infrared signatures in the spectra of Venus and Mars. As previously suggested from the Pioneer Venus measurements in 1982, the D/H ratio in Venus today, as derived from HDO/H_2O, is 120 times higher than the terrestrial value. In the case of Mars, it is 6 times higher than the Earth value. The explanation for HDO enrichment is the following: deuterated water—or heavy water, HDO—escapes slightly more slowly than H_2O; over the age of the solar system, this process leads to an accumulation of deuterium and an enhancement of the D/H ratio. The very high D/H ratio in Venus today is the signature of a very strong water outgassing over the history of Venus; the smaller, but still significant

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

enrichment of deuterium in Mars today indicates a moderate outgassing over the history of Mars. In the case of the Earth, no outgassing occurred since the water is trapped in the oceans. It is worth noticing that the comparison of the D/H ratio in the Earth's oceans and in comets provides an important constraint upon the origin of the atmosphere of the Earth. As recently measured on COMET HYAKUTAKE and COMET HALE–BOPP, the D/H ratio derived from H_2O and HDO in comets is twice as high as its value in the terrestrial oceans. There is no mechanism which could explain a deuterium depletion within the oceans over the history of the Earth. As a consequence, the water on Earth cannot come entirely from comets; about at least half of it must have been outgassed from its interior.

In the case of Venus, the presence of gaseous water in massive amounts must have been important in increasing its surface temperature, through the greenhouse effect: H_2O, like CO_2, is a gas which is spectroscopically very active in the infrared. This process is an amplifying one and is believed to be responsible for the very high surface temperature of Venus observed today (see VENUS: SURFACE). How did water escape from Venus? Several processes have been proposed, including dissociation by solar UV radiation, or reaction with the surface, or reaction with the atmospheric CO, but the question is not fully answered yet, and will require the development of more sophisticated photochemical models.

In the case of Mars, the situation is completely different. Due to the lower temperature, the abundance of gaseous water is severely constrained by saturation and the greenhouse effect has to be much less significant. There was some time in Mars' history, however, where the atmosphere must have been significantly more dense than today, as demonstrated by the signs of intense flooding shown on the surface. How did Mars lose its atmosphere, and how did water disappear? First, because of the smaller mass of the Martian globe as compared with Venus and the Earth, volcanism (whose energy is generated by the radioactive elements of its core) must have stopped earlier, thus interrupting a major contribution to the origin of the atmosphere. In addition, CO_2 and N_2 may have been trapped in the surface in the forms of carbonates and nitrates respectively, but these constituents have not been firmly detected yet. Nitrogen might also have partly escaped gravitationally. Water might be present in the form of permafrost under the Martian surface, as also observed in some places on the Earth. Discovering such water reservoirs under the Martian surface would be of major importance for understanding the whole history of the Martian climate, and this research will be a main objective of the future space exploration of Mars (see MARS: SURFACE).

Finally, the evolution of the terrestrial atmosphere follows a third different scenario: the primitive atmosphere of the Earth probably contained large amounts of CO_2, which would have been able to generate a greenhouse effect comparable to the one on Venus. However, the presence of liquid oceans of water prevented this fatal evolution. Carbon dioxide was trapped in the oceans and reacted with the rocks to form carbonates ($CaCO_3$). The amount of gaseous CO_2 consequently decreased and the greenhouse effect remained limited, so the surface temperature was never high enough for the oceans to evaporate.

Dynamics and circulation of planetary atmospheres

All planetary atmospheres show evidence for temporal variations, on very different time scales, diurnal and seasonal. In the case of the terrestrial planets, the climate is, as in the case of the Earth, dominated by the incoming solar flux and its variation as a function of latitude. The dynamics of the giant planets are more complex, as they are driven both by the incoming solar flux and the internal heat source.

The case of Mars is of special interest as it shows striking analogies with the case of the Earth. The inclination of Mars' rotation axis on the ecliptic is 25°, which generates strong seasonal effects. Both CO_2 and H_2O can condense on Mars. These constituents condense on the northern and southern caps during winter, and partially sublimate (especially CO_2) to recondense on the opposite pole. After the pressure measurements achieved by the two Viking landers over a full seasonal cycle (1976–7), it was realized that this process involves as much as 25% of the mass of the total atmosphere. This enormous variation in the atmospheric mass induces strong meridional transport of heat and momentum; it is also responsible for the transport of water from one pole to another, the permanent CO_2 southern polar cap acting as a cold trap for water vapor. These transport phenomena are associated with violent winds which can generate huge dust storms, lifting particles as high as 50 km. The dust in turn influences the Martian meteorology by increasing the opacity of the atmosphere, heating the atmosphere and/or acting as nuclei for CO_2 or H_2O condensation. The Martian climate is thus the complex product of various seasonal cycles—carbon dioxide, water and dust—which are closely interconnected.

It should be mentioned that another solar system body exhibits climatic changes even stronger than those of Mars, but still with some analogies: Triton, Neptune's largest satellite, has a subsolar point which varies from +52 to −52° in latitude. Its very tiny N_2 atmosphere, constrained by saturation, is subject to seasonal variations in abundance which are probably much stronger than in the case of Mars. On Triton there is probably a transfer from pole to pole comparable to the one on Mars, with N_2 and CH_4 on Triton playing the roles of CO_2 and H_2O respectively on Mars.

Jupiter and Saturn show a cloud structure along parallel belts and zones, which have been monitored by astronomers over the last three centuries. These striking features result from the fast rotation of the giant planets (about 10 h), associated with convective atmospheric motions. After the Voyager investigations—and more recently after the exploration of Jupiter by the Galileo probe—it is now generally believed that the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

zones are cloudy regions of ascending motion, while the belts, more free (if not completely free) of clouds, are regions of subsidence. This type of circulation is similar to the Hadley circulation on Earth, which moves the humid air upward at the equator and brings back dry air downward at the tropics. The space results on the Jovian circulation are also supported by ground-based observations, especially in the infrared range, which show that the belts are associated with 'hot spots': the infrared radiation is stronger in these regions, because it comes from deep atmospheric levels where the temperature is higher. The latest Galileo observations do confirm this interpretation, but also show that the reality is much more complex that this simple scheme. The dimension scale of the hot spots is apparently very small, and the circulation is more complex by far than the simple zone/belt scheme. In addition to the latitudinal variation of the incoming solar flux which governs the climate in the terrestrial atmospheres, one has to take into account the effect of the internal energy which, for all giant planets except Uranus, is comparable to the absorbed solar energy.

Another striking feature of the dynamics of the giant planets is the presence of cyclonic or anticyclonic features which consist of columns of ascending motion rising above their immediate surroundings and which are colder than their environment. The most famous of these features is the GREAT RED SPOT (GRS), in the southern hemisphere of Jupiter, which has been observed over more than three centuries, since the early days of planetary telescopic observations. The stability of this feature is still an enigma. Many structures of this kind exist elsewhere, on the giant planets but also on Earth (they are equivalent to our giant hurricanes), but these structures have short time scales. In particular, a similar feature, the dark spot, was discovered on Neptune at the time of the Voyager 2 flyby, in 1989; however, recent observations by the HUBBLE SPACE TELESCOPE, over the past 2 years, have shown that this feature has now disappeared. Most of the similar features on Jupiter—the so-called 'white ovals'—are also variable with time.

What is the nature of the red material responsible for the Great Red Spot, and what is the constituent which makes the Jovian belts brown? We still do not know. The red color could be due to phosphorus or sulfur compounds, but there is at present no identification of them. More spectroscopic observations of these regions in the infrared and the ultraviolet range, from the Galileo orbiter or with the Hubble Space Telescope, might help to determine their chemical nature. We better understand the white ovals and plumes, most likely associated with ammonia clouds. These NH_3 clouds are also likely to be responsible for the yellow color of Saturn. The greenish color of Uranus might be due to the presence of methane. In large abundances, gaseous methane is responsible for the intense blue color of Neptune, while the white spots are methane cirrus.

The small bodies of the outer solar system

One planet—Pluto—and three satellites—Titan, Triton and Io—are surrounded with a stable atmosphere. Apart from Io, they are all composed of nitrogen and methane; apart from Titan, they are all tenuous, with a surface pressure of a few microbars (Triton and Pluto) or even a few nanobars (Io).

Io, Jupiter's closest Galilean satellite, is another unique object in the solar system: it is the only body showing evidence for active volcanism. The strong tidal forces generated by Jupiter's gravity field, coupled with the eccentricity of Io's orbit and the perturbations due to EUROPA, induce a permanent remodeling of Io's surface. The active volcanoes of Io were first visually identified by Voyager, which also detected a plume of sulfur dioxide above one of them. The evidence for a stable atmosphere came from millimeter observations which detected transitions of SO_2 (its major constituent) and SO. The atmosphere of Io was found to be permanent but variable with time and localized, either produced by SO_2 frost sublimation or by direct volcanic outgassing.

Titan's atmosphere was largely unknown before its exploration by the Voyager spacecraft. Not only did this mission reveal the nature of its atmosphere—primarily nitrogen—and its thermal structure, but the Voyager infrared spectrometer also detected a large number of unexpected complex molecules, mostly hydrocarbons and nitriles. These species are the products of methane photodissociation—the second atmospheric constituent in term of abundance—and the dissociation of nitrogen by energetic particles associated with the magnetic field of Saturn. The fascinating aspect of this discovery is that the complex molecules which were found are exactly those which appear in the laboratory in simulation experiments aiming to form HCN polymers and amino acids from the irradiation of CH_4, H_2O and NH_3 ices. Could a prebiotic life have developed on Titan? Although the presence of a surface, and perhaps even lakes, may favor the development of heavier molecules, the low temperature is definitely a handicap that slows down all chemical reactions considerably. Nevertheless, the study of Titan's atmosphere could possibly shed some light on our understanding of the early stages of the history of our own atmosphere, and this is among the major motivations for the Cassini mission.

Pluto and Triton show striking similarities in their physical properties (diameter and density) but also in the composition of their atmosphere. Pluto's orbit is highly elliptical with a period of 248 years. For a period of 20 years, its heliocentric distance is very close to 30 AU, which makes its incoming solar flux similar that one of Triton. This probably explains why they both at present have a surface pressure of a few microbars, mostly composed of nitrogen, with traces of methane; the surface pressure is apparently constrained by N_2 saturation.

Planetary Exploration

Nine known planets, a large number of natural satellites, planetary rings, comets and asteroids are the constituents of the solar system. Knowing when and how they all formed, understanding the physical and chemical processes that shaped the planets and their moons as well as their relations with the Sun and the wider cosmos are the reasons why we want to explore the solar system. However, the fulfillment of the above scientific goals requires efforts that have embraced, and still do, large sectors of our society. The development of new technologies, more and more sophisticated and miniaturized, is essential for the progress of the exploratory programs, but such development requires investments which can only be supported at the highest political level. That is why the history of the exploration of the solar system is, in a way, the history of the post-world-war-II society.

The first steps to the Moon

It all started with the launch by the USSR of the Luna 1 spacecraft to the MOON, on 2 January 1959. It accomplished its mission successfully and will be remembered as the first man-made craft to leave the Earth's gravity field. The Soviet Union launched, on 12 September 1959, Luna 2, which impacted the lunar surface as planned, and, on 4 October of the same year, Luna 3, which circumnavigated the Moon and sent back the first images of the far side. The effort carried out by the USSR to develop reliable launchers had paid off and put the Soviet planetary program in a leading position for about 5 yr. Indeed, it was only on July 1964 that the US Ranger 7 reached the Moon and sent back thousands of images of that part of the surface named Mare Cognitum. Such a late success of a NASA spacecraft gives to the landing of US astronauts on the surface of Moon, only 5 yr later, a miraculous touch. In fact, the first six Ranger missions had failed for a wealth of technical reasons. The Soviet Union, meanwhile, had launched from 1959 throughout the 1960s a total number of 17 fully successful missions to the Moon.

It is common understanding to consider the landing of Apollo 11 and its crew on the surface of the Moon as the apex of lunar exploration. This landing is also considered as the final victory of the technology of the US over that of USSR. However, we tend to forget that already in 1970 the USSR had been able to return samples from the Moon's surface with a fully automated mission (Luna 16) and that with a periodicity of a mission every other year, until 1976, lunar sample return missions were carried out successfully. NASA landed its first automated rover on Mars in 1996 and we will have to wait until 2003 to see a European lander on another planet.

In the US, between 1967 and 1969, an incredible number of missions to the Moon were successfully launched in preparation of the human landing. The data acquired during those years constituted the main database, together with the Russian data, to be used by the scientists to understand the geology, the geophysics and the geochemistry of the Moon. Five other landings followed the first human landing in 1969, the last of them being the mission of Apollo 17 in 1972. The US had demonstrated, in the course of their successful human landings, their technological superiority and, in particular, their capacity to define a goal that involved politically, scientifically and technologically the entire nation. On the contrary, the hyperprogrammed USSR had failed in coagulating around the conquest of the Moon the different interests of the nation. Contrasting industrial, political and technological interests did not favor the accomplishment of the ultimate goal: landing a Soviet cosmonaut on the surface of the Moon.

New data were made available to the scientific community almost 20 yr later by the CLEMENTINE Mission in 1994 and the LUNAR PROSPECTOR Mission in 1998. The Clementine spacecraft was developed by the US Department of Defense in order to test both new microtechnologies and management procedure for the faster construction of smaller spacecraft. It provided us with extensive maps of the lunar surface, including some multispectral maps. Lunar Prospector, launched on 6 January 1998, was to determine mainly surface chemistry and the lunar gravity field. The most noticeable result acquired by this last lunar mission is the determination of large quantities of hydrogen in the cold lunar polar regions. Some scientists speculated from this result that water ice might be present near the poles of the Moon; however, such a presence has yet to be proven, even after the impact of Lunar Prospector on the surface on 31 July 1998.

The major scientific result of the exploration of the Moon is that we now have a well-measured time scale of its evolution, thus providing us with a comparative basis to interpret the evolution of other planetary bodies, including the Earth. The larger CRATERS on the Moon record a period of intense bombardment which ended about 3.7 billion years ago. Presumably, this is a process that affected all the inner planets more or less at the same time. By counting and measuring the lunar crater density, and by determining accurately the age of the lunar samples with radioisotope dating techniques, we have been able to construct a chronological reference which allow us to interpret the geological history of Mars, Mercury and Venus.

The analysis of the returned samples has revealed that two major provinces constitute the lunar crust: the young, sparsely crated and low-albedo mare terrains, and the old, heavily cratered, high-albedo highlands. Isotopic dating has shown that the youngest mare basaltic lava flows have an age of about 2.5 billion years; the oldest-dated lunar rocks have been found in the lunar highlands and have shown a radiometric age of about 4.5 billion years. Geophysics of the Moon, i.e. its internal constitution and state, is still the subject of intense debate within the scientific community. We know that the Moon had a strong magnetic field during the early phases of its history and

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

that this field had disappeared since. We still do not have clear data and understanding of the internal structure and the presence of a small molten core still needs to be proven definitively. Moreover, all the available geochemical and geophysical data refer to the near side of the Moon and there is still a need to obtain data from the far side in order to complete our geological and geophysical picture of our natural satellite.

Exploring the void: the interplanetary missions

The space within which the solid constituents of the solar system revolve around the Sun is far from being void and knowledge about it is essential to understand the 'environment' of that part of the universe where we live. Indeed, the particles emitted by the Sun, as well as the electric and magnetic fields associated with such emissions, have a strong influence on the planetary bodies and on the spacecraft supposed to explore them. It goes without saying that manned flights outside the Van Allen belt required detailed information on the possible natural hazards the astronauts were supposed to face.

At the beginning of the space age a good number of spacecraft which missed their primary scientific goals and became lost in the interplanetary space provided interesting and novel information on the solar system 'environment'. The PIONEERS 1, 2, 3 and 4 launched between 1958 and 1959, belong to this category. They were indeed supposed to flyby the Moon and reach a final orbit around the Sun, but never accomplished their primary goals. Nevertheless, these missions were the first to show that human beings could have reached the Moon without major problems due to the interplanetary radiation. The following series of Pioneers (6–9), launched between 1965 and 1969, were successfully put in an orbit around the Sun similar to that of our planet and have provided us for many years with vital information on the interplanetary fields and particles and on the Sun itself.

In 1990 a US shuttle launched the ESA-made Ulysses spacecraft. No other name would have been more appropriate for this spacecraft which is still travelling along an out-of-the-ecliptic orbit which takes it periodically above the poles of the Sun.

Ulysses is one of the many spacecraft dedicated to the study of the interplanetary space in the framework of the International Solar Terrestrial Physics Program (ISTP). This program includes a large number of spacecraft mostly provided by the Russian Space Agency (RKA, recently renamed the Russian Aviation and Space Agency, Rosaviakosmos), the Japanese Institute for Space Science (ISAS), NASA, NOAA and ESA (ACE, AKEBONO, ASTRID, CLUSTER, DMSP, EQUATOR-S, ETS-VI, FAST, FREJA, GEOTAIL, GMS-4, GOES, GOMS, IMP-8, INTERBALL-TAIL, INTERBALL-AURORA, LANL S/C, MSX, NOAA/TIROS, OERSTED, POLAR, PRACTICE-4, ROCSAT, SAMPEX, SOHO UARS, WIND).

The exploration of the inner region

Taking for granted that exploration of our planet can be neglected in this context, and having described previously the exploration of the Moon, we are left with two planets: MERCURY and VENUS.

All the planetary bodies orbiting the Sun in a belt between 0.4 and 1.5 astronomical units from the Sun, i.e. Mercury, Venus, the Earth–Moon system and Mars, are mainly composed of rock and metal and are characterized by a relatively small amount of volatiles. A trend of decreasing density from Mercury to Mars is also a noticeable characteristic of the inner planets. This trend could be determined by the thermodynamical behavior of the PROTOPLANETARY NEBULA in which pressure and temperature decrease with increasing distance from Sun. However, it could also be due to local anomalies in the course of the fractionation and re-aggregation of these bodies during the early phases of their collisional accretion. The comparative study of the formation and evolution of the inner planets provides us with a better understanding of the Earth as well of those parameters which determine planetary evolution.

Mercury

What we know of Mercury is due to the NASA mission, MARINER 10, which, launched in 1973, flewby the planet three times. This spacecraft will be remembered as the first one to make use of the 'gravity assist' technique thanks to the brilliant calculations of the Italian scientist Giuseppe Colombo. Indeed, the gravitational attraction of Venus was used to slow Mariner 10's solar orbital velocity down in order to let the spacecraft 'fall' towards the Sun and reach the orbit of Mercury. In the course of its three flybys, Mariner 10 was able to return about 12 000 images, corresponding to a coverage of about 40% of the surface of the planet. The Mariner 10 images revealed a densely cratered surface, dominated by the Caloris Basin, a huge multi-ringed impact crater. Caloris appears to have been filled by lava flows similarly to the Lunar Maria.

The little information we have on Mercury is pushing the major world space agencies to plan new missions to this planet. In particular ESA has identified Mercury as the target of one of its 'Cornerstone' missions, with a launch date in the 2008–10 time frame. NASA and ISAS have also manifested interest in exploring Mercury. At the time of writing an effort of international coordination, led by ESA, is ongoing.

Venus

As for the exploration of the Moon, the Soviet Union had taken the lead in the exploration of Venus. In 1967 the Soviets, after three initial failures, succeeded in letting the VENERA 4 probe descend through the atmosphere of Venus. Shortly afterwards the Venera 5 and 6 probes repeated the atmospheric measurements providing us with the first extended database of '*in-situ*' atmospheric measurements. During the 1970s the Soviets increased the ambition of their program of exploration of Venus by carrying out eight

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

landings during which the only images of the surface still available today were obtained. In the early 1960s NASA was facing a number of technical problems and failures with its first missions to the Moon and did not have many resources to invest in the exploration of other planets. Nevertheless, they had succeeded in sending Mariner 2 to Venus in 1962 (the first probe ever to visit another planet) and in 1967 Mariner 5, which succeeded in measuring the crushing atmospheric pressure at the surface.

The Mariner 10 and PIONEER VENUS (PV) 1 and 2 missions, launched in 1975 and in 1978 respectively, were real successes. The first mission returned 3500 images of the complex atmospheric structure of Venus characterized by a Hadley cell type of circulation as proposed already in 1735 by the eponymous scientist. The missions of the two Pioneers completed our understanding of the Venusian upper atmospheric processes (PV 1) and of the deep structure (PV 2) thanks to the four probes deployed inside the atmosphere.

The complex geology of the planet was revealed by the two Soviet missions Venera 15 and 16 and by the NASA MAGELLAN mission. In fact, these spacecraft made use of imaging radars capable of penetrating the thick atmosphere of Venus and returning images of the surface. Venus's surface is characterized by a large variety of structures: volcanoes, valleys, depressions, faults, plateaus, mountain ridges. Volcanic activity appears to have played a major role in the evolution of the surface, but, strangely enough, Venus's crust seems to be much more static than that of the Earth. Magellan is a typical example of a space saga. Originally called VOIR (Venus Orbital Imaging Radar), this mission was to be launched at the beginning of the 1980s. For financial reasons it was first cancelled and then resurrected under the name of Magellan. However, also the new launch date of 1984 could not be maintained owing to the delays of the shuttle program. Eventually, Magellan was launched in 1989, the first planetary spacecraft launched on a shuttle.

Exploring the outer regions

It is difficult to understand why the Soviet Union was completely absent from the exploration of the outer regions of the solar system: was it lack of interest, technological problems in operating the spacecraft at large distances from the Earth or shortage of funds? Perhaps a combination of all these reasons, plus the large investments made in the manned orbital infrastructure, explains such a strange absence. What is certain is that the missions to the giant planets are made only in the US, with the exception of the CASSINI MISSION that includes major participation by ESA and ASI, the Italian space agency.

Pioneers 10 and 11 were the first missions to be launched towards the external regions of the solar system. Very small and simple spacecraft, they have shown an incredible reliability which has allowed them to survive the hostile environment of JUPITER and SATURN. The most outstanding result of the Pioneer 10 mission was the discovery of an intense magnetic field tilted 11° from the axis of rotation of Jupiter which created wobbling radiation belts around the planet. Pioneer 11 was targeted at Saturn where it discovered very intense magnetic field radiation belts interacting with the dusty rings and a very structured magnetosphere.

Between 1977 and 1989 the NASA VOYAGERS 1 and 2 transformed our understanding of the outer solar system. These planetary probes were designed and launched to exploit the rare opportunity (available every 176 yr) to explore the outer regions of our planetary system: the alignment of the outer planets. In the course of a mission lasting about 13 yr the two Voyagers explored all the gaseous giants, Jupiter, Saturn, Uranus and Neptune. These spacecraft have been able to transmit telemetry and science data from distances of hundreds of millions of kilometers with an emitting power of a few tens of watts. When Voyager 2 reached Neptune the radio signals emitted by the on board antenna took more than 4 h to reach us.

Jupiter was the first planet to be visited by the two spacecraft. They reached this planet following different trajectories characterized by different cruise times. The spacecraft orbits were such that Voyager 1 could obtain the closest approach to the Galilean satellites of Jupiter. Voyager 2 was kept further away from Jupiter in order to minimize the interaction with its radiation belts and preserve it in the best possible conditions in view of the long voyage to Neptune. The acquisition of science data was extended to all phases of exploration of the Jovian system. This has allowed the spacecraft to measure the temporal variability of Jupiter's atmosphere and magnetosphere, of the plasma torus associated with IO's orbit and of the large-scale morphology of the satellites. Among the many results obtained during the long cruise phases it is worth remembering the discovery, at a distance of about 130 000 km from the center of Jupiter, of a 30 km thick dust ring , the measurement of a 5 million volt electric current that flows along the magnetic flux lines between Jupiter and Io and the generation of radio signals probably due to the oscillations of the plasma cloud associated with Io.

After one more year of navigation the Voyagers reached Saturn, which is at an average distance from the Earth of about 1.6 billion kilometers. At that distance, the solar radiation is only 1% of the amount that reaches our planet. The prominent ring system of this planet was eventually studied in great detail as well as TITAN, the only satellite in the solar system characterized by a thick atmosphere that resembles that of the Earth in its early phases. A completely unexpected feature of the ring system was the presence of transient radial spokes due to levitation of dust grains above the plane of the rings. The images of the icy satellites have shown that they all have been subject to an intense meteoritic bombardment. However, noticeable differences in the crater density were detected among the satellites, suggesting the possibility of a non-uniform distribution of the impactors and/or

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

geological reprocessing of the surface, effective just after the most intense phase of the meteoritical bombardment.

The exploration of the Saturnian system concluded the 'nominal' part of the Voyagers' mission in 1981. Immediately a political debate arose on the opportunity to turn the spacecraft off and terminate the funding of the mission. Fortunately, NASA succeeded in obtaining approval for an extended mission, which consisted in the targeting of Voyager 2 towards Uranus and Neptune. In January 1986 Voyager 2 reached URANUS, the only planet of the solar system with a spin axis parallel to the plane of the ecliptic and pointing towards the Sun. Uranus's magnetic field axis is tilted by about 60°. This suggests the hypothesis that the planet's magnetic field might be generated at relatively shallow depths. The images of Uranus returned by Voyager appear particularly sharp thanks to the reprogramming of both the attitude control of the spacecraft and the pointing of the imaging system which now was capable of locking on the target and compensating the motion of the spacecraft with appropriate rotations. It is thanks to this technique that the discovery of Uranus's satellite 1985U1 became possible.

After three more years of interplanetary cruising, Voyager 2 reached NEPTUNE. The scientific payload was still working nominally more than 12 yr after launch. In order to receive in the best possible way the images transmitted by the spacecraft from the borders of the solar system, the antennae of the Deep Space Network were all strung together in order to create a 'virtual' antenna of a much larger size. The images of Neptune show a blue planet, with cloud patterns similar to those of Jupiter, surrounded by rings segmented in arcs and only thinly connected. The discovery of active geysers and plumes on the surface of TRITON, a retrograde satellite of Neptune, was a great surprise.

The two Voyager spacecraft, which are now flying in the depths of interstellar space, have accomplished flawlessly a fantastic mission of exploration to be remembered as one of the brightest successes of the US space technology.

In 1989 the exploration of Jupiter started again with the launch of the GALILEO MISSION. The launch should have concluded a 20 yr long saga caused by changes in the US and NASA launching policy. Unfortunately, the problems started again after launch, when the atypical Galileo deployable high-gain antenna became stuck. It took 2 yr for the mission controllers to find a back-up solution to the antenna malfunction and to put the spacecraft back into an operational mode, which permitted 70% of the original scientific goals to be rescued. On 7 December 1995, Galileo reached Jupiter and, after a close flyby of Io, entered its operational orbit. Extended imaging of the Galilean satellites and in particular of EUROPA, which could be the target of a future NASA mission, was carried out in the course of 4 yr of operations in Jupiter orbit.

Cassini, as mentioned above, is the only mission to the outer planets that includes European participation. The mission was launched from Cape Canaveral on 15 October 1997, on a Titan 4/Centaur expendable launcher. A complex trajectory that includes gravity assists from Venus and the Earth will take Cassini to Saturn in about 6.5 yr. The highlight of the mission will be the deployment of the ESA-built Huygens probe into the dense Titanian atmosphere. Huygens will probe Titan's atmosphere looking for traces of organic and prebiotic compounds.

The leftovers of the cosmic construction

According to the theories of formation and evolution of the solar system, the ASTEROIDS and the COMETS represent the leftovers of the cosmic working area which give rise to our solar system. The study of these numerous but still little-known bodies will allow us to jump back in time and analyze the most ancient and/or uncontaminated materials in the solar system.

The exploration of Halley's comet (COMET HALLEY) marked the beginning of a new era in the understanding of the comets. ESA, the Soviet Union and Japan decided to go chasing the comet that the British scientist Edmund Halley predicted would return in 1758, using Newton's newly formulated laws of motion, after the appearances of 1531, 1607 and 1682. The comet did indeed return as predicted and has since continued to return every 76 yr. The space agencies involved in the exploration of Halley could not miss the launch opportunity when at the beginning of the 1980s they decided to go exploring this comet. An 'armada' of five spacecraft was indeed launched in time: the two Soviet Vegas went on 10 and 14 June 1985; the ESA's Giotto was launched from Kourou on 2 July 1985; the Japanese Sakigake and Suisei probes were launched on 8 January and 18 August 1985 respectively. The closest approach to Halley's nucleus was carried out by the Giotto probe that flewby at a distance of less than 600 km on 14 March 1986. The on-board Multicolor Camera obtained a sequence of images of the nucleus that appeared to be elongated, very dark and characterized by very irregular morphology.

Apart from the interesting scientific results the exploration of Halley's comet will be remembered as the first worldwide effort of coordination of scientific space missions. NASA, which could not provide a spacecraft, joined the other participants by making its Deep Space Network available. Since then the four major space agencies in the world have tried to coordinate their space science programs through the Inter-Agency Consultative Group, an open forum which meets periodically at least once per year.

The GIOTTO spacecraft surprisingly survived its close encounter with Halley. It was decided to put it on an orbit which would have brought the spacecraft back in the vicinity of the Earth every 5 yr, and then hibernate it. In February 1990, 1419 days later, Giotto was reawakened by the ESA mission controllers. Once again Giotto surprised everyone by showing no major sign of deterioration due to the long exposure to the harsh deep space environment.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

The spacecraft was then retargeted towards the Grigg–Skjellerup comet and a very close (100–200 km) flyby of its nucleus took place on 7 July 1992.

The only images of asteroids obtained at the time of writing were obtained in the course of a couple of flybys by the Galileo spacecraft, en route to Jupiter, and by the Near Earth Asteroid Rendezvous (NEAR) mission. NEAR was launched on 17 February 1996 and it is the first of a new class of NASA missions called Discovery. The main characteristic of the Discovery missions is that they are a kind of Principal Investigator mission which have to be implemented with a NASA budget but completely outside the NASA infrastructure. In principle this procedure allows a faster and cheaper implementation of the missions but it also reduces dramatically the technical reliability of the missions and makes international coordination and collaboration very difficult.

The NASA DEEP SPACE 1 mission, mainly devoted to testing electric propulsion as the primary propulsion, was launched in 1998 with the goal to fly by an asteroid and a comet. Some technical problems in the propulsion system have obliged NASA to change the orbital strategy in flight. Asteroid Braille flyby took place successfully on 28 July 1999 at a distance of 15 km.

The Japanese scientific agency ISAS has announced the launch of a technology mission devoted to returning samples from the Nereus asteroid in 2002. The name of the mission is MUSES-C.

In 2003 the ESA ROSETTA mission will be launched with an Ariane 5 from Kourou. This is a major mission of the ESA science program, supposed to reach comet Wirtanen after 8 yr of deep space cruise and orbit its nucleus for at least 2 yr. En route to Wirtanen, Rosetta will fly by two main-belt asteroids, Otawara in 2006 and Siwa in 2008. A major feature of this mission is the deployment of the Roland Lander on the surface of the Wirtanen nucleus. This lander will carry out high-resolution geochemical, mineralogical and geophysical measurements.

The invasion of the red planet

MARS has always had a special place in people's minds since the time that, rather erroneously, some astronomers thought they had identified artificial structures on the surface of the planet. However, it is true that Mars, both climatically and geologically, is the planet that resembles more closely the Earth. Since the 1970s a large number of missions have been sent to Mars; recently, after a break of about 20 yr, the exploration of the red planet has started again with the involvement of a large number of countries.

In the 1960s NASA was the only agency that dared sending spacecraft to Mars. In 1964 Mariner 4, an adaptation of the lunar Ranger spacecraft, reached the red planet, returning 22 images, mostly from the southern hemisphere. NASA sent two more spacecraft, Mariner 6 and 7, 5 yr later; these were technologically more advanced especially in the field of telecommunications. Despite some problems with the on-board battery pack, the spacecraft reached Mars successfully and carried out imaging campaigns as well as measurements of the composition and density of the Martian atmosphere. Unfortunately, because of celestial mechanics constraints on the orbital scenario of the two missions, Mariner 6 and 7 also observed the southern hemisphere, confirming the wrong impression that Mars was a Moon-like body, heavily cratered and lacking signs of geological evolution. When a new favorable launch opportunity presented itself 2 yr later, the Soviet Union decided to launch MARS 2, a simple orbiter, and Mars 3, consisting of an orbiter and a lander. NASA launched Mariner 9. An agreement was stipulated between the two countries to exchange data and assist each other's missions. In particular, Mariner 9, due to reach Mars before the Mars probes, was supposed to provide assistance for the choice of the landing site. When Mariner 9 entered Mars orbit, the on-board cameras found out that the entire surface was obscured by a planet-wide dust storm. The high winds were presumably the cause of the failure of the Soviet lander. When eventually the dust storm subsided, Mariner 9 initiated an observational campaign which revealed the true 'face' of the planet. Hemispherical asymmetry due to very intense and large-scale geological processes, gigantic shield volcanoes and flood-like morphologies demonstrated that Mars had undergone a very intense geological evolution and that perhaps, in a phase of its evolution, liquid water could have been flowing on its surface. After a new failure of the Soviet Mars 4 and 5 missions, NASA 4 yr later launched the VIKING 1 and 2 missions, both consisting of an orbiter and a lander. The Viking missions were extremely successful, but they also caused a terrible disappointment when the biology experiments showed that that there was no active life on the surface of Mars. This outcome, together with a new emphasis at NASA on the manned flights, brought to a halt the exploration of Mars for almost 20 yr. The Vikings will be remembered, however, for having obtained the first high-resolution and panoramic images of two different (landing) sites on Mars, for having determined atmospheric profiles down to the surface, for having studied for extended periods of time the local meteorology and for having provided a medium–high-resolution coverage of the entire surface from orbit.

In 1988 the Soviets tried again an adventure on Mars with the launch of two very complex spacecraft PHOBOS 1 and 2 consisting of orbiters and landers to be deployed on the surface of Phobos, one of the two natural satellites of Mars. The Mars malediction struck again, however. Phobos 1 was lost shortly after launch, while Phobos 2 failed just prior to its rendezvous with the moon Phobos.

The US went back to Mars on 4 July 1997. The MARS PATHFINDER mission, carrying a rover called Sojourner, landed on the surface of the red planet making use of an innovative passive landing technique, the air bag. Pathfinder had an incredible public relations success, rather than a scientific one, and the great merit of spreading 'Mars fever' everywhere in the world. Since then, a robust program of exploration, internationally coordinated by the International Mars Exploration Working Group, has

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

started with the participation of most of the space-faring nations and organizations.

After the failure of the Mars Observer, which exploded during cruise, NASA decided to decrease the complexity of each mission but to increase the launch frequency. The science objectives of Mars Observer were spread over a number of Mars Surveyor Orbiters, the Mars Global Surveyor, launched in 1996, being the first of the new series.

In the US for the first time ever a budget spreading over 10 yr was approved in order to allow the launch of at least two spacecraft at each launch window: Mars Climate Orbiter and the Mars polar Lander in 1998–9; a Mars Surveyor Orbiter and a Lander in 2001 and in 2003; a Mars Sample Return in 2005 and 2007.

Europe reacted as well. After many years of studies and setbacks, ESA succeeded eventually in starting the construction of MARS EXPRESS. This mission is breaking new ground in Europe in terms of rapidity of approval, simplified management procedures and reduction of the cost. This mission will be launched in 2003 also thanks to the strong collaboration of the ASI and the UK which is providing the Beagle 2 lander. ASI could also be involved in other NASA-led missions to Mars. A sample return mission might see a major participation of the French space agency CNES, which is also supposed to coordinate the construction of the Netlander probes meant to constitute the first geophysical network on the surface of Mars.

Last but not least, the Japanese ISAS launched the NOZOMI (formerly Planet-B) spacecraft in 1998. Because of a technical problem this spacecraft will have a delayed arrival at Mars, but it will be able to carry out a 'tandem' mission with Mars Express supposed to arrive on Mars almost simultaneously.

Planetary Interiors

The part of a planet that we can see or directly explore is tiny by comparison to its interior. Inaccessibility does not imply unimportance, however. There are four reasons why planetary interiors are studied. (1) The interpretation of the interior is part of any unifying story for the planet structure and evolution. You cannot hope to understand the formation and history of a planet if you do not know its major constituents and how they are distributed internally. (2) The explanation for many observable features lies inside a planet. For example, you cannot understand why some planets have volcanoes, a magnetic field or a large heat flow without knowing what goes on inside. (3) Even when a phenomenon or planetary attribute is not directly determined by what is inside, the interior still matters. For example, the atmosphere of a planet is often affected by recycling i.e. transport of material into or out of the interior. There is at least as much water inside Earth as in Earth's oceans. (4) Large planets have materials under extreme pressure and high temperature; this is of interest to those who study condensed matter physics (the fundamental science of materials).

What is a planet?

Since the study of planetary interiors involves the study of materials and conditions very different from those at the surface, and since these conditions are determined primarily by the mass of the body and not by whether it orbits the Sun, it is natural to include large satellites in the designation 'planet'. Indeed, Pluto is much smaller than many satellites and even Mercury has a smaller radius than Ganymede or Titan. Small satellites and asteroids are not included in the discussion here, because their internal conditions differ rather little from their surface conditions. At the other extreme, some of the bodies recently discovered in orbit around other stars are ten Jupiter masses or more and could perhaps also be called planets. This designation is uncertain because we know so little about them. They might in some instances have formed in the same way stars formed and thus could better be called brown dwarf companions. Any object exceeding about eighty Jupiter masses can burn light hydrogen and reach the main sequence of conventional stellar evolution and thus should certainly not be called a planet.

Pressures and temperatures

Pressures inside planets are high because of the weight of overlying material. From this physical principle and our knowledge of gravity, we can estimate a pressure deep within a planet of around (1400 bars)$\langle\rho\rangle^2(R/1000\ \mathrm{km})^2$. Here, $\langle\rho\rangle$ is the mean density (mass divided by volume) of the planet in grams per cm^3 (water at one bar pressure has a density of unity in these units), and R is the planet's radius. One bar (=10^5 pascals or 10^6 dynes cm^{-2}) is close to the pressure of EARTH'S ATMOSPHERE at sea level. For Earth's MOON, this equation yields an estimate of around 50 thousand bars (50 kilobars). For Earth, the equation yields an estimate of around 2 million bars or megabars (the 'exact' value for Earth's center being around 3.6 megabars). For JUPITER, the largest planet in our solar system, the estimated 'typical' pressure is around ten megabars. These numbers are of interest because if you ask how much work is done in compressing material to a megabar pressure, it is of the order of an electron volt per atom, and this is the natural energy scale of atoms. In other words, the pressures within planets are sufficient to change the structure of materials and modify greatly their behavior. In a very real sense, the inside of a planet is different from the outside (even when it is made of the same atoms!). Moreover, planets have difficulty eliminating heat, and as a consequence have high internal temperatures, irrespective of whether they are hot or cold externally. The central temperature of Earth is around 6000 K, and temperatures deep within Jupiter are 10^4 K or more. Even the Moon may have a central temperature of around 1600 K. Planets are 'cold' in the sense that thermal energy is small compared to the gravitational energy (indeed, this is much of what distinguishes planets from stars) but they are nonetheless hot enough to be partly molten, or, in the case of giant planets, mostly in the fluid state. In planets larger than about the size of MARS, the high internal temperatures are assured just by the large gravitational energy of formation, much of which is unavoidably converted into heat. These high temperatures can allow massive gravitational *differentiation* (e.g., the separation of a dense iron core from a less dense silicate mantle), particularly during the planet's early history.

Composition and planetary classes

The behavior of a planet depends on the materials from which it is constructed and this depends in turn on the cosmic environment in which the planet formed. Massive planets are made of the most common materials (especially hydrogen), and relatively low mass bodies such as Earth are made of relatively uncommon materials which we call rock. The abundance of elements in the universe is similar to the abundances in the Sun, in most respects, and is dictated by NUCLEOSYNTHESIS, which favors light elements. Hydrogen dominates (it makes up around 70% of the mass of the material from which the Sun formed), followed by helium (27% by mass) and much smaller amounts of oxygen, carbon, neon and nitrogen. Rock forming elements (magnesium, silicon, iron) have still lower abundance.

It is convenient, both on the basis of cosmic abundance and because of how these elements behave, to define three classes of materials: 'gases', 'ices' and 'rock'. These labels refer to composition and are listed in order of decreasing volatility (which refers to their tendency to evaporate easily or resist condensation). Quotation marks are needed to remind us that these labels do not refer to the *state* of the material (e.g., 'gas' can be a metal, as explained below). 'Gases' refer primarily to hydrogen and helium, which do not condense (i.e., form a solid or a liquid)

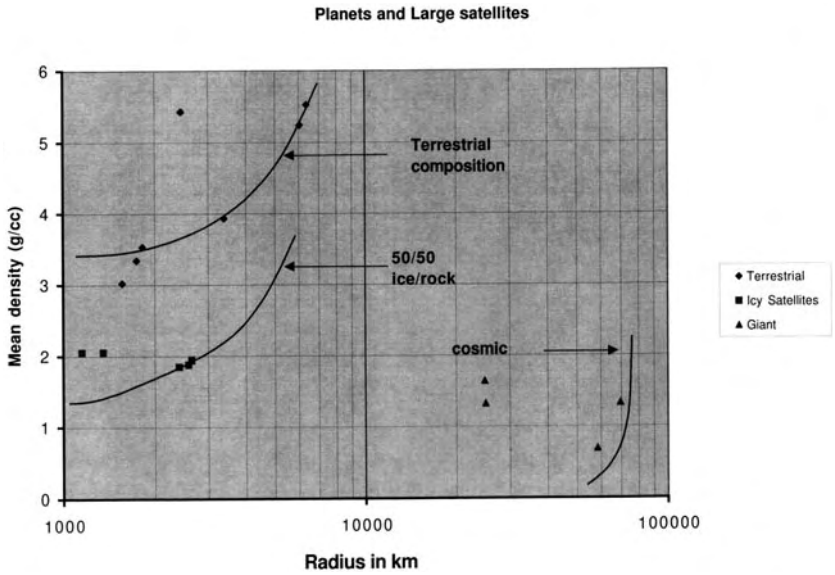

Figure 1. The mean densities and radii for all planets and large satellites in the solar system.

under conditions encountered during the formation of planets. Jupiter and SATURN are the only planets in our solar system that are predominantly 'gas'. 'Ices' refer to the dominant compounds involving oxygen, carbon and nitrogen, and especially to H_2O. The ices partially condense under the cold conditions encountered beyond the asteroid belt and are thus important in all objects from the Jupiter-forming region outwards. 'Rock' refers to the least volatile materials: the silicates, oxides and metallic iron that dominate all bodies interior to Jupiter's orbit. The behavior of these materials can be very different from our everyday experience, primarily because of the high pressures, but also because of high temperature. Thus, 'gas' becomes a liquid metal or semi-metal at the extreme pressures inside Jupiter and Saturn.

Water may become a very good ionic conductor, methane might decompose into hydrogen and diamond, and the minerals that make up rock adopt very different lattice architectures (packing of the atoms). We know about these phenomena through laboratory experiments on Earth, and understand them through the application of quantum mechanics to condensed matter; we then apply this knowledge to our understanding of the planets. As a result, we can predict the expected mean density of a planet for a particular assumption about its composition. The actual mean density is easily determined from the observed mass and radius.

Figure 1 shows the mean densities and radii for all planets and large satellites in the solar system. In the giant planet group, there are two clusters, each containing two points: the gas giants, Jupiter and Saturn, are to be found in the lower right corner, with the ice rich bodies, URANUS and NEPTUNE, at somewhat higher densities and lower radii.

At somewhat similar densities but much smaller radii, there are bodies that have comparable amounts of ice and rock (GANYMEDE, CALLISTO, TITAN, PLUTO and TRITON, although the latter two are somewhat less icy than the first three). If one made bodies of much larger mass (and hence radius) than this composition, they would have much higher density. The bodies that are primarily rocky, MERCURY, VENUS, Earth, Moon, Mars, IO and perhaps EUROPA (though the latter has a significant component of H_2O), form the remaining higher density group. Mercury, Venus, Earth and Mars are called the *terrestrial planets* for obvious reasons.

How is internal structure determined?

Although we can estimate mean composition from mean density, the layering, the thermodynamic state and the dynamics of a planet's interior are much more difficult to determine. *Seismology* is by far the best technique for this. On solid planets, seismology usually means the study of travel times for body or surface waves created by the brittle failure of the rock, but the study of normal modes (oscillatory deformations of the entire body, analogous to the ringing of a bell) are also very important. Normal modes are readily detected for the Sun and you might hope to achieve something similar on giant planets. But the motions exciting the modes are far weaker, so no convincing detection has been made yet. Seismology has proved to be of paramount importance in our study of Earth, where it has enabled to determine crustal thickness, to confirm the existence of major mineral phase transitions in the mantle, and to establish the fluidity of the outer core and the solidity of the inner core. Seismic tomography (the 'imaging' of lateral velocity anomalies) also provides clues on the dynamic state of the mantle (warm upwellings and cold downwellings of large scale convection, carrying heat out of EARTH'S INTERIOR and driving plate tectonics). However, seismology is difficult to employ elsewhere. We

Dirac House, Temple Back, Bristol, BS1 6BE, UK

have only limited seismic data for our Moon, little yet of value for Mars, and no data for other planets.

Gravity

Gravity has assumed a central role in determining planet structure because of the technical or fundamental limitations of planetary seismology. Planets are not spherically symmetric and, as a consequence, the external gravity field may have a rich harmonic spectrum which influences the trajectory of a passing or orbiting spacecraft detectably. The planet's gravity field can usually be thought of as three rather well separated components: the part that comes from the total mass (and which yields the familiar contribution to the total gravitational force that varies as the inverse square of distance from the planet's center of mass); the part that comes from the rotational (and sometimes tidal) distortion of the planet; and the part that comes from internal dynamics or finite strength of the materials. The rotational or tidal responses are particularly important because (unlike the internal dynamical effects) the driving force for the planet's distortion is precisely known. Consider, for simplicity, the case of a rapidly rotating planet with relatively small tidal effects (e.g. Jupiter or even Earth). The next most important contribution to the gravitational force beyond inverse square is a term that varies as the inverse fourth power of radial distance (the gravitational quadrupole). The dimensionless number that is a measure of its strength is a 'gravitational moment' called J_2. Theory relates this J_2 to the difference between the polar and equatorial moments of inertia of the planet. These two moments of inertia differ by only a small amount but we would really like to know the mean moment of inertia, since that can tell us whether the planet is differentiated or well mixed. However, theory also tells us that provided the body behaves like a fluid on long time scales, J_2 is proportional to the ratio of centrifugal to direct gravitational forces at the equator (a known quantity) with a constant of proportionality that depends on the mean moment of inertia. This *theory of figures*, developed a century ago and refined subsequently, is our main way of estimating the internal structure of all giant planets and also the Galilean satellites (where the permanent tidal bulges also provide similar information). It is an *approximate* theory and, in the case of giant planets, it imposes a much more complicated constraint than merely determining the mean moment of inertia. It does not work for Mercury or Venus because they rotate so slowly that J_2 is very small, thus poorly determined and not dominated by rotational effects. Major uncertainties persist for the interiors of these planets for this reason. It might seem remarkable that this theory should work for Earth, a primarily solid body, but in fact most of Earth's solid material flows in response to stresses as though it were a fluid, provided we allow sufficiently long times to elapse. A timescale less than a million years is sufficient, far less than the ages of the planets (all about 4.5 billion years). This approach has been superseded for Earth, Moon and Mars where we possess additional geodetic information (precession or nutation of the polar axis) and can directly determine the principal moments of inertia, confirming but also refining the approach based on fluidity of the body.

Our everyday concept of a liquid or fluid is an implicit estimate of the viscosity. A low viscosity material flows readily under stress but a very high viscosity material such as water ice or a terrestrial planetary mantle (silicate rocks) might seem to us to be solid on a human timescale, despite flowing. Planets which are fluid in the everyday sense of the word (Jupiter, Saturn, Uranus and Neptune) are made predominantly of materials that flow so easily that there are no detectable long-lived non-hydrostatic contributions to gravity. Terrestrial planets by contrast can often create and support non-hydrostatic loads corresponding to stresses of the order of ten to even thousands of bars. Though these may be tiny compared to the mean stress state deep down (the pressure) they yield detectable gravity and shape anomalies. These are generally interpreted to tell us: (a) the depth above which the planetary material has finite strength on long timescales rather than behaving like a fluid; and (b) something about the scale and magnitude of the dynamic (convective) density anomalies deep within the planet's solid mantle. Indirectly, these tell us something about the temperature and viscosity structure, since the ability of a solid to flow depends very strongly on its temperature.

Heat flow

Heat flow also provides information on temperature structure. There are two major sources of heat in planets, radioactivity and gravitational energy release. Gravitational energy can be converted into heat either primordially (as the planet forms and perhaps differentiates to form a core) or as an ongoing process (the gradual settling of heavier material). Tidal flexing is an additional source that is mainly of interest for large satellites around giant planets; it leads to Io being the most volcanically active body in the solar system.

In terrestrial planets (including the Moon), the dominant source of heating is long-lived radioactive elements (primarily ^{238}U, ^{232}Th and ^{40}K). For a volumetric heating source like this, the heat flux (energy flow per unit area) scales as mass to surface area, or approximately one power of radius. Large planets thus have higher heat fluxes. Planets are also expected to cool on billion year timescales, if only because the radioactive sources slowly decay, but also because they began hot due to the partial conversion of their gravitational energy of formation to internal heat. Gradual cooling might contribute as much as one half of the total heat output, but this is still poorly understood. Heat flows of terrestrial planets are difficult to measure and it is well known only for Earth. However, there is little doubt that the heat flow is so large as to require transport to be predominantly convective.

In Jupiter, Saturn, Uranus and Neptune, gravitational energy dominates, partly because these bodies are so massive but also because only a small fraction of the mass is

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

in the rocky component that carries radioactive elements. A simple model assumes that the heat flow arises from steady cooling from an initial hot state. For a fully convective, adiabatic planet, the heat flow is then limited by the opacity of the atmosphere. This model works quite well for Jupiter but underpredicts the Saturnian heat flow and overpredicts the heat flows of Uranus and Neptune. The shortfall for Saturn is most likely explained by the rainout of helium, which has limited solubility in metallic hydrogen.

Some satellites, notably Io and Europa, are in eccentric, close orbits and undergo tidal heating in addition to radioactivity. This arises because all real solid or partial solid materials are imperfectly elastic and dissipate heat as they are flexed. Io's heat flux is roughly thirty times greater than Earth, and as a consequence, Io is the most volcanically active body in the solar system.

Magnetism

Magnetism can arise as a microscopic (quantum) property of the constituent materials, as in the permanent magnetism of iron or magnetite, but it can also arise from macroscopic currents in an electrical conductor. Since permanent magnetism can only occur below the Curie temperature of the material, it is thought to be restricted to a thin outer layer of solid planets, all of which have hot interiors. The fractional abundance of permanently magnetized materials is also frequently small compared to the major rock-forming minerals, and the spatial distribution of magnetization directions is often complex because of tectonic processes or magnetic field reversals. On Earth, the net contribution of permanent magnetization to the measured field is only one part in a thousand or less at most locations. On this basis, it is thought likely that when coherent, large dipole fields (e.g. surface fields of the order of one Gauss) are observed, they must be caused by macroscopic electrical currents deep within the planet. These currents can be sustained by a *dynamo*, which depends on electromagnetic induction within an electrically conducting, circulating fluid. Temporal variation of the field confirms that it is a dynamic property, but this temporal variation has only been seen for Earth. Planetary magnetic fields (PLANETARY MAGNETOSPHERES) can therefore tell us something of the internal dynamical state and material properties. Earth is the only terrestrial planet that currently possesses a large field, but Mars exhibits evidence of an ancient large field, expressed in unusually high permanent magnetism of ancient rocks. Mercury has a global field that is over two orders of magnitude smaller than Earth's and not understood. Venus has no detectable global field. The Moon may have had an early large field, but the evidence could also possibly be explained by some local process (e.g., impact magnetization). The inference is that only Earth among the terrestrial planets still has the convective core motions needed for a dynamo. Although the other terrestrial bodies are likely to have at least partially liquid cores, they may not be convecting, because the heat flow is sufficiently low that it can be carried by conduction alone. Surprisingly, Ganymede appears to have a dynamo field, probably generated in a liquid iron core. Despite the presence of a water ice mantle, Ganymede thus has some Earth-like attributes.

All the giant planets possess substantial fields, indicating that their deep interiors are convecting and electrically conducting. In Jupiter and Saturn, the conductivity arises from the partial metallization of hydrogen at extreme pressure (a semimetal is sufficient). In Uranus and Neptune, ionic conduction (transport by mobile protons) is the likely explanation.

Volcanism and petrology

Terrestrial planetary mantles consist of a mixture of minerals and as a consequence do not have a single melting point, but a range of melting temperatures. Despite the ability of solids to flow and convect heat at high temperature, some melting occurs and this is expressed at the surface as volcanism and the formation of crust. This melt mainly forms basalt on freezing, which is also a mixture of minerals (those that melt most readily). Basaltic volcanism has dominated the volcanic history of all but the most earliest periods for all terrestrial bodies. The composition and distribution of these basalts, which is the science of petrology, tells us much about what takes place within the planet. The continents on Earth are *not* basalt and are not thought to arise in a simple way; there are no known close analogs to continents on any other planet (though there are places where the topography is high). Volcanism is also a major, sometimes dominant, factor in determining the atmospheric composition of a planet.

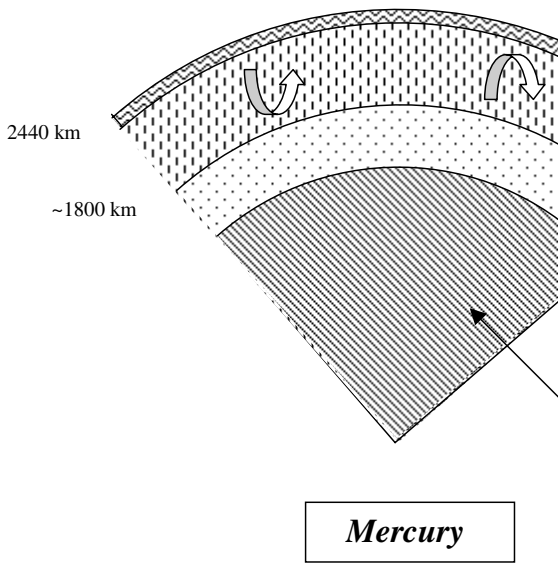

Figure 2. The interior of Mercur

Dirac House, Temple Back, Bristol, BS1 6BE, UK

Giant planets are fluid throughout, except maybe for the very central region, and cannot have volcanism in the usual sense. However, their atmospheric compositions are affected by mixing and differentiation processes within. The most striking example is the lower than cosmic abundance of helium and neon in the atmosphere of Jupiter, and probably Saturn, arising from the formation of helium raindrops deep within the planet.

Icy bodies may also have volcanism if the ice mixture includes appropriate constituents other than water ice. Ammonia and methane are good candidates for driving volcanic activity. (See also VOLCANISM IN THE SOLAR SYSTEM.)

Electromagnetic response

When a planet with a moderately conducting interior is subjected to time-variable external magnetic fields, internal currents are induced and can be detected. On Earth, these are called magnetotelluric currents and they flow both in the ocean water and in the (moist) continental crust. On the Moon, the detection of these induced currents enabled estimates of the conductivity of the deep interior, implying that the rocks are hot (around 1500 K or more). In Europa and Callisto, induced currents and their associated magnetic fields appear to require a conducting layer that is near (i.e. within about 100 km of) the surface. Were this layer to be of salty water (like Earth's oceans) then it must have a thickness exceeding about ten kilometers, strong evidence for at least a thin water ocean in these bodies. Ganymede may also have a water ocean, but the effect is presumably masked by the much larger dynamo field that this body possesses.

Models of planetary interiors

It is easier to send a spacecraft to Jupiter than to send a probe to Earth's core. Not surprisingly, our understanding of planetary interiors is incomplete. 'Models', as described below, provide a summary of our current best efforts to organize our understanding and expectations.

Mercury is unusually dense for its size, and thus must be iron rich. Most of this iron is thought to be in an iron core, much of which may now have frozen. Possibly, Mercury started out with a conventional (Earth-like) composition and then lost part of its silicate mantle in a massive collision with another body similar in mass.

Venus is remarkably similar to Earth in mass and mean composition and may have a similar internal structure. Volcanic structures, presumably built of basalt, provide topographic relief that is of similar magnitude to Earth. The surface is devoid of ancient (heavily cratered terrains) implying resurfacing on a half billion to billion year timescale. However, Venus does not appear to have plate tectonics, at least at present, and may even be heating up internally. Either this or the absence of an inner core may explain why Venus does not currently have a magnetic field. The high surface temperatures may preclude retention of significant permanent magnetism in the rocks.

Earth is in some ways the best understood of the planets, because of the large amount of seismic information, yet many aspects remain mysterious. The greatest puzzle centers around plate tectonics, which is a very efficient way of eliminating Earth's internal heat, yet appears to be unique, at least at present, among the terrestrial planets. Plate tectonics also provides for a large amount of volcanism, most of which takes place on the sea floor. Although the ocean basins would exist even if there were no water to fill them (provided plate tectonics persisted), it is possible that water is indirectly responsible for plate tectonics through its influence on the ability of solid rocks to flow easily beneath the plates. The solid inner core may provide a crucial part of the buoyancy needed for convection in Earth's core and thus sustain the dynamo and the geomagnetic field.

Moon is iron poor and thus has little or no core. The lunar highlands are made of rocks that would occur by freezing from a fully molten outer layer of early Moon; this and other evidence attests to an early traumatic and very hot epoch of Moon's history. The currently favored explanation is that the Moon was born from a giant impact of a Mars-sized or larger body on early Earth. The splash-out from this impact could have placed a short-lived disk of material in Earth's orbit, from which the Moon quickly formed, perhaps in 100 years! All of this took place around 4.5 billion years ago. The mare on the Moon (the darkest regions) are basaltic and came up to a billion years later. The Moon is 'geologically dead' in the sense that there are no surface features that result from internal processes that are more recent than a few billion years ago.

Mars is only one tenth the mass of Earth and appears to have similarity to Earth in bulk composition. It evidently had a large magnetic field for at least the first few hundred million years of its history, during a period of massive crustal production. The northern hemisphere, at least, may have had plate tectonics or some form of recycling, thus explaining why it now has a much thinner crust than in the south. The volcanic province, just northward of the equator, is more recent geologically, and it is likely that volcanic activity on Mars has not entirely ceased. The iron core of Mars is likely to be at least partially liquid and may be entirely liquid if it possesses enough sulfur.

Jupiter is easily the most massive planet and the most Sun-like in its composition. Even so, it does

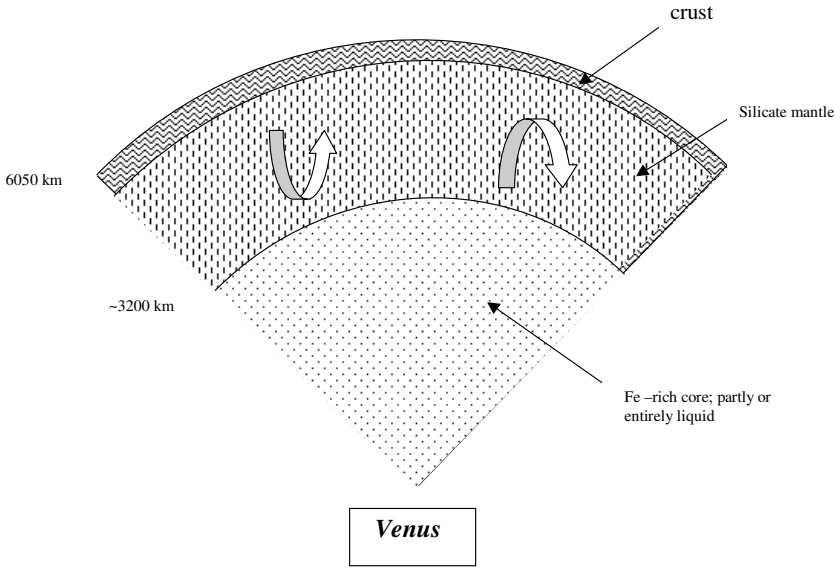

Figure 3. The interior of Venus.

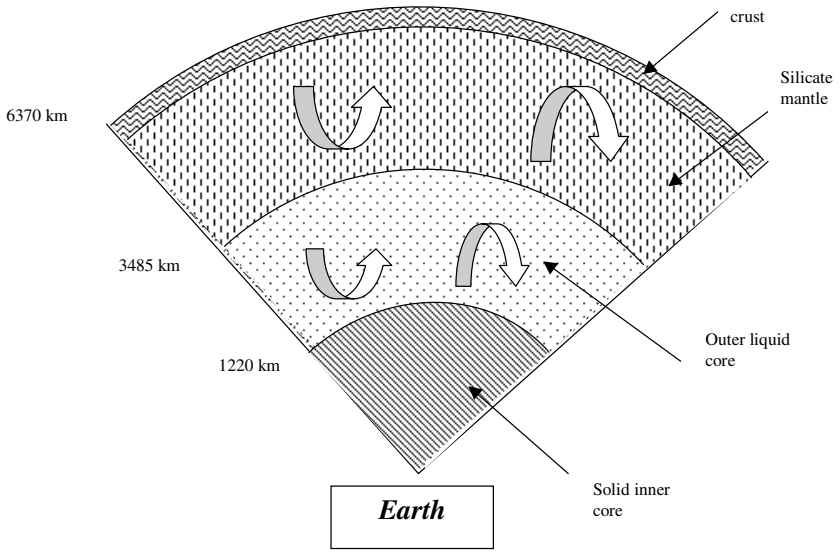

Figure 4. The interior of Earth.

not have the same composition as the primordial Sun, and the differences in composition, though small, are very important. It has long been suspected that Jupiter possesses a core of rock and/or ice, perhaps about ten Earth masses. However, this would be only ∼0.3% or less of the entire mass of the planet and thus very hard to detect! The very precise gravity data obtained by spacecraft do not tell us with certainty whether this core exists, partly because there are still uncertainties in the high pressure behavior of the dominant constituents (hydrogen and helium), and partly because gravity data always admit multiple interpretations. Unlike terrestrial planets, where the core is thought to form by a differentiation event (because of the inability of iron and silicates to remain well-mixed when partially or completely molten), the presence of a core in Jupiter and other giant planets is expected for the popular formation scenario in which a rock–ice core forms first and then gas is added on top. The atmosphere is enriched in a number of elements, notably carbon (in the form of methane) and heavier noble gases; this is probably due to the infall of icy bodies, perhaps including bodies that formed at far greater distance from the Sun where temperatures were very low.

The Galilean satellites are as rich and complex as an entire planetary system. *Io* is roughly Earth-like in composition, though possibly with more volatiles (e.g. a

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

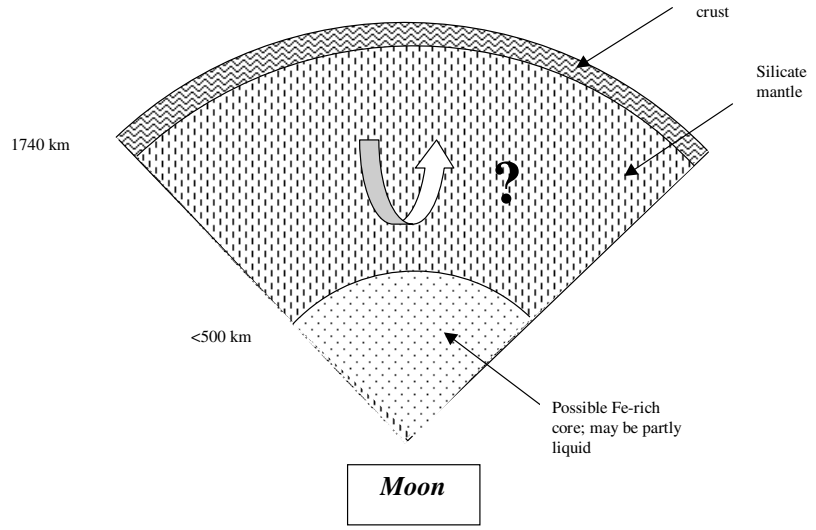

Figure 5. The interior of the Moon.

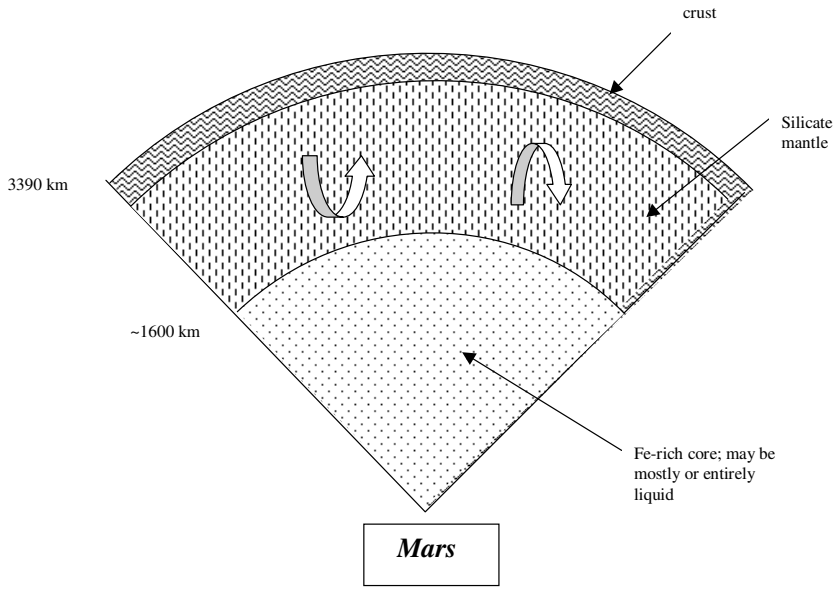

Figure 6. The interior of Mars.

more nearly cosmic sulfur to iron ratio). Gravity data tell us that Io possesses a core, presumably a liquid core of iron and sulfur. Tidal heating has made it the most volcanically active body in the solar system and it has been suggested that a large fraction of the interior is continuously molten. *Europa* is also mostly Earth-like in composition but has a 100–200 km layer of H_2O (as ice or water) on the outside. Tidal heating may cause a large part of this layer to be in the form of an ocean, and the proximity of this layer to the surface has led to speculation about Europa as a possible habitat for past or present life. *Ganymede* is the largest satellite in the solar system and is roughly half (water-dominated) ice and half rock by mass. Gravity data tell us that the body is differentiated, with the central region being Io-like in structure. The evidence of past ice tectonics on the surface suggest that Ganymede has been through an epoch of severe internal heating, possibly tidal in origin. *Callisto* is very similar to Ganymede in size and bulk composition yet remarkably different in other ways: it is only partially differentiated (i.e., the rock and ice are partly mixed), it does not have a large magnetic field and it exhibits none of the tectonic terrains (so-called grooved terrains) that are so common on Ganymede. The differences between Ganymede and Callisto are not well understood.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

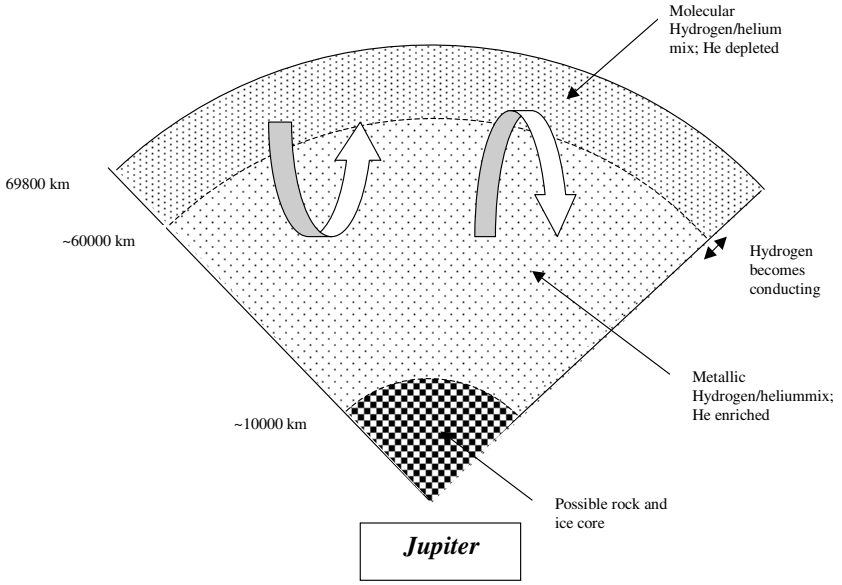

Figure 7. The interior of Jupiter.

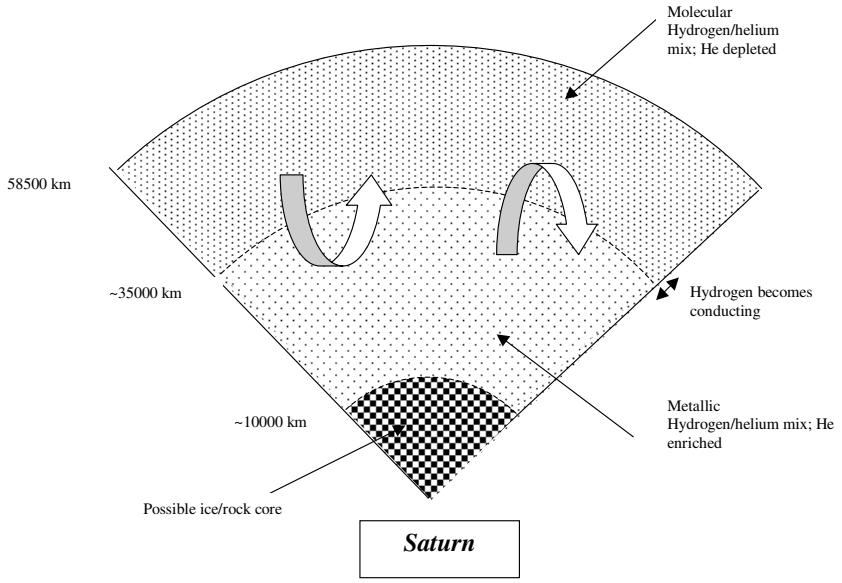

Figure 8. The interior of Saturn.

Saturn is in many ways similar to Jupiter: similar bulk composition, large magnetic field and heat flow. The lower mass means that hydrogen becomes an electrical conductor at greater depths, the magnetic field is generated deeper down, and there is more reliance on helium rain as an energy source. There is somewhat stronger evidence for a central ice/rock core in Saturn than in Jupiter, mainly because it is plausibly around ten Earth masses and thus a bigger fraction of the total mass and easier to detect. Saturn's atmosphere is more enriched in elements such as carbon than is Jupiter's atmosphere, consistent with a large influx of comet-like planetesimals after planet formation (see PLANETARY ATMOSPHERES).

Titan has similarities to Ganymede and Callisto, except that it is richer in some volatile elements and accordingly has a dense, opaque atmosphere consisting mainly of nitrogen and methane. The continuous destruction of methane by solar UV leads to the requirement that Titan has the equivalent of a kilometer of liquid methane or more (some of which has now been converted to liquid ethane and other hydrocarbons). This hydrocarbon reservoir may be partly on the surface as

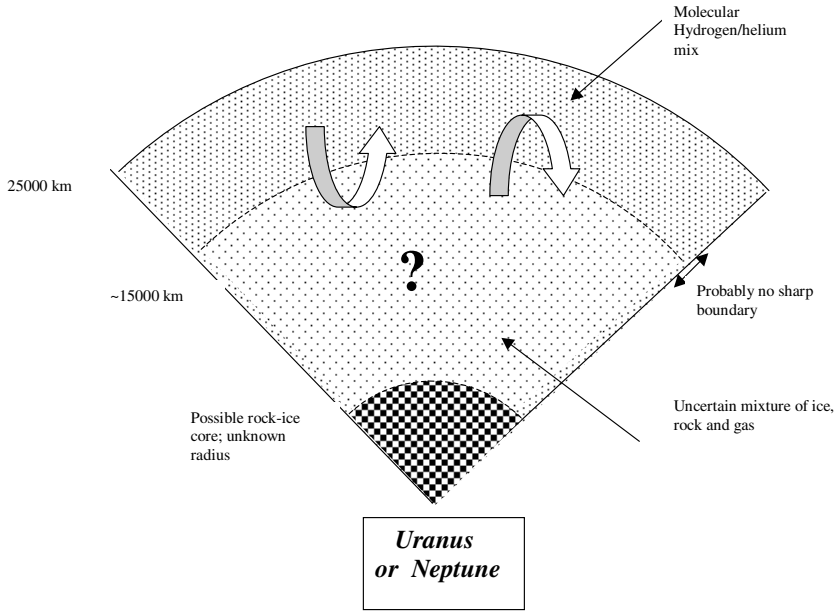

Figure 9. The interior of Uranus or Neptune.

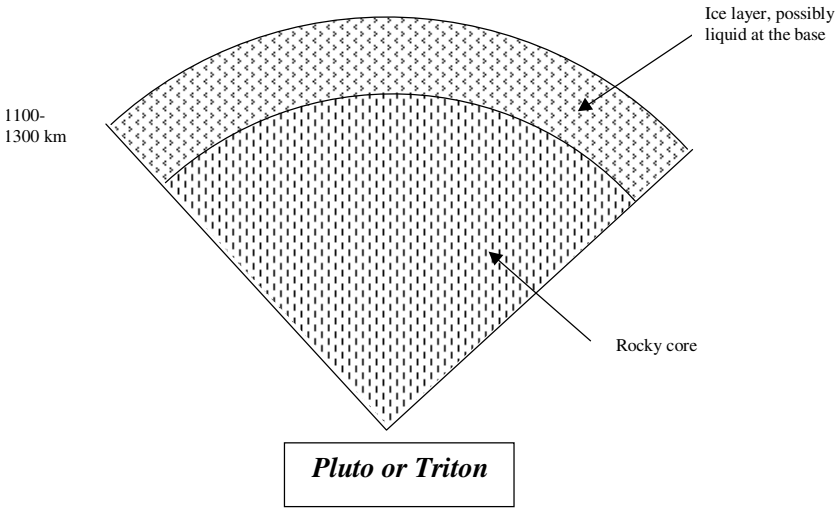

Figure 10. The interior of Pluto or Triton.

oceans or lakes and partly subsurface (analogous to aquifer storage of water in Earth's crust).

Uranus and *Neptune* are very similar but form a distinct class of planets in which no one or two of the three categories of materials ('gas', 'ice' and 'rock') dominates over the other(s). Certainly they possess several Earth masses of solar composition (hydrogen-dominated) material primarily in the outer regions which is responsible for the large radius and low mean density. However, most of the mass is in ice and rock, distributed in an unknown way deep down. Neptune has a higher heat flow than Uranus, but both have magnetic fields, suggesting that both have convective shells at pressures and temperatures where water can conduct electricity.

Triton, *Pluto* and *Charon* have many similarities. Triton is a moon of Neptune, though probably captured, and thus formed in a way that may be indistinguishable from the formation of Pluto. Charon is the moon of Pluto. All of these bodies have mean densities of around 2 g cm^{-3} and must have a lower ice mass relative to rock than we find in the large icy satellites (Ganymede, Callisto, Titan), though with uncertain amounts of other volatiles (methane, molecular nitrogen) that are mostly frozen out on the surface or contained internally.

The future

Progress in understanding the interiors of planets may be slow, partly because it relies heavily on seismology (solid bodies) or deep atmospheric probes (giant planets)—and these are difficult missions—and partly because appropriate laboratory experiments are difficult. Mars is probably the body where the greatest advances, including the installation of a seismic network, can be expected in the coming decade. Detection and characterization of extra-solar system planets (EXOPLANETS) provides much hope for a fuller display of planetary menageries.

Planetary Ionospheres

Most planets and many satellites in our solar system are surrounded by envelopes of gravitationally bound gases. The interaction of solar radiation and charged particles of solar wind and planetary magnetospheric origin with these gases produces weak IONIZATION that creates planetary ionospheres embedded within the more dense PLANETARY ATMOSPHERES. Additional sources of ionization which are relatively more important in the outer solar system include resonance scattering of solar radiation by interplanetary atomic hydrogen, cosmic rays and UV starlight from the southern Milky Way and the Orion region. The free electrons and ions that result from this interaction are dominated by a thermal population with energies generally comparable to, but not much higher than, the neutral atmosphere and bound to the planet or satellite by gravitational and/or magnetic forces. This thermal population of gravitationally bound electrons and ions is one possible way to define a planetary ionosphere. The interaction of plasma in the inner Jovian magnetosphere with the atmospheres of the Galilean satellites produces ionospheres that strain this definition (see MAGNETOSPHERES: JUPITER, SATELLITE INTERACTIONS). In this case frequent collisions between the ions and the neutral atmosphere can be a sufficient constraining force on the ionospheric plasma with respect to $\boldsymbol{v} \times \boldsymbol{B}$ convection away from the satellite.

Planetary ionospheres can be classified according to the major categories of planetary atmospheres: (a) the H_2–He atmospheres of the GIANT PLANETS, (b) the CO_2 atmospheres of MARS and VENUS and (c) the N_2 atmospheres of EARTH, PLUTO and satellites TITAN and TRITON. In addition to these categories there is the volcanic generated SO_2 atmosphere of IO, tenuous sputter generated O_2 atmospheres of the other Galilean satellites, and exospheres on MERCURY and the MOON.

Nomenclature

When an electrically conducting layer was discovered (or perhaps better, verified experimentally) in the Earth's upper atmosphere by reflected radio waves, E V APPLETON, to whom the Nobel prize for physics was awarded in 1947, labelled it the 'E-layer' for the reflected wave's electric field. When he inferred additional layers experimentally, he named them D and F layers, and since then this 'letter' terminology has been firmly established in the nomenclature of Earth's ionosphere and by analogy to ionospheres elsewhere in the solar system. Figure 1 presents a schematic of these layers/regions, which are defined below.

D region

The 60–95 km region in the Earth's ionosphere is characterized by a total neutral atmosphere column density of $\sim 10^{20}$ cm^{-2} between the region and the top of the atmosphere. Absorption of solar Lyman-α by NO and solar x-rays below 10 Å and cosmic rays by air are the principal ionization mechanisms. Positive ions are molecular: NO^+ and hydrated ion clusters with three-body reactions being important in the formation of these clusters. A Chapman layer description is generally valid for this region (see below). Near the bottom of this region, negative ions are present.

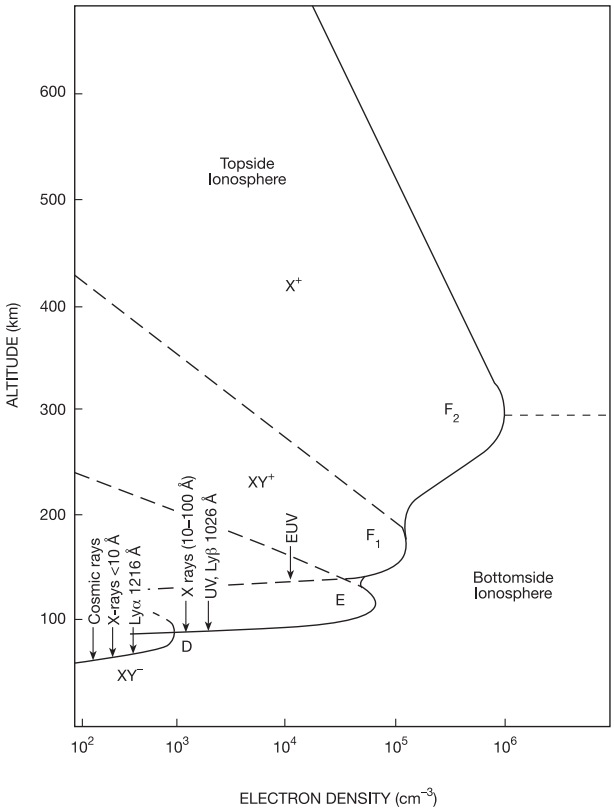

Figure 1. Schematic diagram of the Earth's principal ionospheric regions. X^+, XY^+, and XY^- designate positive atomic ion, positive molecular ion, and negative molecular ion respectively. (After Bauer 1973.)

E region

The 95–135 km region in the Earth's ionosphere is characterized by a total neutral atmosphere column density of $\sim 10^{19}$ cm^{-2} between the region and the top of the atmosphere. Atmospheric absorption of soft solar x-rays and EUV radiation produces the ionization and the terminal ions are predominantly O_2^+ and NO^+. A Chapman layer model with photochemical equilibrium and chemical loss proportional to the electron density squared are a good description. Plasma transport is generally negligible.

F1 region

The 135–200 km region where the peak production of atomic ions occurs and ion loss is controlled by dissociative recombination (see below) is known as the F1 region. In many instances this region is not a distinct layer, but merely a ledge in electron density. The total neutral

atmosphere column density between the region and the top of the atmosphere is $\sim 10^{17}$ cm^{-2}, the inverse of a typical absorption/ionization cross section of an atom and molecule for FUV and near EUV radiation.

F2 region
This is the region above 200 km, where production of ionization is in the optically thin limit and ion loss is limited by ion–atom and ion–molecule reaction rates with a linear dependence on electron density. Plasma transport due to diffusion and neutral wind induced drifts is extremely important. The electron density in the Earth's ionosphere reaches an absolute maximum where the chemical ion loss time constant is equal to the time constant for plasma transport.

Ionization

The binding energy of an outer shell electron known as the ionization potential (IP) is fairly large, with a typical range of 9–25 eV, as given in table 1. The notable exceptions are the alkali metals with IPs as low as 5 eV. Thus only solar radiation shortward of ~1300 Å and mostly below 1000 Å is important in producing ionospheric plasma. For comparison purposes the energy required to break apart a simple molecule known as the bond dissociation energy is typically ~5 eV, with CO and N_2 being the most notable exceptions. Charged particles must have a high velocity to have sufficient energy to remove an electron from a neutral atom or molecule and to attain a large cross section or probability for ionization of neutrals. Consequently, faster moving electrons are far more important than ions in generating ionospheric plasma.

Absorption of solar radiation and the classical Chapman production rate expression

The attenuation of monochromatic solar radiation at wavelength, λ, through a purely absorbing atmosphere with height, z, measured from the surface, is given by the expression

$$f(\lambda, z) = f(\lambda, \infty) \exp[-\tau(\lambda, z) \sec \chi] \qquad (1)$$

where

$$\tau(\lambda, z) = \sigma_a \int_z^\infty n \, \mathrm{d}z$$

σ_a is the total absorption cross section and χ is the solar zenith angle. If the absorbing gas is in hydrostatic equilibrium, then $\int_z^\infty n \, \mathrm{d}z = nH$, where H is the scale height of the absorbing gas. If more than one constituent absorbs solar radiation at the same wavelength, the optical depth, τ, must be summed over all absorbing species. When absorption of solar radiation leads to ionization, the photoionization rate of the ith constituent, q_i, at a given height is proportional to the attenuated solar flux, the cross section for ionization σ_i and the atmospheric concentration of the ith constituent. Integrating over wavelength, the photoionization rate is

$$q_i(z) = n_i(z) \int_{\lambda(\mathrm{IP})}^0 \sigma_i(\lambda) f(\lambda, z) \, \mathrm{d}\lambda. \qquad (2)$$

Table 1. Ionization potentials (IP) for atoms and molecules of interest in planetary ionospheres. Dissociation energies for molecules.

Species	IP (eV)	$\lambda(IP)$ (Å)	Dissociation energy (eV)
K	4.34	2857	—
Na	5.14	2412	—
Mg	7.64	1621	—
NO	9.26	1340	6.5
CH_3	9.83	1261	4.69
NH_3	10.15	1222	4.40
SO	10.29	1205	5.36
S	10.36	1197	—
C	11.256	1102	—
C_2H_2	11.4	1088	5.38
O_2	12.1	1025	5.115
H_2O	12.6	984	5.118
SO_2	13.1	947	5.65
CH_4	13.1	947	4.5
H	13.595	912	—
O	13.614	911	—
CO_2	13.79	899	5.453
CO	14.0	886	11.09
N	14.545	853	—

Ar	15.75	787	—
Ne	21.56	575	—
He	24.58	504	—

For simplicity assume $\sigma_i = \sigma_a = \sigma$, a single atmospheric constituent in hydrostatic equilibrium, and a monochromatic beam of sunlight, then

$$q(z) = \sigma n(z) f(\lambda, \infty) \exp[-\sigma n(z) H \sec \chi] \qquad (3)$$

provided $\chi \leq 80^\circ$. The peak production, $q_{\max}$, occurs where $\mathrm{d}q/\mathrm{d}z = 0$. This occurs where the slant optical depth is unity

$$q = q_{\max} = \sigma n f(\lambda, \infty) \, \mathrm{e}^{-1} = \frac{f(\lambda, \infty) \, \mathrm{e}^{-1}}{H \sec \chi}$$

where

$$\tau_{\mathrm{slant}} = \sigma H n \sec \chi = 1. \qquad (4)$$

Note that $q_{\max} \propto \cos \chi$, and $q_{\max}$ is largest when $\chi = 0^\circ$, i.e. overhead sun. Also the height of the peak production z_{peak} is at a minimum altitude when $\chi = 0^\circ$, since at $\tau = 1$, $\sigma H n \propto 1/\sec \chi$ reaches its maximum value with $\chi = 0^\circ$.

Let $h = z/H$, and $n = n_0 \exp(-h)$, then (3) can be transformed to the classical Chapman production rate expression

$$q(h) = \frac{f(\lambda, \infty)}{H} \exp(-h - \mathrm{e}^{-h} \sec \chi) \qquad (5)$$

where the reference levels $h = 0$ and $z = 0$ are the location of $q_{\max}$ when $\chi = 0^\circ$, and $q(h = 0) = q_{\max}(\chi = 0)$. The peak, when $\chi \neq 0$, is located at $z_{\mathrm{peak}} = H \ln \sec \chi$ and $h_{\mathrm{peak}} = z_{\mathrm{peak}}/H$.

For the major constituents in planetary atmospheres, the ionization rate

$$I_\infty = \int_{\lambda(\mathrm{IP})}^{0} \sigma_i(\lambda)\, f(\lambda, \infty)\, \mathrm{d}\lambda \tag{6}$$

at 1 AU (the Earth's orbital distance from the Sun) is in the range of $(0.5\text{–}10) \times 10^{-7}\ \mathrm{s}^{-1}$ with the low values appropriate for H, H_2, He and the large values for species with low ionization potentials such as NO. For O, O_2, N_2, the rates are in range of $(2\text{–}5) \times 10^{-7}\ \mathrm{s}^{-1}$. Of course these rates must be adjusted by the inverse of the planetary distance from the Sun squared ($1/r^2$ factor) for other planets and there is also a factor of 2–3 variability due to solar cycle variation of the Sun's EUV and FUV flux output.

A description of the penetration and ionization rate profile for charged particles is beyond the scope of this article. Generally the required description involves the solution of either a Boltzmann equation or a Fokker–Planck equation. Based on experimental data for ionization and penetration of electrons and some ions, range formulae have been determined to estimate penetration depth in an atmosphere in units of g cm^{-2}. For electron energies above 100 eV, the electron interaction with most gases generates an ion–electron pair for every 35 eV of energy expended. Thus a 3.5 keV electron would produce a total ionization rate of 100 electron–ion pairs.

Ionospheric chemistry

The primary production of ions in a planetary atmosphere is due to ionization of the dominant constituents. For the EARTH'S ATMOSPHERE of N_2, O_2 and O in the thermosphere, the major ionization sources are

$$\begin{aligned} &\mathrm{O} + h\nu \rightarrow \mathrm{O}^+ + \mathrm{e} \\ &\mathrm{O}_2 + h\nu \rightarrow \mathrm{O}_2^+ + \mathrm{e} \text{ or } \mathrm{O} + \mathrm{O}^+ + \mathrm{e} \\ &\mathrm{N}_2 + h\nu \rightarrow \mathrm{N}_2^+ + \mathrm{e} \text{ or } \mathrm{N} + \mathrm{N}^+ + \mathrm{e} \end{aligned} \tag{7}$$

where the electron is ejected with most of the excess translation energy and may have sufficient energy to ionize other atoms or molecules and collisionally excite atoms and molecules. For the H_2–He atmospheres of the giant planets, one can substitute H for O in the first two equations above. Atomic helium ions are also created. In CO_2 atmospheres, CO_2^+ is the major ion initially produced. Once the primary ions are formed they may undergo a variety of chemical reactions. Symmetric charge exchange reactions ($X^+ + X \rightarrow X + X^+$) have no net chemical effect, but provide a mechanism for converting hot ions into hot neutrals which can enhance the escape rate of atmospheric species near the exobase. Charge exchange reactions involving unlike atoms are generally very slow at normal ionospheric temperatures, unless the reaction is accidently resonant (i.e. the atoms have almost the same ionization potential) with the most notable example being $H^+ + O \leftrightarrow H + O^+$. Ions may subsequently react in ion–atom and ion–molecule interchange reactions generically written as

$$\mathrm{A}^+ + \mathrm{BC} \rightarrow \mathrm{AB}^+ + \mathrm{C}$$

$$\mathrm{AB}^+ + \mathrm{C} \rightarrow \mathrm{A}^+ + \mathrm{BC}. \tag{8}$$

At normal ionospheric temperatures these reactions occur by an induced dipole polarization interaction for which the theoretical rate constant known as the Langevin rate constant is given by

$$k_L = 2.6 \times 10^{-9} \left(\frac{\alpha}{\mu}\right)^{1/2}\ \mathrm{cm}^3\ \mathrm{s}^{-1} \tag{9}$$

where α is the polarizability of the neutral in units of $10^{-24}\ \mathrm{cm}^3$ and μ is the reduced mass of the system in atomic mass units (amu). Most ion–atom and ion–molecule reactions proceed at or near the Langevin rate. There are, however, some notable exceptions which are extremely important reactions in the Earth's upper ionosphere, which allow the F region to attain electron densities as high $10^6\ \mathrm{cm}^{-3}$:

$$\begin{aligned} &\mathrm{O}^+ + \mathrm{N}_2 \rightarrow \mathrm{NO}^+ + \mathrm{N} \qquad k \sim 10^{-12}\ \mathrm{cm}^3\ \mathrm{s}^{-1} \\ &\mathrm{O}^+ + \mathrm{O}_2 \rightarrow \mathrm{O}_2^+ + \mathrm{O} \qquad k \sim 10^{-11}\ \mathrm{cm}^3\ \mathrm{s}^{-1}. \end{aligned} \tag{10}$$

These reaction are two and three orders of magnitude slower than the Langevin rate, but

$$\mathrm{N}_2^+ + \mathrm{O} \rightarrow \mathrm{NO}^+ + \mathrm{N} \qquad k \sim 10^{-10}\ \mathrm{cm}^3\ \mathrm{s}^{-1} \tag{11}$$

is faster.

The direction of ion–atom and ion–molecule reactions is always to yield an ion whose neutral progenitor has a lower ionization potential, as a consequence of the necessity for the reaction to proceed via an exothermic channel. This leads to the concept of the terminal ion. In the absence of loss processes which remove ionization (e.g. recombination or transport) ion–atom and ion–molecule reactions will convert all ions to the one whose neutral progenitor has the lowest ionization potential, hence the term terminal ion. For example, in pure air containing only atoms and molecules of nitrogen and oxygen, NO has the lowest ionization potential (cf table 1) and thus NO^+ will be the terminal ion. Introduce an alkali metal such as Na and it will now have the lowest ionization potential and the terminal ion will be Na^+.

Recombination

Ionospheric plasma can recombine by radiative recombination also known as radiative association

$$\mathrm{A}^+ + \mathrm{e} \rightarrow \mathrm{A} + h\nu \qquad \alpha_{\mathrm{rad}} \sim (1\text{–}10) \times 10^{-12}\ \mathrm{cm}^3\ \mathrm{s}^{-1} \tag{12}$$

which is extremely slow because the excess energy (=the ionization potential) must be radiated away. This is generally an inefficient energy loss process due to the mismatch in radiative lifetimes and the time interval when the electron and ion are in close vicinity to each other. Thus terminal atomic ions can potentially attain high densities in the absence of other loss processes. The preferred path for recombination of ionospheric plasma is the conversion of atomic ions to molecular ions which then proceeds via a

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

dissociative path involving the formation and dissociation of intermediate state AB*

$$AB^+ + e \rightarrow AB^* \rightarrow A + B \qquad \alpha_d \sim (0.1\text{–}10) \times 10^{-7}\ \mathrm{cm^3\ s^{-1}}. \tag{13}$$

The ionization potential energy is partially consumed by the dissociation of the molecule AB and in many instances either fragment A or B or both are electronically excited. With two fragments the rest of the energy can easily be carried away as translational energy.

The relative velocity for recombination is the electron's velocity and dissociative and radiative recombination rates are faster at lower electron temperatures due to the longer Coulombic interaction time interval at low velocities. Dissociative and radiative recombination rates vary with electron temperature typically as $T_e^{-(0.75\pm0.25)}$.

For the Earth's ionosphere the three major recombination reactions are

$$\begin{aligned} &O_2^+ + e \rightarrow O + O \\ &NO^+ + e \rightarrow N + O \qquad \alpha_d \sim (2\text{–}4) \times 10^{-7}\ \mathrm{cm^3\ s^{-1}} \\ &N_2^+ + e \rightarrow N + N \end{aligned} \tag{14}$$

whereas the following reactions are negligible loss paths

$$\begin{aligned} &O^+ + e \rightarrow O + h\nu \qquad \alpha_r \sim 3 \times 10^{-12}\ \mathrm{cm^3\ s^{-1}} \\ &O_2^+ + e \rightarrow O_2 + h\nu \qquad \alpha_r \sim 10^{-10}\ \mathrm{cm^3\ s^{-1}} \end{aligned} \tag{15}$$

due to their slow rates.

But $O^+ + O^- \rightarrow O + O$ is fast, $\alpha = 2.7 \times 10^{-7}(T/300)^{-0.45}\ \mathrm{cm^3\ s^{-1}}$. However, negative ion densities are negligible above the mesopause (pressures less than 0.01 mbar). Negative ions are primarily produced by three-body reactions

$$e + AB + M \rightarrow AB^- + M \tag{16}$$

which require high pressures (>0.01 mbar) to form negative ions quickly, and are destroyed by the photodetachment process

$$AB^- + h\nu \rightarrow AB + e. \tag{17}$$

Generally the electron affinities of neutral atmospheric species are small (<1 eV, e.g. 0.44 eV for O_2) so visible sunlight can readily detach the electron. A notable exception is NO_3^-, with an electron affinity of 3.9 eV. At night in the absence of an ionization source the ionosphere recombines rapidly and negative ions are not important even though photodetachment is inoperative.

To understand some of the general ionospheric features let us consider the ionospheric plasma to be composed of atomic ions A^+ and molecular ions M^+ in a neutral gas M with electron density [e]. Charge neutrality is an excellent approximation throughout the ionosphere and requires that $[e] = [A^+] + [M^+]$.

The relevant reactions are

$$\begin{aligned} &A + h\nu \rightarrow A^+ + e \qquad q = I_\infty[A](\mathrm{cm^{-3}\ s^{-1}}) \\ &A^+ + M \rightarrow M^+ + A \qquad \gamma(\mathrm{cm^3\ s^{-1}}) \\ &A^+ + e \rightarrow A + h\nu \qquad \alpha_r(\mathrm{cm^3\ s^{-1}}) \\ &M^+ + e \rightarrow A + A \qquad \alpha_d(\mathrm{cm^3\ s^{-1}}) \end{aligned} \tag{18}$$

where $\gamma = \epsilon k_L$ and ϵ is ratio of the actual rate to the Langevin rate (9). The relevant continuity equations are

$$\frac{\partial[e]}{\partial t} = q - \alpha_d[M^+][e] - \alpha_r[A^+][e] \tag{19}$$

$$\frac{\partial[A^+]}{\partial t} = q - \gamma[M][A^+] - \alpha_r[A^+][e] \tag{20}$$

$$\frac{\partial[M^+]}{\partial t} = \gamma[M][A^+] - \alpha_d[M^+][e] \tag{21}$$

where [] denotes number density. In photochemical (stationary or steady) state equilibrium the last continuity equation is

$$\frac{[(A)^+]}{[M^+]} = \frac{\alpha_d[e]}{\gamma[M]} \tag{22}$$

and then charge neutrality can be written as

$$[e] = \left(\frac{\alpha_d[e]}{\gamma[M]} + 1\right)[M^+] \tag{23}$$

and in photochemical equilibrium, the electron continuity equation becomes

$$q = \left\{\left(\frac{\alpha_d[e]}{\gamma[M]} + 1\right)^{-1} + \frac{\alpha_r[M^+]}{\gamma[M]}\right\}\alpha_d[e]^2. \tag{24}$$

The second term on the right-hand side is due to radiative recombination and will always be small in comparison to the first term ($\alpha_d\alpha_r[M^+][e] \ll \gamma^2[M]^2$) for weakly ionized planetary atmospheres. Hence this equation can be rewritten as

$$\frac{1}{q} = \frac{1}{\gamma[M][e]} + \frac{1}{\alpha_d[e]^2}. \tag{25}$$

When $\gamma[M] \gg \alpha_d[e]$, appropriate for the lower ionosphere, then $[M^+] \gg [A^+]$, i.e. mostly molecular ions, and $q = \alpha_d[e]^2$. This is known as the E-region solution which is most appropriate for the 95–135 km region of the Earth's ionosphere and is also called the square-law loss formula due to quadratic dependence on electron density. When $\gamma[M] \ll \alpha_d[e]$, which is valid for low pressures and high in the ionosphere, then $[M^+] \ll [A^+]$ and $q = \gamma[M][e]$ which is known as the F2-region solution, appropriate for above 200 km and is also called the linear loss formula. In this region the ionosphere is composed of mostly atomic ions. For the Earth's ionosphere one may adopt typical values of $q \sim 10^3\ \mathrm{cm^{-3}\ s^{-1}}$, $\alpha_d \sim 10^{-7}\ \mathrm{cm^3\ s^{-1}}$, $\gamma \sim 10^{-12}\ \mathrm{cm^3\ s^{-1}}$, $[M] \sim 10^9\ \mathrm{cm^{-3}}$ to estimate $[e] = (q/\alpha_d)^{1/2} \sim 10^5\ \mathrm{cm^{-3}}$ in the square loss region and $[e] = q/\gamma[M] \sim 10^6\ \mathrm{cm^{-3}}$ in the linear loss region as representative electron concentrations.

The continuity equation with plasma transport

At and above the F_2 peak (in electron density) plasma transport becomes important. Plasma can be transported by ambipolar diffusion and by neutral winds dragging ions and electrons up and down field lines. Ionospheric plasma satisfies the plasma approximation which means that the inverse of the product of the plasma density times the Debye length cubed is a small number. Hence the ionospheric plasma behaves as if it were an ideal gas, in spite of the Coulombic interaction of electrons and ions, because the mean kinetic energy is much greater than the interparticle potential energy. Ionospheric temperatures generally are equal to or exceed the neutral temperatures in planetary ionospheres. While it is not necessary for a planet or satellite to have a magnetic field, one test of the relative importance of a planetary magnetic field is the plasma beta parameter, which is the ratio of total plasma pressure to magnetic pressure, or equivalently, the ratio of plasma thermal energy to magnetic energy

$$\beta = \frac{n_i k T_i + n_e k T_e}{B^2/8\pi} \tag{26}$$

where k is Boltzmann's constant. In a magnetic field in the absence of collisions a charged particle executes helical motion perpendicular to the magnetic field with a cyclotron or gyrofrequency given by $\omega = eB/mc$ and corresponding gyroradius or Larmor radius $a_L = v_{\rm perp}/\omega$. The ratio of the gyrofrequency to the collision frequency with neutrals determines whether the motion of electrons and ions is constrained by magnetic fields (large ratio) or unaffected by magnetic fields (small ratio).

In an ionized gas electrons diffuse much more rapidly than ions, but for length scales in excess of the Debye length, the electrons and ions must diffuse with the same velocity by virtue of a strong electrostatic polarization field coupling the electrons and the ions. This process is known as ambipolar diffusion. In planetary ionospheres plasma diffusion and wind induced transport is most important at low pressures and high altitudes, where the ratio of the electron gyrofrequency to the electron collision frequency with neutrals is extremely large (effectively infinite) and the ratio of the ion gyrofrequency to the ion collision frequency with neutrals is large ($\gg$1).

To illustrate the importance of plasma transport which can strongly influence the vertical density distribution of ionospheric plasma let us consider the continuity equation for the number density of the major ion species i

$$\frac{\partial n_i}{\partial t} + \nabla \cdot (n_i \boldsymbol{v}_i) = P_i - L_i n_i \tag{27}$$

where P_i is the production rate per unit volume per unit time, L_i is the loss rate per unit time and v_i is the ion velocity of species i. On a planet or satellite with a magnetic field which may be internal and intrinsic, induced, or imposed by the parent planet or solar wind, the vertical ion flux, ϕ_i, in the limit of a large ratio of the ion gyrofrequency to the ion collision frequency with neutrals, is given by

$$\begin{aligned}\phi_i = n_i w_i &= -n_i \sin^2 I [D_a \mathcal{D} + v_n \cos I \sin I] \\ &= -\sin^2 I D_a \left(\frac{\partial n_i}{\partial z} + \frac{n_i}{H_{eff}} \right)\end{aligned} \tag{28}$$

where w_i is the vertical ion velocity

$$\nu_{\rm in} = k_L n_n$$

is the ion–neutral collision frequency

$$D_a = \frac{k(T_e + T_i)}{\nu_{\rm in} m_i}$$

the ambipolar diffusion coefficient

$$H_i = \frac{k(T_e + T_i)}{m_i g}$$

is the plasma scale height

$$H_{\rm eff} = H_i \left(1 + \frac{H_i}{T_e + T_i} \frac{\partial (T_e + T_i)}{\partial z} + \frac{H_i v_n \cot I}{D_a} \right)^{-1}$$

is the effective plasma scale height and

$$\mathcal{D} = \frac{1}{n_i (T_e + T_i)} \frac{\partial}{\partial z} [n_i (T_e + T_i)] + \frac{1}{H_i}$$

where the latter expression represents the net imbalance between the upward plasma pressure gradient and the downward force of gravity. The subscript n denotes neutral gas and I is the magnetic dip angle measured from the horizontal to the magnetic field vector, which is positive in the downward direction. Thus a neutral horizontal wind component along the magnetic field line ($v_n \cos I > 0$), induces a downward ion flux when the magnetic dip angle is positive.

From the continuity equation terms, time constants for the three important processes can be defined as

(a) diffusion time constant

$$\tau_{\rm diff} = \frac{H_i^2}{\mathcal{D}_a \sin^2 I} \tag{29}$$

(b) wind time constant

$$\tau_{\rm wind} = \frac{H_i}{|v_n| \cos I \sin I} \tag{30}$$

(c) transport time constant

$$\tau_{\rm tran} = \{\tau_{\rm diff}^{-1} + \tau_{\rm wind}^{-1}\}^{-1} = \frac{H_i}{(\mathcal{D}_a \sin^2 I / H_i) + v_n \cos I \sin I} \tag{31}$$

(d) chemical time constant

$$\tau_{\rm chem} = L_i^{-1}. \tag{32}$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

With transport included, the peak electron density will occur approximately where the time constants for chemistry and transport are equal, i.e. at a neutral density given by

$$n_n = \frac{b_a \sin^2 I}{H_i\{H_i L_i^{-1} - v_n \cos I \sin I\}} \tag{33}$$

where $b_a = [k(T_e + T_i)]/(k_L m_i) = n\mathcal{D}_a$ is the ambipolar collision coefficient. When winds drag ions up the field lines ($v_n < 0$), then the ionospheric peak is raised in altitude. But there must be net flow downward due to the presence of a chemical sink at lower altitudes and therefore the diffusion velocity should exceed the vertical drift velocity induced by the neutral winds. This statement implies that the peak must occur at a density where

$$n_n = \left| \frac{b_a \tan I}{v_n H_i} \right|. \tag{34}$$

When $v_n = 0$, then ambipolar diffusion and chemistry determine the location of the electron density peak. When winds drag ions down the field lines ($v_n > 0$), then the ionospheric peak is lowered and ambipolar diffusion and winds act in concert.

Note that winds also alter the shape of the electron density profile, especially in the vicinity of the maximum density as evident from the ratio of the effective to actual plasma scale height $H_{\rm eff}/H_i$. Because D_a decreases exponentially with altitude, $H_{\rm eff}$ rapidly approaches H_i within one to two scale heights above the density peak.

At extremely high altitudes in a planetary ionosphere, ambipolar diffusion overpowers wind induced transport and the electron density profile depends on the upper boundary conditions. The diffusion differential equation possesses two basic solutions: (a) a no-flow, static equilibrium with the plasma density distribution given by the plasma scale height H_i, and (b) a non-zero diffusion velocity with the plasma density distribution given by the neutral gas scale height which in thermal equilibrium is one-half the plasma scale height. The latter solution represents the maximum upward flux under steady state conditions and is applicable when the magnetic field lines are open or non-existent and plasma is sufficiently energetic to escape the gravitational field of the planet or satellite. Along closed magnetic field lines the ionospheric plasma is confined and the no-flow solution is applicable.

Unlike the neutral gas species, which above the homopause are in gravitational diffusive equilibrium independent of each other, a mixture of multiple ion species in gravitational diffusive equilibrium are *not* independent of each other because the polarization electric field acts on all ions according to their masses, charge states and temperatures.

Ionospheric currents

In the Earth's E region, especially the ratio of the electron gyrofrequency to the electron collision frequency with neutrals, $\omega_e/\nu_{\rm en}$ is extremely large whereas the ratio of the ion gyrofrequency to the ion collision frequency with neutrals $\omega_i/\nu_{\rm in}$ is $\sim$1. As a consequence the ion motion is strongly coupled to neutral winds through frequent collisions, but the electrons are frozen to move along magnetic field lines. The net effect is a substantial difference in the electron and ion velocities, which leads to current flow in the ionosphere. The presence of a magnetic field generates a highly anisotropic conductivity in the ionosphere, which can be represented mathematically by a tensor. The current flowing parallel to the magnetic field lines (or in the absence of a magnetic field) is given by

$$j_\parallel = \sigma_0 E_\parallel$$

where

$$\sigma_0 = e^2 \sum_{e,i} \frac{n_j}{m_j \nu_{jn}} \tag{35}$$

where the sum is performed over electrons and ions and σ_0 is the longitudinal or direct conductivity and the current perpendicular to the magnetic field lines is given by

$$\boldsymbol{j}_{\rm perp} = \sigma_1 \boldsymbol{E}_{\rm perp} + \sigma_2 c \frac{\boldsymbol{B} \times \boldsymbol{E}_{\rm perp}}{B^2} \tag{36}$$

where

$$\sigma_1 = e^2 \sum_{e,i} \frac{n_j}{m_j \nu_{jn}} \left(\frac{\nu_{jn}^2}{\nu_{jn}^2 + \omega_j^2} \right)$$

and

$$\sigma_2 = e^2 \sum_{e,i} \frac{n_j \omega_j}{m_j (\nu_{jn}^2 + \omega_j^2)} \tag{37}$$

with σ_1 known as the Pedersen conductivity which is parallel to the electric field and perpendicular to the magnetic field and σ_2, the Hall conductivity, which is perpendicular to both the electric and magnetic fields. Note that ω_j is positive for ions and negative for electrons in (37). The electric field can be an imposed field from the magnetosphere, a polarization field, or an induction field $\boldsymbol{v}_n \times \boldsymbol{B}$ due to neutral winds.

Generally in planetary ionospheres, vertical length scales are much smaller than horizontal length scales and to lowest order the vertical electric current is zero. Thus the electric currents in the ionosphere are essentially horizontal. With a right-handed horizontal coordinate system (x, y) and y parallel to the vertical plane containing $\boldsymbol{B}$, Ohm's law may be written as

$$\begin{pmatrix} j_x \\ j_y \end{pmatrix} = \begin{pmatrix} \sigma_{xx} \sigma_{xy} \\ -\sigma_{xy} \sigma_{yy} \end{pmatrix} \begin{pmatrix} E_x \\ E_y \end{pmatrix} \tag{38}$$

where for magnetic dip angles $I \geq 3^\circ$,

$$\sigma_{xx} = \sigma_1, \sigma_{xy} = \frac{\sigma_2}{\sin I}, \sigma_{yy} = \frac{\sigma_1}{\sin^2 I} \tag{39}$$

and in the vicinity of the magnetic equator, $I \leq 3^\circ$,

$$\sigma_{xx} = \sigma_1 + \frac{\sigma_2^2}{\sigma_1} = \sigma_3 = \text{Cowling conductivity},$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

$$\sigma_{xy} = 0, \sigma_{yy} = \sigma_0. \tag{40}$$

The Cowling conductivity is exceedingly large, of the order of the direct conductivity. A highly conducting strip is formed along the magnetic equator which carries a large current known as the 'equatorial electrojet' and the region is known as the dynamo region, which is confined to a few degrees in width, where $\sigma_0 \sin^2 I \ll \sigma_1 \cos^2 I$. The very high conductivity along the magnetic field lines ensures that these lines are approximately electric equipotentials. Because $\sigma_2 \gg \sigma_1$ in the dynamo region, the major electric field is the polarization field rather than the $\boldsymbol{v} \times \boldsymbol{B}$ field, and the major current is the Hall current.

Plasma temperatures in the ionosphere

In the ionization process by either photons or energetic particles the majority of the excess energy is converted into translation energy of the ejected 'photoelectrons' with very little energy going to the ion. At low altitudes in the ionosphere, collision frequencies are sufficiently high to ensure thermal equilibrium among electrons, ions and neutrals. With increasing altitude and exponentially decreasing collision frequencies of electrons and ions with neutrals, the time constant for photoelectrons to lose their energy to neutrals is no longer extremely short in comparison to plasma recombination times and the average electron random kinetic energy can exceed both ion and neutral temperatures. The photoelectrons can cool by collisions with thermal electrons, ions and neutrals. Their collisions with thermal electrons elevate the electron temperature, where it is assumed that the electron velocity distribution has a Maxwellian shape at low velocities and the photoelectrons constitute the high-energy tail of the distribution. If the thermal electrons cool preferentially by collisions with the ions and there is an approximate balance between heat input into the electron gas, Q_e, and heat transfer to the ions, then a first order representation of this equilibrium is given by

$$\frac{Q_e}{n_e n_i} \sim 8 \times 10^{-6} \frac{T_e - T_i}{m_i T_e^{3/2}} \text{ eV cm}^3 \text{ s}^{-1} \tag{41}$$

where the right-hand side has a maximum cooling rate for fixed T_i at $T_e = 3T_i$. Beyond this limit the electrons would have to cool by collisions with neutrals and/or by thermal heat conduction downward to denser regions where cooling rates are faster. Application of similar arguments to the ion gas when an equilibrium between heat input from the electrons is balanced by cooling through collisions with the neutrals leads to the first-order expression

$$T_i \sim \frac{T_n + \psi T_e^{-1/2}}{1 + \psi T_e^{-3/2}} \qquad \psi \sim 6 \times 10^6 \frac{n_e}{n_n}. \tag{42}$$

At low altitudes where the ionosphere is a very weakly ionized gas, $T_i \to T_n$ and thermal equilibrium holds, whereas at high altitudes ψ is large and $T_i \to T_e$. While these simple expressions are only approximate they do illustrate the essential aspects of disequilibrium among the electron, ion and neutral gases in planetary ionospheres. For accurate quantitative vertical profiles of the temperatures of these gases, detailed calculations of thermal heat conduction, non-local effects of photoelectron transport when their mean free path exceeds a scale height and comprehensive treatment of all important energy transfer processes among the gases are required.

The ionospheres of the terrestrial CO_2 planets

In the CO_2 atmospheres of Mars and Venus, photoionization of CO_2 is the dominant source of ions

$$CO_2 + h\nu \to CO_2^+ + e. \tag{43}$$

The CO_2^+ reacts rapidly with atomic oxygen, which is abundant in the upper atmosphere, to form oxygen ions

$$CO_2^+ + O \to O^+ + CO_2$$

$$CO_2^+ + O \to O_2^+ + CO. \tag{44}$$

The formation of an ionospheric F2 region of predominantly O^+ is suppressed by the fast reaction of

$$O^+ + CO_2 \to O_2^+ + CO \tag{45}$$

ensuring that O_2^+ is the dominant, terminal ion in the ionospheres of Mars and Venus. In terms of Earth-based nomenclature, the peak ionization region is an F1 region.

The ionospheres of the giant planets

The giant planets with an upper atmosphere comprising of H_2, He and H have as the major ionization sources

$$\begin{aligned} &H + h\nu \to H^+ + e \\ &H_2 + h\nu \to H_2^+ + e \text{ or } H + H^+ + e \\ &He + h\nu \to He^+ + e \end{aligned} \tag{46}$$

and an equivalent set due to electron impact on these species. Atomic hydrogen has the lowest ionization potential (cf table 1) and the expectation would be that H^+ would be the terminal ion as

$$\begin{aligned} &H_2^+ + H_2 \to H_3^+ + H \\ &He^+ + H_2 \to H^+ + H + He \end{aligned} \tag{47}$$

and H_3^+ would recombine dissociatively with a fast rate leaving behind H^+ which could only recombine radiatively and hence very slowly. In view of its long chemical time constant, protons are subject to plasma transport. With the exception of Saturn with its nearly dipole magnetic field aligned with the rotational axis, the other giant planets have highly distorted magnetic fields with quadrupole and octupole components comparable to the dipole components at ionospheric heights. Thus the calculation of plasma transport is considerably more complicated than in the Earth's ionosphere.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

There is one potential loss path for protons at high altitudes and low H_2 densities involving vibrationally excited H_2

$$H^+ + H_2(v \geq 4) \rightarrow H_2^+ + H. \quad (48)$$

This reaction is exothermic when $v \geq 4$, or equivalently H_2 has a lower ionization potential when it is excited into the $v \geq 4$ vibrational level. At higher pressures, but still sub-microbar, the three-body association reaction becomes important

$$H^+ + H_2 + H_2 \rightarrow H_3^+ + H \quad (49)$$

and at still higher pressures, in the vicinity of the homopause, protons react with CH_4 to produce initially CH_3^+ and CH_4^+. Subsequent reactions with more complex C_2H_x hydrocarbons lead to more complex ions.

The ionospheres of planets and satellites with nitrogen atmospheres

The Earth's ionosphere has been discussed in some detail and is unique because of the presence of life and the associated highly oxidizing atmosphere. The other nitrogen atmospheres of Pluto, Titan and Triton are mildly reducing with CO as the most important oxygen-bearing molecule with a maximum volume mixing ratio of, at most, 0.001 in any of these atmospheres. The primary ions produced are N_2^+ and N^+, which in the atmospheres of Pluto and Titan react with CH_4

$$\begin{aligned} N_2^+ + CH_4 &\rightarrow CH_3^+ + N_2 + H \\ N^+ + CH_4 &\rightarrow CH_3^+ + N + H \\ &\rightarrow CH_4^+ + N \\ &\rightarrow H_2CN^+ + H + H \\ &\rightarrow HCN^+ + N + H_2. \end{aligned} \quad (50)$$

Given the large suite of organic molecules in Titan's atmosphere and possibly in Pluto's atmosphere, the terminal ions are certainly more complex than indicated above and definitely molecular in composition. This ensures fast recombination and low electron densities with negligible plasma transport. On Triton with less CH_4, a volume mixing ratio $\sim 2 \times 10^{-4}$ at the surface and subject to significant photochemical depletion in the lower atmosphere, CO plays a fundamental role in the ionosphere as the dominant source of C atoms and C^+ ions, while suppressing the N^+ concentrations

$$\begin{aligned} N_2^+ + CO &\rightarrow CO^+ + N_2 \\ N^+ + CO &\rightarrow CO^+ + N \\ N^+ + CO &\rightarrow NO^+ + C \\ CO^+ + e &\rightarrow C + O \\ C + h\nu &\rightarrow C^+ + e. \end{aligned}$$

The net effect is to make C^+ the dominant, terminal atomic ion in the lower and middle ionosphere and N^+ the dominant ion in the upper ionosphere.

More specific information on ionospheres of specific planets and satellites may be found in the separate articles on each planet and the major solar system satellites, as indicated in the cross-references above. Additionally, the references listed below may be consulted.

Bibliography

For additional information on ionospheric physics and chemistry, there are a number of books which thoroughly discuss the subject in depth. Highly recommended are:

Banks P M and Kockarts G 1973 *Aeronomy, Parts A and B* (New York: Academic)

Bauer S J 1973 *Physics of Planetary Ionospheres* (Berlin: Springer)

Kelley M C 1989 *The Earth's Ionosphere: Plasma Physics and Electrodynamics* (San Diego: Academic)

Rishbeth H and Garriott O K 1969 *Introduction to Ionospheric Physics* (New York: Academic)

For discussions of individual ionospheres, an excellent set of chapters can be found in the University of Arizona Press's space science series of books: *Jupiter, Venus, Saturn, Mercury, Uranus, Mars, Neptune and Triton* and *Pluto and Charon*, listed here in chronological order of publication.

Planetary Magnetospheres

A definition of a planetary magnetosphere is the region surrounding a planet within which its own magnetic field dominates the behavior of electrically charged particles. A magnetosphere can also be thought of as a magnetic cavity around which the SOLAR WIND is deflected. These definitions are not precise and the term magnetosphere does not imply a spherical shape but is used in a looser sense, as in the phrase 'sphere of influence'. The solar wind is not completely excluded from a magnetosphere and important phenomena result from the coupling between the solar wind and the PLASMAS and magnetic fields that are inside the magnetosphere. Furthermore, modern usage is more inclusive and is generally used to also encompass the solar wind interaction with non-magnetized objects as well as the interactions of satellites that are themselves embedded within magnetospheric plasmas. If a moon has sufficiently strong magnetization, it may carve out a true magnetosphere completely contained within the magnetosphere of the parent planet.

A schematic illustration of a 'generic' magnetosphere is given in figure 1 which shows how the solar wind is diverted around a surface called the magnetopause that encloses the planet. Upstream of the magnetosphere in the solar wind there is a bow shock, a standing shock wave, because the solar wind flow is 'supersonic' (the flow speed is faster than the speed of waves that propagate in the solar wind plasma). After passing through the bow shock, the solar wind flows around the sides of the magnetic barrier formed by planet's magnetic field. The magnetopause is the interface between the solar wind and magnetospheric plasmas. Most of the solar wind is deflected around the magnetosphere with some solar wind plasma leaking into the magnetospheric cavity. A characteristic dimension of a magnetosphere is the distance, on the sunward side, of the magnetopause from the center of the planet (R_M). To first order, this distance is controlled by the balance between the internal pressure of the planet's magnetic field and the external ram pressure of the solar wind. The magnetic field accompanying the solar-wind plasma merges with that of a planet and stretches it out to produce a long, turbulent magnetotail, or wake, on the downwind side of the planet. Spacecraft have determined that a magnetotail can extend up to 100 times farther down stream than the subsolar magnetopause distance (specifically in the cases of Earth and Jupiter; see MAGNETOSPHERE OF EARTH: MAGNETOPAUSE, JUPITER: MAGNETOSPHERE). Thus, magnetospheres are very far from spherical, having an aspect ratio (1:100) that is similar to that of a comet (or a 30 m long pencil).

The nature of the interaction between the solar wind and non-magnetized objects (figure 2) depends on the electrical conductivity of the body. If conducting paths exist across the planet's interior or ionosphere, then electrical currents flow through the body and into the solar wind where they create forces that slow and divert the incident flow. The net result is a region very similar to a magnetosphere around which the solar

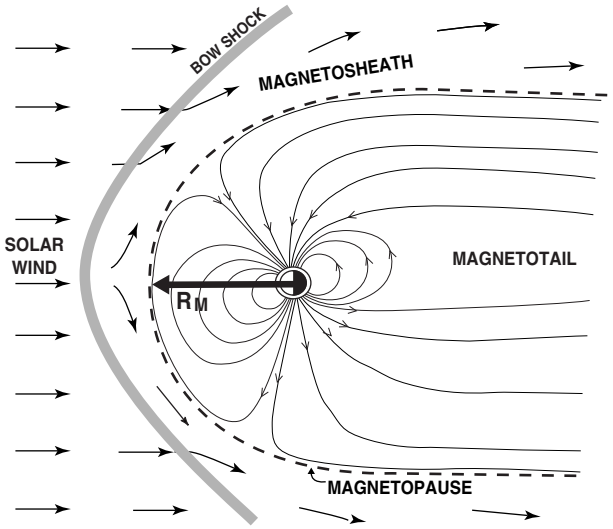

Figure 1. Magnetospheric structures formed by the solar wind interaction with a magnetized planet. The subsolar distance of the magnetopause, R_M, is measured from the center of the planet.

wind is diverted. The interplanetary magnetic field is draped around the planet and stretched out downstream to form a magnetotail (figure 2(*a*)). Mars and Venus have ionospheres which provide the required conducting paths to generate such an 'induced magnetosphere'. The barrier that separates the planetary plasma from the solar wind plasma is referred to as an ionopause. A bow shock forms upstream of the conducting obstacle to the solar wind. The Earth's Moon, with no ionosphere and a surface of low conductivity, does not carry sufficient current to deflect the solar wind. Instead, the solar wind runs directly into the surface of the Moon where it is absorbed (figure 2(*b*)). The absorption leaves the region immediately downstream of the Moon, the wake, devoid of plasma. Farther downstream, the void fills in as the solar wind plasma flows towards the center of the wake.

The interactions of magnetospheric plasma with moons have similarities with the solar wind interaction with planets. An important aspect of the nature of the interaction is that the plasma flows into the moons at subsonic speeds so that the magnetospheric flow is deflected and no bow shock is formed. Since Titan (Saturn), Io (Jupiter) and Triton (Neptune) each have an atmosphere and ionosphere the interaction of these satellites with the magnetospheric plasma can be considered variations of the Mars–Venus case. Europa and Callisto are closer to the Moon's case except the variable magnetic field of Jupiter induces substantial currents (probably in a liquid layer) within these satellites.

Planetary magnetic fields

Because the characteristic time scale for thermal diffusion is greater than the age of the solar system, the planets tend to have retained their heat of formation. At the same

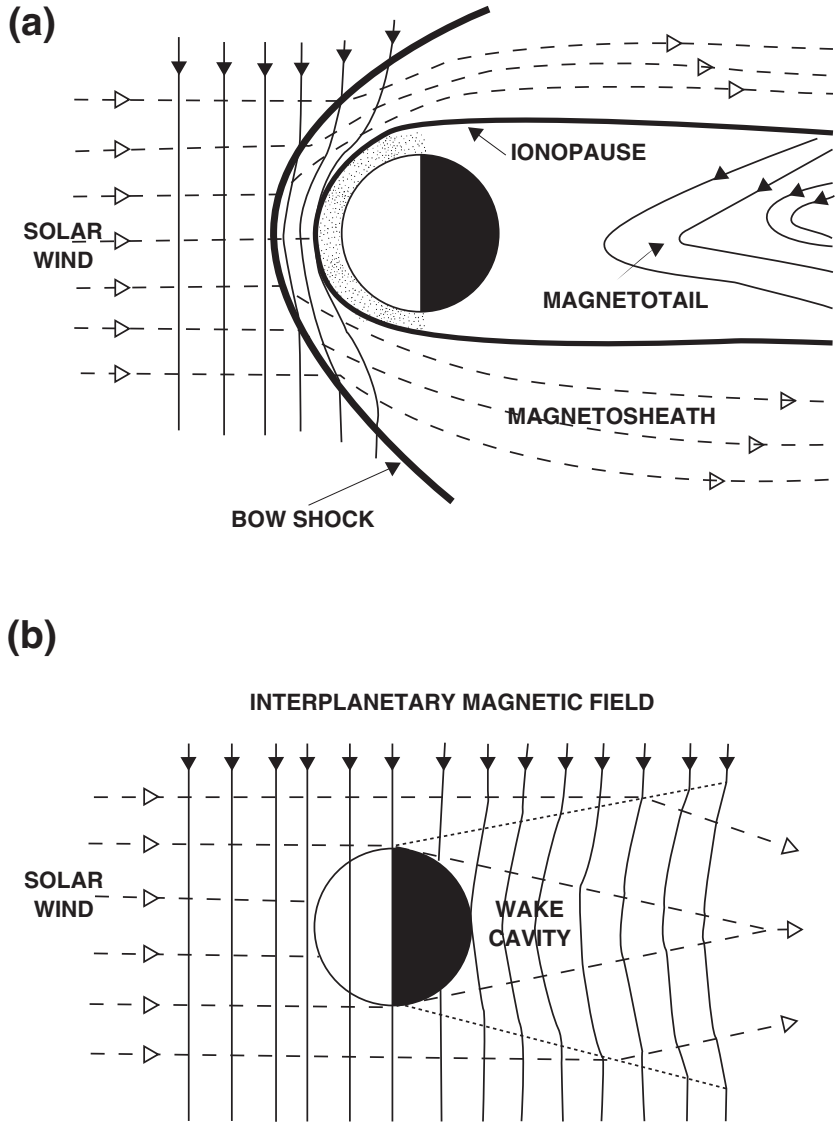

Figure 2. The interaction regions surrounding non-magnetized objects: (*a*) a planet such as Mars or Venus which is sufficiently conducting that currents close through the planet or its Ionosphere (shown by dots on the dayside); (*b*) a body such as the Moon which has no ionosphere and low surface conductivity.

time, the characteristic time scale for diffusive decay of a magnetic field in a PLANETARY INTERIOR is much less than the age of the planets. Consequently, primordial fields and permanent magnetism are small and the only means of providing a substantial planetary magnetic field is an internal dynamo (see DYNAMO THEORY). For a planet to have a magnetic dynamo, it must have a large region that is fluid, electrically conducting and undergoing sufficiently vigorous convective motion. The deep interiors of the planets and many larger satellites are expected to contain electrically conducting fluids: terrestrial planets and the larger satellites have differentiated cores of liquid iron alloys; at the high pressures in the interiors of the giant planets JUPITER and SATURN, hydrogen behaves like a liquid metal; for Uranus and Neptune a water–ammonia–methane mixture forms a deep conducting 'ocean'. The fact that some planets and satellites do not have dynamos tells us that their interiors are stably stratified and do not convect. Models of the thermal evolution of terrestrial planets show that, as the object cools, the liquid core ceases to convect and further heat is lost by conduction alone. In some cases, such as the Earth, convection continues because the nearly pure iron solidifies out of the alloy in the outer core, producing an inner solid core and releasing gravitational energy that can drive continued convection in the liquid outer core. The more gradual cooling of the giant planets allows convective motions to persist.

Table 1. Planetary magnetospheres.

	Rotation period (days)	Dipole moment (Earth = 1)[a]	Field at equator (G)	Field ratio[b] maximum/ minimum	Tilt of Tilt of dipole[c]	Typical magnetopause distance (R_{plane})	Typical magnetopause distance (km)	Plasma sources[d]
Mercury	59	0.0007	0.003	2	+14°	1.5	0.04×10^5	W
Venus	243 (R)[e]	<0.0004	<0.0003	?	–	–	–	A, W
Earth	1.00	1	0.305	2.8	+10.8°	11	0.7×10^5	W, A
Mars	1.03	$<2.5 \times 10^{-5}$[f]	$<5 \times 10^{-5}$[f]	?	–	–	–	A, W
Jupiter	0.41	20 000	4.2	4.5	−9.6°	80	60×10^5	S, A, W
Saturn	0.44	600	0.20	4.6	<−1°	20	12×10^5	S, A, W
Uranus	0.72 (R)[e]	50	0.23	12	−59°	20	5×10^5	A, W
Neptune	0.74	25	0.14	9	−47°	25	6×10^5	S, A, W

[a] Earth's dipole moment = 7.906×10^{25} G cm^3 = 7.906×10^{15} T m^3.

[b] Ratio of maximum surface field to minimum equals 2 for centered dipole field.

[c] Angle between the magnetic and rotation axes. Minus/plus sign indicates dipole moment antiparallel/parallel to spin vector.

[d] W, solar wind; A, atmosphere; S, satellite(s) or rings.

[e] (R), retrograde.

[f] These values are upper limits on a global magnetic field. The Mars Global Surveyor has shown Mars to have 2000 km × 200 km regions of strong, local magnetization, presumed to be remnant magnetization produced by an ancient (now inactive) dynamo.

The characteristics of the six known planetary fields are listed in table 1. Assuming each planet's magnetic field has the simplest structure, a dipole, we are able to compare the equatorial field strength (B_0) and the tilt of the dipole axis with respect to the planet's spin axis. Note that while the net magnetic moment of the magnetized planets varies by nearly eight orders of magnitude, the surface fields are on the order of a gauss = 10^{-4} T (except for MERCURY) indicating that the strength of the dynamo scales with planetary size. The degree to which this dipole model is an oversimplification of a more complex structure is indicated by the ratio of maximum to minimum values of the surface field. This ratio has a value of 2 for a dipole. The larger values, particularly for URANUS and NEPTUNE, are indications of strong non-dipolar contributions to the planets' magnetic fields. Similarly, the fact that the magnetic axes of these two planets are strongly tilted (see figure 3) also suggests that the dynamos in the icy giant planets may be significantly different to those of the aligned, dipolar planetary magnetic fields.

Exploration of VENUS has provided an upper limit to the degree of magnetization comparable with the crustal magnetization of the Earth suggesting that its core is stably stratified and that it does not have an active dynamo. In the case of MARS, until the Mars Global Surveyor, the only spacecraft that were instrumented with magnetometers did not approach very close to the surface. There has been vigorous debate about whether the weak fields that were detected are due to a dynamo or are due to currents in the ionosphere. The upper limit to the Martian dipole moment is 2×10^{-5} that of the Earth, corresponding to a surface field of 5×10^{-5} G (5 nT). In September 1997 the Mars Global Surveyor spacecraft began its orbital tour of Mars, the first few orbits bringing the spacecraft within ~120 km of the surface where the magnetometer measured regions of surprisingly strong magnetic fields (~400 nT on the surface). The patchy nature of the magnetic field suggests that it is crustal rather than generated by an active internal dynamo. From the preliminary data the magnetization appears to be frozen into the rock when regions of molten lava solidified and is a remnant of a dynamo that was active in Mars' early history. PLUTO has yet to be explored. While models of Pluto's interior suggest it is probably differentiated, its small size makes one doubt that its core is convecting and any magnetization is likely to be remanent. GANYMEDE is the only moon where a substantial magnetic field has been measured. Earth's MOON has a negligibly small planet-scale magnetic field although localized regions of the surface are highly magnetized. The first Galileo flyby of Io has provided suggestions that Io might have an internally generated magnetic field but close-up measurements are needed to separate a dynamo field from the effects of the plasma interaction with Io's atmosphere (see IO: PLASMA TORUS).

For the six planets known to generate magnetic fields in their interiors the size of a planet's magnetosphere (R_P) depends on the ambient solar wind density and the planet's radius and magnetic field. Thus we expect a planet with a strong magnetic field to have a large magnetosphere, and even the weak fields of Uranus and Neptune produce moderately sized magnetospheres in the tenuous solar wind of the outer solar system (see URANUS AND NEPTUNE: ATMOSPHERES, IONOSPHERES, AND MAGNETOSPHERES). The measured sizes of planetary magnetospheres generally agree quite well with the theoretical R_M values. Jupiter is the only notable exception, where the plasma pressure inside the magnetosphere is sufficient to further 'inflate' the

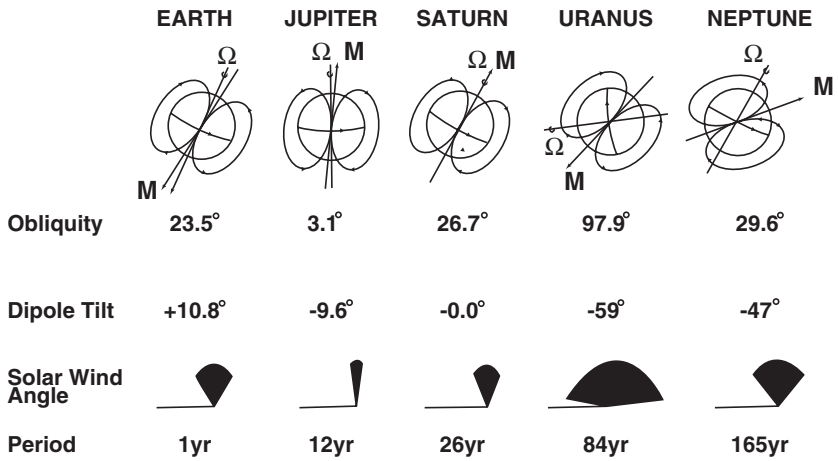

Figure 3. Magnetic field orientations at the Earth and giant planets. The obliquity is the angle between the rotation axis and the normal to the ecliptic. The dipole tilt is the angle between the planet's magnetic and rotation axes. The above two angles contribute to the seasonal variation in the angle between the solar wind flow direction (approximately radial from the Sun) and the planet's magnetic axis (range shaded) over the planet's rotation and orbital periods.

magnetosphere. This makes the magnetosphere of Jupiter a huge object—about 1000 times the volume of the Sun, with a tail that extends at least 6 AU in the antisunward direction, beyond the orbit of Saturn. If the Jovian magnetosphere were visible from Earth, its angular size would be twice that of the Sun, even though it is at least 4 times farther away. The magnetospheres of the other giant planets are smaller (although large compared with the MAGNETOSPHERE OF EARTH), having a similar scale of about 20 times the planetary radius, comparable with the size of the Sun. With only a weak magnetic field and being embedded in the denser solar wind close to the Sun, Mercury has a very small magnetosphere (see MERCURY: MAGNETOSPHERE).

While the size of a planetary magnetosphere depends on the strength of a planet's magnetic field, the configuration and internal dynamics depend on the field orientation (illustrated in figure 3). The orientation of a planet's magnetic field is described by two angles: the tilt of the magnetic dipole field with respect to the planet's spin axis and the angle between the planet's spin axis and the solar wind direction, which is generally within a few degrees of being radially outward from the Sun. Since the direction of the spin axis with respect to the solar wind direction varies only over a planetary year (many Earth years for the outer planets), and the planet's magnetic field is assumed to vary only on geological time scales, these two angles are constant for the purposes of describing the magnetospheric configuration at a particular epoch. Earth, Jupiter and Saturn have both small dipole tilts and small obliquities. This means that the orientation of the magnetic field with respect to the solar wind does not vary appreciably over a planetary rotation period and that seasonal effects are small. Thus Mercury, Earth, Jupiter and Saturn have symmetric and quasi-stationary magnetospheres, each exhibiting only a small wobble at the planetary rotation period owing to their $\sim 10^\circ$ dipole tilts (or a barely detectable wobble in the case of Saturn). In contrast, the large dipole tilt angles of Uranus and Neptune mean that the orientation of their magnetic fields with respect to the interplanetary flow direction varies considerably over a planetary rotation period, resulting in highly asymmetric and time-variable magnetospheres. Furthermore, Uranus' large obliquity means that the configuration of Uranus' magnetosphere will have strong seasonal changes over Uranus' 84 yr orbit.

Magnetospheric plasmas

Magnetospheres contain considerable amounts of plasma, electrically charged particles in equal proportions of positive charge on ions and negative charge on electrons, from various sources (see table 1). The main source of plasma in the solar system is clearly the Sun. The solar CORONA, the upper atmosphere of the Sun (which has been heated by some, as yet undetermined, process to temperatures of 1–2 million K), streams away from the Sun at a more or less steady rate of 10^9 kg s^{-1} in equal numbers (8×10^{35} s^{-1}) of electrons and ions. The boundary between the solar wind and a planet's magnetosphere, the magnetopause, is not entirely plasma tight. Wherever the interplanetary magnetic field has a component antiparallel to the planetary magnetic field, magnetic reconnection is likely to occur and solar wind plasma will enter the magnetosphere across the magnetopause. Solar wind material is identified in the magnetosphere by its energy and characteristic composition of protons (H^+) with $\sim$4% alpha particles (He^{2+}) and trace heavy ions, many of which are highly ionized.

Secondly, although ionospheric plasma is generally cold and gravitationally bound to the planet, a small fraction has sufficient energy to escape up magnetic field lines and into the magnetosphere. In some cases, field-aligned potential drops accelerate ionospheric ions and

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

increase the escape rate. Ionospheric plasma has a composition that reflects the composition of the planet's atmosphere (e.g. abundant O^+ for the Earth and H^+ for the outer planets).

Thirdly, the interaction of magnetospheric plasma with any natural satellites or ring particles that orbit within the magnetosphere can generate significant quantities of plasma. Magnetospheric plasma flowing by a satellite can ionize the outermost layers of its atmosphere thus providing a major source of plasma (as much as 1 ton^{-1} of sulfur and oxygen ions in the case of Jupiter's satellite Io). Energetic particle sputtering of the satellite surface or atmosphere can create an extensive cloud of neutral atoms that are eventually ionized, possibly far from the satellite. The distributed sources of water-product ions (totaling $\sim$2 kg s^{-1}) in the magnetosphere of Saturn suggest that energetic particle sputtering of the rings and icy satellites is an important process (see SATURN: MAGNETOSPHERE). Although the sputtering process, which removes at most a few microns of surface ice per thousand years, is probably insignificant in geological terms, sputtering has important consequences for the optical properties of the satellite or ring surfaces.

The composition of the ionic species indicates the primary sources of magnetospheric plasma: satellites in the cases of Jupiter, Saturn and Neptune; the planet's ionosphere in the case of Uranus. In the magnetospheres where plasma motions are driven by the solar wind, solar wind plasma enters the magnetosphere, becoming the primary source of plasma in the case of Mercury's small magnetosphere and a secondary plasma source at Uranus and Neptune. At Earth, both the ionosphere and the solar wind are important sources. Earth's moon remains well beyond the region in which sputtering or other plasma effects are important. In the magnetospheres where plasma flows are dominated by the planet's rotation (Jupiter, Saturn and within the Earth's plasmasphere), the plasma is confined by the planet's strong magnetic field for many days so that substantial densities are accumulated.

Giant rotating magnetospheres

The magnetospheres of Jupiter and Saturn are gigantic, dwarfing all the other planetary magnetospheres. The strong planetary magnetic fields allow the magnetospheric plasma to tap the planet's rotational energy and accelerate particles to high energies. The interactions of magnetospheric plasma with the moons (and ring matter, in the case of Saturn) produce prodigious amounts of new plasma (see MAGNETOSPHERES: JUPITER, SATELLITE INTERACTIONS). The magnetospheric plasma generates powerful radio emissions and stimulates strong auroral emissions in the planets' polar atmospheres.

The study of Jupiter's magnetosphere has an interesting history. When Burke and Franklin discovered in 1955 that Jupiter is a source of radio emission, it was soon realized that this radio emission must come from energetic charged particles in a strong magnetic field (see MAGNETOSPHERES: JUPITER, RADIO EMISSIONS). This remarkable discovery came before Van Allen's detection of the Earth's radiation belts and the *in situ* verification of the solar wind. A more puzzling discovery came in 1964 when it was revealed that the component of the Jovian radio emission at decametric ($\sim$tens of meters) wavelengths was influenced by Io, the innermost of the four Galilean satellites. The component of the radio emission at decimetric ($\sim$tens of centimeters) wavelengths was assumed to be synchrotron radiation from electrons with energies of >10 MeV that gyrate around dipolar magnetic field lines at a distance of a few Jovian radii. This basic picture of a strong magnetic field trapping a large, energetic particle population was confirmed by PIONEERS 10 and 11 which reached Jupiter in 1973 and 1974, respectively. The Pioneers also revealed that farther from the planet the magnetic field is considerably stretched out so that the Jovian magnetosphere is shaped more like a disk than a sphere (see figure 4). Although the large size and radial distension implied the presence of a substantial amount of plasma at lower energies, the Pioneer plasma detector provided little information on the thermal population. Nevertheless, the theorists had already come out strongly in favor of a magnetosphere dominated by the planet's rotation. A few months before the Pioneer 10 encounter optical emission was detected using a ground-based telescope, coming from neutral sodium atoms in the vicinity of Io. The first direct evidence of the presence of high densities of ionized material at low energies near Jupiter came with the discovery of optical emission from S^+ ions. Borrowing techniques from studies of more remote astronomical gaseous nebulae, planetary astronomers concluded that the S^+ emission comes from a dense (500–3000 cm^{-3}) ring of cold (2.3×10^5 K) plasma that is corotating with Jupiter inside the orbit of Io. In 1979 the VOYAGER 1 spacecraft confirmed that Io is the major source of plasma in the Jovian magnetosphere; a fact that seemed less surprising when the Voyager cameras revealed the satellite's active volcanoes. Bright ultraviolet emission and local plasma measurements revealed an extensive torus of hotter ($\sim10^6$ K) plasma outside the inner ring of cold plasma.

In the two years between September 1979 and August 1981 the magnetosphere of Saturn was explored by three spacecraft, Pioneer 11 and Voyagers 1 and 2. Overall, Saturn's magnetosphere (figure 5) was found to be similar to the Jovian magnetosphere: satellites are the major source of magnetospheric plasma and the plasma dynamics are dominated by the planet's rotation. Nevertheless, the magnetosphere of Saturn is considerably smaller and the multiple sources of plasma are much weaker and less distinct than at Jupiter. Moreover, Saturn's magnetosphere is less compressible. This behavior indicates that the planetary field stands off the solar wind with little contribution from the internal plasma pressure. The magnetosphere of Saturn is separated by a boundary at about 15 Saturn radii into two regions: an inner region where the plasma density and temperature vary smoothly with distance and an outer region where

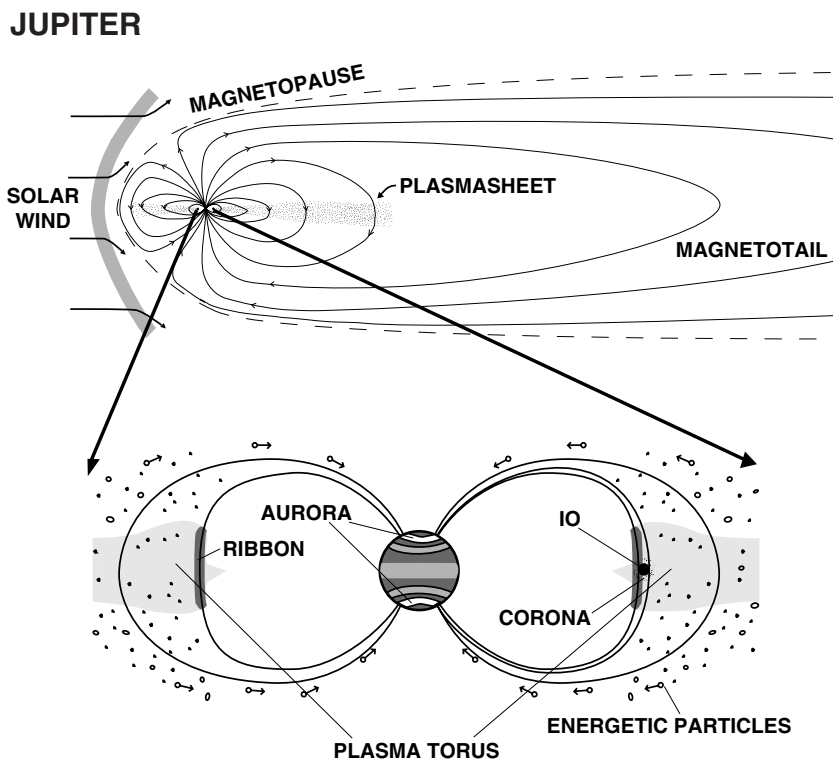

Figure 4. Magnetosphere of Jupiter. Deeply embedded within the magnetosphere of Jupiter is the satellite Io. The ionization of Io's atmosphere and extended neutral corona deposits 1 ton s^{-1} of plasma into the torus. In the process of plasma spreading out from the torus in to the extended plasmasheet, the charged particles are accelerated. Some of the energetic particles are scattered and stream along magnetic field lines into the atmosphere of Jupiter where they stimulate intense auroral emissions.

the plasma densities and temperatures vary erratically. While there is wide agreement that the source of plasma in the inner region of the magnetosphere is the icy satellites Dione and Tethys (with lesser contributions from Rhea, the small inner satellites and the rings) there is strong debate over the source and loss processes. In the outer region, debate also remains about the role of Titan (see SATURN: MAGNETOSPHERE INTERACTION WITH TITAN).

Asymmetric magnetospheres

Early magnetospheric studies were based on experience of Earth, Jupiter and Saturn and only considered symmetric magnetospheres. When the planet's magnetic field can be closely approximated by a dipole at the center of the planet with its axis roughly parallel to the planet's spin axis then the magnetospheric configuration is symmetric and remains constant as the planet spins (convective motions of plasma in the magnetosphere are quasi-steady in the inertial reference frame). Once the magnetic tilt angle becomes appreciable this is no longer true.

Voyager 2 made the first-ever encounter with Uranus on 24 January 1986. It was realized ahead of time that the rotational axis of Uranus would, in early 1986, be within 8° of the planet–Sun line, whereas those of all other planets (except Pluto) are approximately perpendicular to their orbital planes. If Uranus' magnetic and rotational axes were nearly parallel, as is the case for other magnetized planets, one magnetic pole would be pointed almost directly at the Sun and a very unusual magnetospheric topology would be expected. If they were inclined markedly to one another, each magnetic pole would move in a sweeping, conical path as the planet spun—creating an even more exotic magnetosphere.

Voyager 2 ended our many years of conjecture. It found that Uranus has a substantial magnetic field with an orientation and asymmetry very different from expectations. Uranus' magnetic axis is tilted a huge 59° from the rotational axis and is highly asymmetric (see table 1 and figure 3). Its large magnetosphere contains plasma and a large population of energetic particles. As at Saturn, the absorption of energetic particles by satellites Miranda, Ariel and Umbriel, and by particulate matter in rings, controls the development of the inner magnetosphere. However, unlike the situation at Saturn, the diurnal wobble of the tilted magnetic equator creates a very complex relationship between the orbiting satellites and the magnetic field's topology.

At Uranus the rotation axis is currently nearly parallel to the solar wind direction (figure 3) so that the solar wind driven convection and the direction of planetary rotation are orthogonal and hence de-coupled. In the reference frame rotating with Uranus the solar wind driven

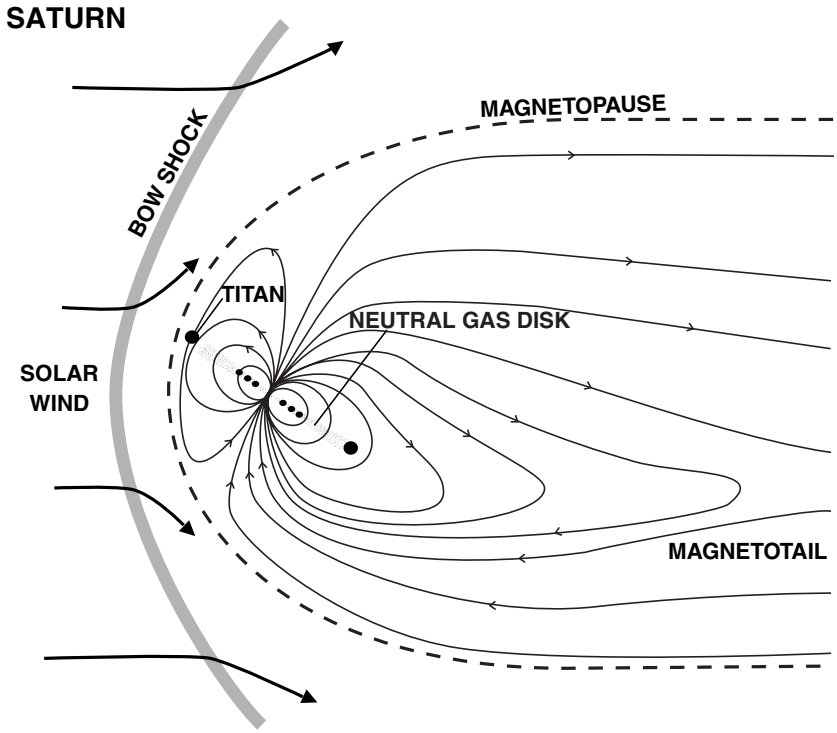

Figure 5. Magnetosphere of Saturn. The magnetosphere of Saturn is populated by the ionization of an extensive disk of neutral gas which was generated by the sputtering of the rings and icy satellites by energetic radiation belt particles.

convection is quasi-steady and permeates throughout the magnetosphere. Thus the plasma corotates with the planet once every 17 h but on a longer time scale (days) the plasma is circulated through the magnetosphere by the solar wind driven convection. Elements of plasma exhibit helical trajectories, spiraling sunward at the magnetic equator and anti-sunward at high latitudes. Figure 6 (top) shows two configurations of Uranus' magnetosphere separated by half a planetary rotation. To a first approximation, the magnetosphere of Uranus resembles that of the Earth but revolving every 17 h around the planet–Sun line.

When Voyager 2 flew past Neptune in August 1989 it discovered an extensive magnetosphere with a large population of trapped charged particles. The magnetometers detected a magnetic field whose surface intensity is similar to the Earth's, but whose distribution was completely different. Neptune appeared to have a magnetic field with a higher degree of asymmetry than any other planet. To first order, Neptune's magnetic field can be described as a dipole that is tilted 47° from the planet's spin axis. As the planet spins over Neptune's 16 h spin period, the orientation of the planet's magnetic field drastically changes with respect to the solar wind. When the magnetic dipole is perpendicular to the solar wind, the configuration is, momentarily, symmetrical like that of Earth, Jupiter and Saturn. When the angle between the magnetic dipole and the solar wind direction is small, we have a unique configuration with the magnetic axis pointed 'pole-on' into the solar wind. These configurations lead to very different magnetic field topologies (see figure 6 (bottom)). Complete reconfiguration of Neptune's magnetosphere must occur every 16 h spin period.

Neptune's large satellite TRITON is comparable in size with Ganymede which raises the question of whether it too could have an internal magnetic field. The large moon orbits at $14.6R_N$ ($1R_N$ is a Neptune radius), well inside the magnetosphere. Voyager 2 detected protons and nitrogen ions in Neptune's magnetosphere, consistent with a source of $\sim$200 g s^{-1} from Triton and strong inward diffusion with a time scale of a few days. It appears that the rapid transport does not allow large plasma densities to build up. The nitrogen ions are thought to be produced directly in the interaction of the magnetospheric plasma with the satellite's atmosphere while the protons come from the ionization of a large hydrogen cloud that extends from Triton's orbit in to about $8R_N$. Closer to the planet there appear to be significant losses due to waves which scatter the ions and electrons along the magnetic field into the atmosphere of Neptune. The charged particles transfer their energy to atmospheric molecules which then glow as dramatic auroras. Neptune's tilted and asymmetric magnetic field concentrates the bombarding charged particles into an irregular region at mid-latitudes rather than the simple auroral ovals at the poles of other planets.

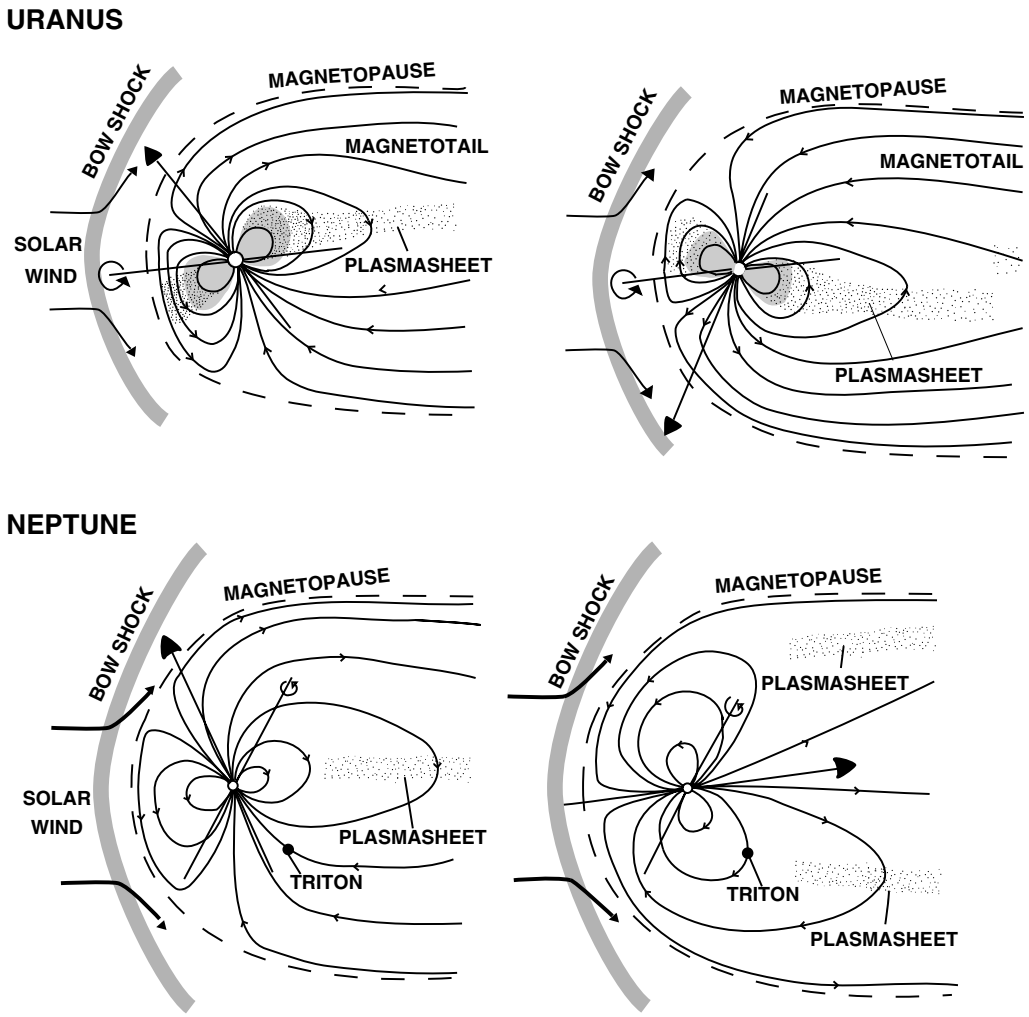

Figure 6. The magnetospheres of Uranus and Neptune. The large angle between these planets' magnetic and rotation axes leads to substantial variations over a planet's rotation period, particularly for Neptune.

Small magnetospheres

Before 1974 it was thought that only large planets would have magnetic fields and that convective motions in smaller objects would have halted as the interiors cooled. The discovery of weak but significant magnetic fields of smaller bodies, first Mercury and recently Ganymede, has challenged our view of both the dynamo process and the nature of small-scale magnetospheres. Mercury and Ganymede have magnetospheres that are comparable in size with the diameter of the Earth (see figure 7).

The magnetosphere of Mercury (figure 7 (top)) contains field lines that connect to the planet at both ends but the Mercurian magnetic field is too weak to maintain a belt of trapped particles. Low-energy plasma was detected by the MARINER spacecraft's traversals through the nightside magnetosphere but it is not clear whether this plasma originated in the solar wind or from ionization of Mercury's tenuous atmosphere. More notable, however, are the intense bursts of energetic particles that were measured in the magnetotail. These bursts have been compared with magnetic storms on Earth and suggest Mercury's magnetosphere is dynamic. The time scales of $\sim$1 min for the Mercurian storms (compared with hours at Earth) are consistent with the much smaller scale of the magnetosphere.

One of the greatest surprises of the Galileo mission to Jupiter was the discovery of Ganymede's magnetic field. This was the first magnetosphere within a magnetosphere (figure 7 (bottom)). The Jovian plasma, in which Ganymede is embedded, flows at speeds much slower than the solar wind and slower than the local speeds of waves that can propagate in the magnetospheric plasma. Hence, there is no bow shock upstream of Ganymede. Models of the interaction of plasma in Jupiter's magnetosphere with Ganymede's magnetic field suggest that there is a small region where magnetic field lines are closed. However, the magnetosphere of Ganymede is too small to have stably trapped radiation

belts or a magnetotail or contain substantial amounts of plasma. There is thought to be a pattern of convection, similar to solar wind driven convection at Earth, but in this case driven by the interaction of Ganymede's magnetic field with the surrounding magnetospheric plasma. Orbiting Jupiter at a distance of 19 Jovian radii, Ganymede is located in the middle magnetosphere region (see figure 4). Ganymede experiences a periodic change in plasma conditions and background magnetic field orientation as the plasma sheet, tilted by the 10° of Jupiter's magnetic field with respect to the equator, passes over the satellite twice per 10 h rotation.

Magnetospheric scaling laws

Magnetopause distance.

In a true magnetosphere, the scale size is set by the distance, R_{MP}, along the planet–Sun line at which the sum of the pressure of the planetary magnetic field and the pressure exerted by plasma confined within that field balances the dynamic pressure of the solar wind. (The dynamic pressure is ρu^2 where ρ is the mass density and u is its flow velocity in the rest frame of the planet. The thermal and magnetic pressures of the solar wind are small compared with its dynamic pressure.) Assuming that the planetary magnetic field is dominated by its dipole moment and that the plasma pressure within the magnetosphere is small, one can estimate R_{MP} as $R_{MP} \approx R_P(B_o r/2\mu_o \rho u^2)^{1/6}$. Here B_o is the surface equatorial field of the planet and R_P is its radius. Table 1 shows the vast range of scale sizes in terms both of the planetary radii and of absolute distance. The large scale sizes of the magnetospheres of the outer planets arise both because R_P is large and because the solar wind density is so small at the orbits of the outer planets that the solar wind pressure is not effective in balancing a strong magnetic field.

Dynamics

Magnetospheric configuration is generally well described by MAGNETOHYDRODYNAMICS (MHD) in which the magnetic field can be considered to be frozen into the plasma flow. Thus we need to consider the processes controlling magnetospheric flows. The two largest sources of momentum in planetary magnetospheres are the planet's rotation and the solar wind (see figure 8). The nature of any large-scale circulation of material in the magnetosphere depends on which momentum source is tapped. For planetary magnetospheres, corotation of plasma with the planet is a useful first approximation with any departures from strict corotation occurring when certain conditions break down. It may be helpful to think of plasma in the magnetosphere as mass that is coupled by means of magnetic field lines to a giant flywheel (the planet) with the ionosphere acting as the clutch.

For magnetospheric plasma to rotate with the planet, the first two conditions are that the upper region of the neutral atmosphere must corotate with the planet and must be closely coupled to the ionosphere by collisions. The (Pedersen) electrical conductivity of the ionosphere, σ^i, is large so that in a corotating ionosphere (with velocity $\boldsymbol{V}^i$) horizontal currents (perpendicular to the local magnetic field) are given by Ohm's law, $\boldsymbol{J}^i_\perp = \sigma^i_\perp(\boldsymbol{E}^i + \boldsymbol{V}^i \times \boldsymbol{B})$. Just above the ionosphere the plasma particles in the (collision-free) magnetosphere are tightly bound to the magnetic field and do not easily conduct currents across the magnetic field so that $\boldsymbol{E}^m = -\boldsymbol{V}^m \times \boldsymbol{B}$. Because the plasma particles are far more mobile in the direction of the local magnetic field, the parallel conductivity in the magnetosphere $\sigma^m_\parallel$ is large and the field lines can be considered to be equipotentials ($\boldsymbol{E} \cdot \boldsymbol{B} = 0$). Thus the electric field in the magnetosphere can be mapped into the ionosphere. Because the ionosphere is relatively thin, the electric field $\boldsymbol{E}^m$ just above the ionosphere is the same as $\boldsymbol{E}^i$ so that we can write $\boldsymbol{J}^i_\perp = \sigma^i_\perp(\boldsymbol{V}^i - \boldsymbol{V}^m) \times \boldsymbol{B}$. The condition for corotation of the magnetospheric plasma is that the ratio J^i/σ^i is sufficiently small that $\boldsymbol{V}^m = \boldsymbol{V}^i = \Omega \times \boldsymbol{r}$. For a dipolar magnetic field that is aligned with the rotation axis, the corotational electric field (in the equatorial plane) is therefore radial with magnitude $E_{co} = \Omega B_o/r^2$.

It is clear that large ionospheric conductivities facilitate corotation. The large $\sigma^m_\parallel$ also means that any

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

currents in the magnetosphere that result from mechanical stresses on the plasma are directly coupled by field-aligned currents to the ionosphere. Thus corotation breaks down when mechanical stresses on the magnetospheric plasma drive ionospheric currents which are sufficiently large that the ratio $J^{\mathrm{i}}/\sigma^{\mathrm{i}}$ becomes significant. Such conditions might occur in regions of the magnetosphere where there are large increases in mass density due to local ionization of neutral material, where there are strong radial motions of the plasma or where there are sharp gradients in plasma pressure. When the magnetosphere imposes too large a load, the ionospheric clutch begins to slip.

Next let us consider how the momentum of the solar wind may be harnessed by processes occurring near the magnetopause where the external solar magnetic field interconnects with the planetary magnetic field. At the poles the planetary magnetic field lines are open to the solar wind. The solar wind drives a plasma flow across the polar caps and the field lines from the polar region move in the direction of the solar wind flow, being pulled by the solar wind over the poles and back into the extended magnetotail. Conservation of flux requires that field lines are further cut and reconnected in the tail.

The MHD condition of the field being frozen to the flow can be written as $\boldsymbol{E} + \boldsymbol{V} \times \boldsymbol{B} = 0$ which allows the convection electric field to be written $\boldsymbol{E}_{\mathrm{cv}} = -\eta \boldsymbol{V}_{\mathrm{sw}} \times B_{\mathrm{o}}/R_{\mathrm{M}}^3$ (where η is the efficiency of the reconnection process in harnessing the solar wind momentum, $\sim$0.1 for the Earth). In simple magnetospheric models E_{cv} is assumed constant and the corresponding circulation is given by the $\boldsymbol{E} \times \boldsymbol{B}$ drift, $V_{\mathrm{cv}} = \eta V_{\mathrm{sw}}(r/R_{\mathrm{M}})^3$ where R_{M} is the magnetopause distance. After being carried tailward at high latitudes, the plasma then drifts towards the equatorial plane and eventually returns in a sunward flow to the dayside magnetopause.

Comparison of the corresponding electric fields indicates whether the magnetospheric circulation is driven primarily by the solar wind or the planet's rotation. Since E_{co} is proportional to R^{-2} and E_{cv} proportional to R^3 it seems reasonable to expect that corotation dominates close to the planet while solar wind driven convection dominates outside a critical distance R_c. Thus, the magnetosphere corotates out to a distance of $R_{\mathrm{c}}/R_{\mathrm{M}} = (R_M\Omega/\eta V_{\mathrm{sw}})^{1/2}$. This formula simply says that magnetospheres of rapidly rotating planets with strong magnetic fields are dominated by rotation while the solar wind controls the plasma flow in smaller magnetospheres of slowly rotating planets.

Orientation and seasonal variations

If a planetary rotation axis is not approximately aligned with either the magnetic dipole axis or the solar wind flow direction then there exists no reference frame in which the plasma flow is steady. The degree of variability over a planetary rotation period is governed by the solar wind angle (see figure 3), the angle between the solar wind and the dipole axis. When the solar wind angle is near 90° the configuration is symmetrical (as approximated by Earth, Jupiter and Saturn). When the solar wind angle is small the configuration has the magnetic axis pointed 'pole-on' into the solar wind, a configuration that was expected for Uranus before Voyager 2 found a large dipole tilt. These configurations lead to very different magnetic field topologies. Figure 3 shows how the solar wind angle varies for the major magnetospheres. At the time of the Voyager 2 encounter in 1989, Neptune's northern hemisphere was close to mid-winter with the rotation axis tipped 23° degrees from the Sun, i.e. 67° from the radial, solar wind direction. The 47° tilt of the magnetic dipole means that the angle between the solar wind and the dipole axis changes between 20° and 114° over the 16.1 h planetary rotation. Complete re-configuring of the magnetosphere must occur every planetary rotation (figure 6(*b*)).

A planet's obliquity is responsible for seasonal variations over the planet's orbital period. For a planet such as Jupiter with a very small obliquity there are very small changes in the solar wind angle and, hence, magnetospheric configuration over Jupiter's 12 yr orbital period. On the other hand, the high obliquity of Uranus leads to dramatic variations in the solar wind angle (covering all orientations) over the planet's 84 yr orbital period. Earth, Saturn and Neptune, with moderate obliquities (23.5°–30°), are intermediate cases with moderate seasonal variations.

Energetic particle populations

All magnetospheres have significant populations of particles with energies (keV–MeV) well above the thermal population. These particles are largely trapped by the strong planetary magnetic field in long-lived radiation belts. Where do these energetic particles come from? Since the interplanetary medium includes energetic particles of solar and galactic origins an obvious possibility is that these energetic particles were 'captured' from the external medium. In the cases of the giant planets, the observed high fluxes are hard to explain without additional internal sources. Compositional evidence also implies that some fraction of the thermal plasma is accelerated to high energies, either by tapping the rotational energy of the planet, in the cases of Jupiter and Saturn, or by processes in the distorted magnetic field in the tail, in the cases of Earth, Uranus and Neptune. Particle drifts in a non-uniform magnetic field lead to the ions and electrons drifting in opposite directions around the planet, producing an azimuthal electric current: the *ring current*. If the energy density of the energetic particle populations is comparable with the magnetic field energy then the ring current produces a magnetic field that significantly perturbs the planetary magnetic field. This is the case for Jupiter and Saturn, where the high particle pressures inflate and stretch out the magnetic field and generate a strong ring current in the magnetodisk. While Uranus and Neptune have significant radiation belts, the energy density remains small compared with the magnetic field

and the ring current is very weak. The Dessler–Parker–Sckopke relation compares the magnetic field produced by the ring current with the kinetic energy of the trapped particle population, scaled to the dipole magnetic energy external to the planet. Applying the Dessler–Parker–Sckopke relation to planetary magnetospheres we find that while the total energy content of magnetospheres varies by many orders of magnitude and the sources are very different, it appears that the particle energy builds up to only 1/1000 of the magnetic field energy in each magnetosphere. Earth, Jupiter and Saturn all have energetic particle populations close to this limit. The radiation belts of Uranus and Neptune are much less than this limit, perhaps because it is harder to trap particles in non-dipolar magnetic fields.

Where do these energetic particles go? The majority appear to diffuse inwards towards the planet. Loss processes for energetic particles in the inner magnetospheres are satellite absorption, charge exchange with neutral clouds and scattering by waves so that the particles stream into the upper atmospheres of the planets where they can excite auroral emission and deposit large amounts of energy.

Planetary Nebula Central Star Mass Loss/Winds

The ultraviolet spectra of the central stars of PLANETARY NEBULAE frequently show broad emission–absorption features which are indicative of stellar winds with typical velocities of several thousand km s^{-1}. The collision of these winds with the surrounding slower-moving nebular gas is important in shaping the nebula. In some cases, mass loss in the form of narrow jets is observed, which may indicate the presence of a companion to the central star.

Mass loss and the formation of planetary nebulae

Planetary nebulae are isolated clouds of gas, ionized by a hot central star. It is generally accepted that planetary nebulae form during the penultimate stage in the evolution of low- and intermediate-mass ($<8M_{\odot}$) stars, after they have become RED GIANTS for the second time. The red giant progenitor eventually expels its envelope at a relatively low velocity ($\sim$15 km s^{-1}), and this ejected gas is subsequently ionized by the ultraviolet radiation of the red giant core. The stellar core—now the central star—will eventually cool to its final configuration, a WHITE DWARF. After the primary mass-loss event which expelled the nebula, mass loss from the central star does not immediately cease. A low-density, high-velocity (typically, several thousand km s^{-1}) stellar wind develops, driven by the radiation pressure of the central star (see RADIATIVELY DRIVEN STELLAR WINDS FROM HOT STARS). This wind will have important dynamical effects on the morphology and dynamics of the nebula, sweeping the previously ejected envelope into a well-defined shell.

The details of the mechanism by which the red giant (technically, an *asymptotic giant branch star*) expels its envelope remain obscure. We know that, as the star evolves, it experiences a series of thermonuclear flashes in a shell near the degenerate core where helium is being converted to carbon. With each shell flash, the star becomes more luminous and its radius increases. A slow ($\sim$10 km s^{-1}) stellar wind ensues, which carries off an increasing amount of mass; the mass loss eventually reaches values of $\sim 10^{-4} M_{\odot}$ yr^{-1}, the so-called 'superwind phase'. Such a wind could by itself remove the stellar envelope in a few thousand years. On the other hand, the mass loss may terminate with a more dramatic event. One suggestion is that mixing of carbon into the base of the envelope increases the opacity suddenly, increasing the radiation pressure and lifting off the entire envelope. In the case of stars with close binary companions, the companion may spiral in to the giant star, spinning up and ejecting its envelope: we know such interactions must occur, because some planetary nebula central stars have binary companions whose distance from the central star is less than the size of their asymptotic giant precursors (see CLOSE BINARY STARS).

Following the removal of the hydrogen-rich envelope, there will be a period when the central star is not hot enough to produce much ultraviolet radiation ($T_{\rm eff} <$ 30 000 K) and the nebula will not be ionized. During this phase, the central star is heavily obscured by a dense cloud of neutral gas. This is the PROTOPLANETARY NEBULA phase. Many of these nebulae are strongly asymmetric and have bipolar jets. The jet velocity may be a few hundred km s^{-1}, intermediate between the speed of the nebula and the speed of the later stellar winds. It is suspected that many of the morphological features seen in mature planetary nebulae are determined in the protoplanetary stage.

Observational evidence of winds

The presence of stellar winds is usually signaled by the appearance of 'P-Cygni profiles' in the star's spectrum. These are broad lines with a deep absorption component on the short-wavelength ('blue') side and an emission component on the long-wavelength ('red') side. The absorption component is formed in the gas between the star and the observer, which is blueshifted by the DOPPLER EFFECT as it streams outwards, while the emission component is due to gas beside and beyond the star. P-Cygni profiles are only seen in strong lines of those ionization stages which are dominant in the wind. Because of the high temperatures of planetary nebula central stars, these are lines at ultraviolet wavelengths, such as C IV 155 nm and N V 124 nm. As a result, it was only with access to the ultraviolet by satellites such as the International Ultraviolet Explorer (IUE) that it was discovered that up to half of all central stars have winds.

The maximum blueshift of the absorption component of the P-Cygni profile provides v_{∞}, the terminal velocity of the stellar wind. It is believed that the wind is driven by the pressure of radiation scattered by strong absorption lines, and v_{∞} is always a few times the escape velocity from the stellar surface. Since the surface gravity (and hence the escape velocity) increases greatly as the central star evolves toward the white dwarf stage, we find a considerable range of v_{∞}, with values generally between 500 and 4000 km s^{-1}.

Another wind parameter is the density, which multiplied by v_{∞} gives us the rate of mass loss, $\dot{M}$. The mass-loss rate is more difficult to determine than v_{∞}, but results are available for a number of stars. $\dot{M}$ is found to vary greatly and is not a function of a single parameter such as stellar temperature or v_{∞}. In table 1 we give values for a few central stars, chosen to illustrate the range of properties encountered. The second column gives the surface temperature of the star, $T_{\rm eff}$, in thousands of kelvins, but it should be noted that the definition of the 'surface' is somewhat arbitrary for a star with an extended atmosphere. The last column is the mass-loss rate in units of $10^{-8} M_{\odot}$ yr^{-1}.

Part of the variation in $\dot{M}$ is associated with the chemical composition of the central star's atmosphere. One group of central stars retain a remnant (less than $\sim 10^{-4} M_{\odot}$) of the red giant envelope, which gives them a hydrogen-rich stellar atmosphere—they are stars of spectral type 'O' or 'Of'. The other group has hydrogen-poor atmospheres: a typical chemical composition would

be 60% helium, 30% carbon and 10% oxygen. These stars may show Wolf–Rayet spectra. Wolf–Rayet spectra are dominated by broad emission lines of carbon and helium; such stars have very extended atmospheres and strong stellar winds. (Planetary nebula central stars with Wolf–Rayet spectra should not be confused with the more massive and luminous 'classical' WOLF–RAYET STARS.) Not all hydrogen-poor central stars are Wolf–Rayet stars, however. Those which are hotter and which have higher gravities may be PG 1159 STARS or O VI stars. The PG 1159s are hot, hydrogen-deficient stars with at most feeble stellar winds. Some of them pulsate, and only about half of the known members of this class are associated with planetary nebulae. The O VI stars (now usually called (WC)-PG 1159 stars) seem to be intermediate between Wolf–Rayets and PG 1159s, very hot but still having a substantial fast wind. In fact, one PG 1159 star, Longmore 4, became an O VI star for a few weeks. During this outburst, the carbon and helium absorption lines went into emission and a stellar wind developed; the star then returned to its previous state.

We might summarize by saying that, as planetary nebulae evolve, the temperatures and surface gravities of their central stars increase. As a result, the velocities of the central star winds increase, while the wind mass-loss rate drops. However, there is a second factor at work: those stars which have lost their hydrogen will have atmospheres of higher opacity, increasing the effective radiation pressure and driving stronger winds than in the case of stars with a hydrogen atmosphere.

Dynamical effects of winds on nebulae

After it was discovered that strong central star winds were common, it was realized that these winds could have a dynamical effect on the nebula itself. Pikel'ner considered such effects in 1968 and by the early 1980s the 'two-wind model' developed by S Kwok and others was widely accepted. In this model, the fast stellar wind overtakes the earlier slow red giant wind and sweeps it into the hollow shell we see as a planetary nebula. Because the nebulae are rarely spherical, but often have an axis of symmetry, it was necessary to modify the two-wind model by postulating

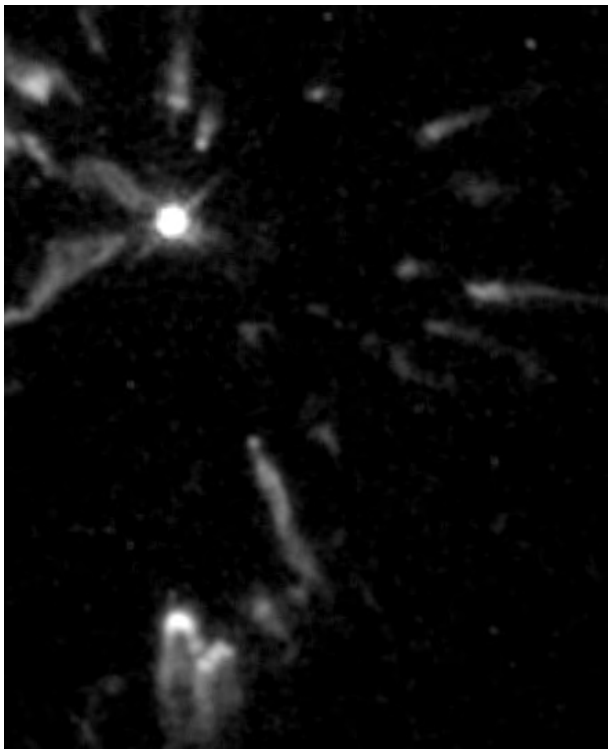

Figure 1. The wind from the central star of Abell 30 (upper left) sweeps past nearby nebular material.

that the red giant wind was not spherical but had a denser equatorial plane. Computer simulations based on this modified two-wind model have been successful in reproducing many of the basic observed morphologies. Such models, however, leave unanswered the question of why the red giant wind should be strongly aspherical, since it is not expected that the red giant would have a significant rotational velocity. This has led to speculation about the presence of companions—which might include substellar brown dwarfs or even massive planets—which could spin up the progenitor star and impart the needed asymmetry to the slow wind.

Another outstanding question concerns the physical processes affecting the fast stellar wind after its collision with the nebula. A wind moving at 1000 km s^{-1} will be heated to over 10^7 K by such a collision. If this gas is able to cool within a few hundred years, only its momentum will accelerate the nebula. If it does not cool, however, the heated wind will fill the interior of the nebula, and the pressure of this hot, thin gas will be more effective in accelerating the planetary nebula outwards than the momentum alone. In the case of one nebula, BD+30 3639, x-rays have been observed from a 3×10^6 K plasma, providing direct evidence for the still-hot bubble of shocked stellar wind.

The high spatial resolution provided by the HUBBLE SPACE TELESCOPE (HST) has revealed a wealth of unexpected structure in planetary nebulae. Many nebulae have been

Dirac House, Temple Back, Bristol, BS1 6BE, UK

found to have neutral globules embedded in the ionized gas, which are in the process of evaporation. The comet-like tails streaming outwards from these globules give dramatic evidence of the interaction of the stellar wind with the nebula (figure 1).

Jets in planetary nebulae

In a few nebulae, such as NGC 6543 and IC 4593, HST images have revealed narrow jets. Many more nebulae have been found to possess 'point symmetry', where features are located symmetrically with respect to the star, even though there is no single *axis* of symmetry. Such structures immediately suggest the action of a bipolar jet, with a shifting axis. The discovery of such structures came as a surprise, because previously known stellar jets, such as those from protostars, arise from ACCRETION DISKS, which are not expected around isolated planetary nebula central stars—stars from which material has been expelled not accreted. Nevertheless, the existence of jets must be explained, and many astronomers now believe they are strong evidence for the existence of some sort of companion to the central star. The presence of such a companion could allow mass transfer, resulting in at least a transient accretion disk and collimated jets. As mentioned above, there are planetary nebulae where the central star has a close binary companion and which must have evolved through a mass-transfer phase. Companions have also been invoked to explain the dense equatorial wind of the modified two-wind model. These considerations point to a whole range of complicated mass-loss phenomena that have yet to be explored.

Bibliography

There is some discussion of the central stars of planetary nebulae in this recent text:

Planetary Nebulae

Planetary nebulae, shells of illuminated gas that surround old and dying stars, were discovered by William Herschel, who in 1785 referred to the 'planetary', or 'disk-like', appearance of the object we now call NGC 7009 (figure 1). He later discovered that one of his 'planetaries' (NGC 6543) had a central condensation or star. Some 2000 planetary nebulae are known today, the best known being the Ring Nebula in Lyra (see figure 2). All have central stars. The central stars were once the nuclear burning zones of giant stars that have lost their outer envelopes and are on their way to becoming WHITE DWARFS, the fleeing envelopes making the ephemeral planetaries.

Spectra and parameters

Although Herschel thought the nebulae were made of 'shining fluid', their actual natures were not proven until William Huggins examined NGC 6543 (figure 3) in 1864 with a visual spectroscope and found three emission lines, demonstrating that the nebulae are made of low-density gas. One in the blue (Hβ at 4861 Å) was quickly associated with hydrogen, but the green lines at 4959 Å and 5007 Å defied identification, becoming known as the 'nebulium' lines. Huggins and others subsequently discovered additional emission lines, including more from hydrogen, others later found to be helium, and yet others that added to the mysterious 'nebulium' list.

The origin of the hydrogen emissions was worked out in 1927 by Hermann Zanstra. The blue central stars are very hot, above 25 000 K, and emit copiously in the ultraviolet beyond the Lyman ionization limit of hydrogen at 912 Å. The nebula is primarily a plasma filled with protons, free electrons and neutral and ionized atoms that have their electrons in the lowest orbits or energy levels (the ground states). Each Lyman photon is capable of ionizing one hydrogen atom, the electron freed with an energy equal to the difference between the ionizing photon's energy and hydrogen's ionization energy. The electron is eventually recaptured by another proton and can land on any energy level. The best chance is for the

Figure 1. The discovery object, NGC 7009, is about 3500 ly away and about 1 ly across. Ionized by a hot star with a temperature of 90 000 K, the nebula consists of a complex, highly elliptical shell punched through by 'FLIERS' that make the ansae that gave the nebula the name 'Saturn Nebula'. electron to land back in the ground state. If it does, the UV photon is re-created and will ionize another atom.

Absorption and re-creation continue until the free electron lands in an upper level. If it goes to the second, it produces a photon of the Balmer continuum, which flies out of the nebula, as there are few atoms able to absorb it. From level 2, the electron drops to level 1, creating a Lyman α photon that bounces around in the nebula until it escapes or is destroyed by hitting a dust grain, by ionizing another element or in the creation of a pair of lower-energy photons that escape.

If the electron lands above level 2, it has several choices. If it first goes to, say, level 4 (as in figure 4), it can jump directly to level 1, creating a Lyman γ photon that is immediately reabsorbed by a neutral atom, the electron returning to level 4. Eventually the electron will jump to level 2 or 3. If it goes to 2, a Balmer photon is created that leaves the nebula. If it goes to 3, the same process operates until the electron jumps to level 2. The result is that each Lyman photon from the star produces one Balmer photon from the nebula. The ionization probabilities are high, while the recombination probabilities are low. As a result, the optically visible nebular gas is well over 99% ionized, there being essentially one free electron for each proton. In a real nebula, a variety of atoms act in a similar way to produce 'recombination lines' of helium, oxygen, nitrogen, neon and others.

The nebulium problem was solved in 1928 by I S Bowen. While exploring the energy-level structure of doubly ionized oxygen, he found levels just above the ground state with energy differences appropriate to Huggins' 4959 Å and 5007 Å (and eventually other) lines. Downward transitions from these levels to the ground state are 'forbidden' under simplified quantum rules. In truth, they are allowed, just improbable, the upper levels being 'metastable' with long lifetimes. Electrons freed from hydrogen with sufficient energy (a few electron volts for the optical lines) collide with O^{2+} ions and kick the bound electrons into the metastable states. Upward and downward collisions establish an equilibrium and relatively high populations in the metastable states. Given a stable population, there will be a steady stream of downward radiative transitions that produce the 'forbidden lines', denoted by square brackets around the spectral signatures (the forbidden lines of doubly ionized oxygen called '[O III]', etc). Forbidden lines are produced by various ionization stages of oxygen, nitrogen, neon, sulfur, iron and other elements from the ultraviolet through the infrared. Although the forbidden lines are intrinsically weak, the recombination lines are weaker (the odds of a recombination quite low as a result of low density). The strongest forbidden lines therefore dominate the nebulae.

Temperatures, densities and chemical compositions are easily derived. The free electrons thermalize quickly by rapid collision and establish gas kinetic (electron) temperatures (that reflect velocities) between about 8000 K and 20 000 K that depend on the balance between heating and cooling. The gas is heated by ultraviolet radiation from the central star, so the hotter the star (temperatures range to over 200 000 K), the hotter the nebula. The electrons are cooled when they lose energy in exciting the forbidden lines, principally [O III], so the more heavy atoms, the cooler the nebula. Electron temperatures are measured by comparing forbidden lines from a given ion that arise from levels that lie at different energies above the ion's ground state, for example from the ratio of the 4363 Å and 5007 Å intensities of [O III] or the 5754 Å and 6584 Å intensities of [N II]. Electron densities (in the range from 10 to 10^5 electrons cm^{-3}) can be measured from pairs of forbidden lines that arise from closely spaced levels that have different excitation and radiative probabilities, notably from the ratios of the 3729 Å and 3726 Å lines of [O II] and the 6731 Å and 6717 Å lines of [S II].

Once the physical conditions are known, we find the ionic abundances of the nebulae from the strengths of the recombination and forbidden lines. To find the elemental compositions we add the individual ionic compositions and use predictive radiative models to calculate the abundances of unobserved ions, in effect fine-tuning the model's abundances and parameters until the predicted spectra match the observed spectra. Planetary nebulae in the Galactic disk have basic compositions similar to those of the Sun and other POPULATION I STARS, while those in the Galactic halo are notably deficient in heavy elements. Superimposed on these basic compositions can be powerful enrichments of helium, nitrogen and carbon, these elements having been created in the giant stars and dredged to the stellar surfaces before the creation of the nebulae. Helium abundances can be double normal, while those of nitrogen and carbon can be up by over a factor of 10. Nitrogen- and helium-enriched nebulae (figure 5) are generally referred to as 'Type I', the other chemical types (whose terms are rarely used) having lower enrichments or none at all.

Distances, dimensions and masses

Physical diameters of the planetaries follow from angular diameters (which range from sub second of arc to a quarter of a degree) and distances. Masses equal the volumes multiplied by the mean proton (electron) densities multiplied by the proton mass. Distances, however, are poorly known. All but a handful of nebulae are too far away for PARALLAXES, and these have high errors. Distances can be found for some objects through association with clusters or companions, from their degree of interstellar reddening by dust or by comparing their angular expansions with their measured expansion velocities. We can also examine nebulae in the MAGELLANIC CLOUDS. From all these we find ionized masses typically a few tenths that of the Sun.

Since the total energy radiated in the standard Hβ line, $E(\mathrm{H}\beta)$, depends on the product of the electron and proton densities (multiplied by a recombination coefficient), $E(\mathrm{H}\beta)$ can be related to mass. The flux in Hβ at the Earth, $F(\mathrm{H}\beta)$, depends on $E(\mathrm{H}\beta)$ and distance. Adopting

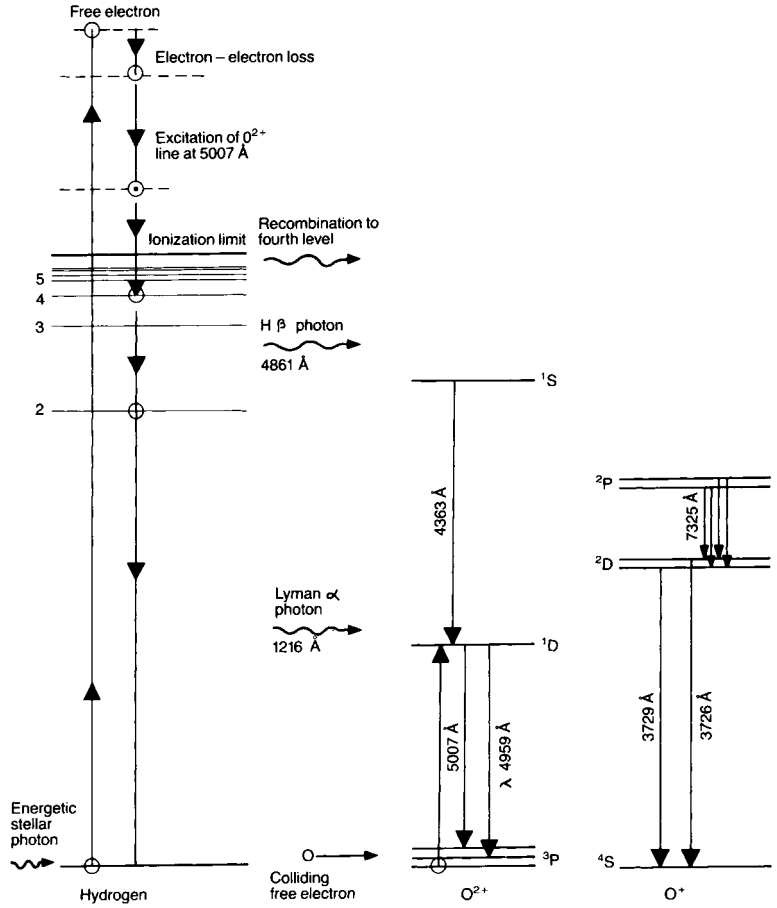

Figure 4. Nebular emission lines are produced by a combination of ionization, recombination and collisional excitation. On the left, a hydrogen atom is ionized by a stellar photon. The freed electron undergoes various energy losses and recombines with another proton (here to the fourth energy level) to create the hydrogen lines. While free, the electron can collisionally excite the electrons of heavier atoms into long-lived metastable states, descent from which makes the forbidden lines. In the center we see the excitation of doubly ionized oxygen, at right of singly ionized oxygen (these two diagrams doubled in size for clarity). The ratio of the intensities of the lines at 4363 Å and 5007 Å (or 7325 Å with 3726 Å + 3729 Å of [O II]) gives electron temperature, whereas the 3726:3729 intensity ratio gives density. From Kaler J B 1989 *Stars and their Spectra* (Cambridge: Cambridge University Press).

a standard mass allows the computation of 'statistical distances'. These are used to find most nebular radii, which range from about 0.01 pc to over 1 pc. Distances combined with radial velocities allow determination of nebular kinematics. Nebulae in the disk have the motions of other population I stars, those in the halo having high velocities typical of population II.

The ionized mass is only a portion of a nebula. Planetaries fall into two broad categories, those in which the central star ionizes all the surrounding matter and some of the stellar radiation escapes ('optically thin') and those in which the radiation is all absorbed, leading to a bubble (a Strömgren sphere) of ionization that is nested inside a neutral shell ('optically thick'). In this simplified view, only optically thin nebulae are subject to the above statistical distance method, as the optically thick planetaries may have very low ionized masses, leading to distance overestimates, although corrective estimates can be made with enough calibrating objects.

Reality is more complex. A nebula may be optically thin in one direction, thick in another. Planetaries also exhibit a great range in total mass, which leads to an even greater range in ionized mass, from $0.03M_{\rm Sun}$ to $0.5M_{\rm Sun}$ or so (making statistical distances even more uncertain). Nebular structures are complex as well, commonly consisting of nested shells and disks. A dense inner shell may be optically thin, radiation leaking to a more tenuous outer shell that may be optically thick. This shell may also be optically thin, radiation leaking to a larger outer halo that may also be thick or thin. If the inner shells are thick, the outer will not be visible, or might be seen as fragmented if radiation leaks in one direction and not in another.

High-dispersion spectra reveal internal velocities. The emission lines are broadened or split from the expansion of a shell. Expansion velocities increase

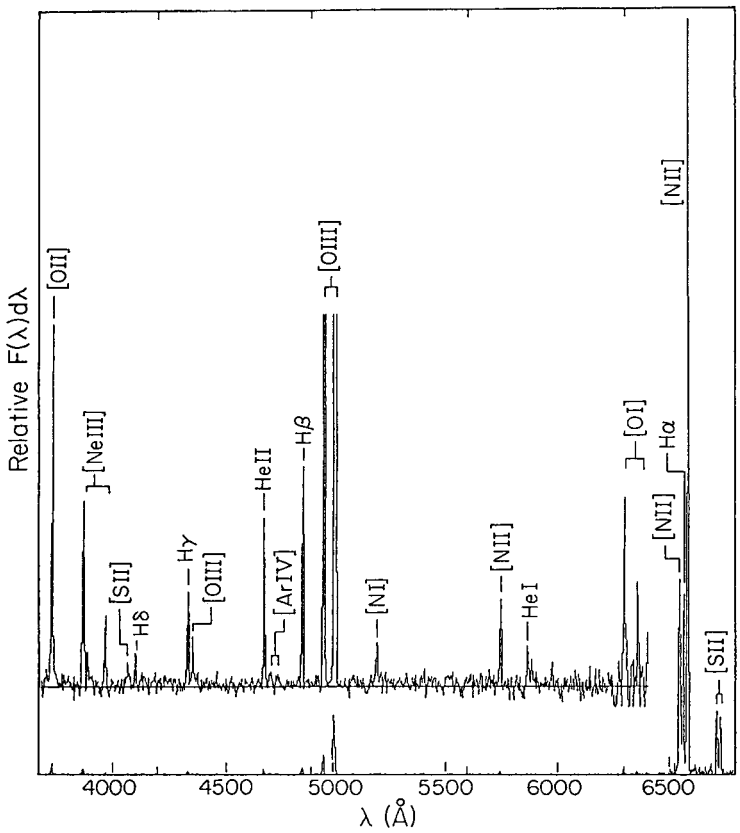

Figure 5. The spectrum of a type I nebula (BV-1), one highly enriched in nitrogen and helium, displays powerful singly ionized nitrogen lines as well as a host of others. Two scales are used to show the full range of intensities. NOAO, from Kaler J B, Chu Y-H and Jacoby G H 1988 *Astron. J.* **96** 1407.

outward from the center, and are typically a few tens of kilometers per second. From dimensions and expansion velocities we find ages that range from a few hundred to tens of thousands of years. Some 50 000 yr after the nebulae are formed by ejection from their parent stars, the nebulae merge with the interstellar medium and are too faint to be seen, leaving behind white dwarfs.

Infrared observations of molecular emissions show the traditional nebulae to be surrounded by molecule-rich shells in which we find H_2, CO and even polycyclic aromatic hydrocarbons. These shells may or may not also be visible in the optical. Radiation longward of 912 Å leaks into the molecular gas, exciting it and producing a 'partially dissociated region' that will someday become ionized as the nebula expands and high-energy radiation attacks it. In other cases, molecular gas is rather thoroughly mixed in with the ionized gas, at least in projection, and in some cases physically. Intimately involved is dust, which radiates an infrared continuum and emits spectral signatures of carbon and silicates. Dust can both be buried in the nebula and surround it. When all these structures are taken into account, nebular masses—ionized, neutral and molecular—can range upward to well beyond solar.

The central stars

Excepting neutron stars, planetary nebula central stars are the hottest known and are exceedingly luminous. They are faint to the eye only because of high bolometric corrections for invisible ultraviolet radiation. From Zanstra's mechanism, the total Balmer photon luminosity equals the stellar ultraviolet photon luminosity. Recombination theory relates the total Balmer photon luminosity to the Hβ energy luminosity. Assuming a blackbody, the stellar ultraviolet photon luminosity can be related to its ultraviolet energy luminosity, which can therefore be found from the Hβ energy luminosity (and distance). Comparison of the stellar ultraviolet luminosity with the star's visual luminosity yields the effective (surface) temperature (the 'Zanstra temperature'), distance factoring out. If a nebula is optically thin and ionizing radiation escapes, we do not count all the emerging ultraviolet photons and therefore derive only a lower limit to temperature.

Because the strengths of the ionized helium lines depend on the amount of ionizing radiation shortward of the helium Lyman limit at 228 Å, a similar temperature can be found by comparing the flux in the He II 4686 Å line (Paschen α) with the visual magnitude. A nebula

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

may be optically thin for hydrogen, but thick for helium. As a result, the He II Zanstra temperature is almost always greater than or equal to the hydrogen Zanstra temperature. If the two are equal, the nebula is probably thick. Reliable Zanstra temperatures range from around 25 000 K to nearly 300 000 K. Temperatures combined with visual magnitudes and distances yield bolometric luminosities that range from a few solar luminosities to tens of thousands. Other temperature methods use the slope of the stellar flux in the observed ultraviolet and the determination of the energy balance in the nebula, equating heating (from the recombination lines) with cooling (from the forbidden lines).

Temperatures and luminosities, as well as surface gravities and stellar compositions, can also be found by modelling the stellar absorption line spectra. Surface gravities and assumed masses combined with temperatures yield luminosities and thus another way to find distances. Modelled temperatures are in the range of the Zanstra temperatures. Specific disagreements with Zanstra temperatures suggest that some stars may not be blackbodies.

Central star spectra are varied and complex. Some stars exhibit simple O-type absorption spectra. Lower-luminosity stars can be hydrogen rich or hydrogen poor, appearing as preludes to different kinds of white dwarfs. Higher-luminosity stars commonly show emissions from winds, some mimicking the spectra of the carbon WOLF–RAYET (WC) STARS. Spectra of lower-temperature stars can be so filled with emission lines that the continuum cannot even be seen. At the high-temperature end, the stars may radiate strong O VI lines. Many of these 'O VI stars' vary with periods of minutes, much as do the PG 1159 white dwarfs. We commonly observe P Cygni lines in the ultraviolet that reveal terminal wind velocities that range from a few hundred km s^{-1} to 5000 km s^{-1} and give mass loss rates of 10^{-7}–10^{-9} solar masses per year. The winds can be variable, leading to variations in line strengths. The winds also add considerable complications to modelling and may result in poorly determined temperatures (see PLANETARY NEBULA CENTRAL STAR MASS LOSS/WINDS).

Wind modelling, however, shows enrichments in helium in the Of type of spectra, with He/H ratios of 0.2 or so. The WC spectra exhibit no hydrogen lines. These helium stars have C/He ratios of unity and oxygen mass fractions of 4–10%. White dwarf DA and DB characteristics begin early, during the planetary nebula stage. The compositions of the stars are consistent with those of the dust grains found in the nebulae, carbon-rich stars having carbon grains, the others having silicate grains.

Temperatures and luminosities allow the placement of planetary nuclei on the HR diagram (the log L–log T plane) for the establishment of empirical evolutionary tracks and for comparison with theoretical tracks (figure 6). Distance errors, however, greatly smear the luminosities. The best recourse is to use planetary nebulae in the Magellanic Clouds, although the low metallicity of the Clouds may make these nebulae different.

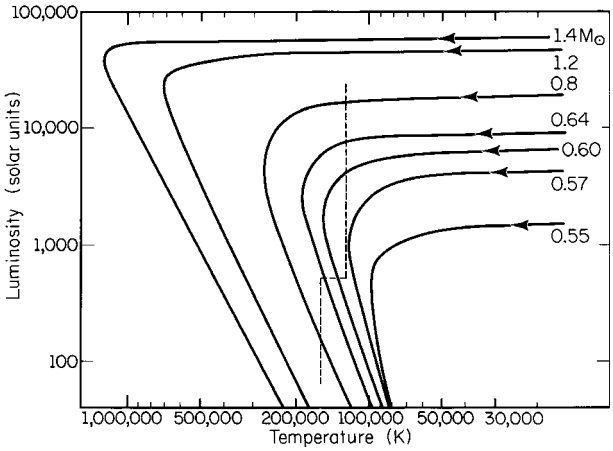

Figure 6. Planetary nebula central stars evolve from the right (from AGB stars) along horizontal evolutionary tracks, reach maximum temperatures, and then cool and descend to become white dwarfs, the tracks depending critically on final (core) masses. Most observed planetary nebula stars fall to the right of the dashed line. From R A Shaw, evolutionary tracks by I Iben Jr.

The direction of evolution on an evolutionary track is revealed by nebular expansion. The stars enter the planetary regime of the HR diagram at high luminosity and low temperature, then move to the left, increasing T at constant L, where they exhibit the wind phenomena that make for highly divergent spectra. At a high temperature that typically falls between 100 000 and 200 000 K, the empirical track reverses, and the stars descend in luminosity while cooling to temperatures of 70 000 K or so, at which point the nebulae effectively dissipate. The empirical track leads directly to the tracks followed by white dwarfs. The birth rate of planetary nebulae found from the space density (pc^{-3}) and the mean expansion velocity is of the order of 10^{-12} pc^{-3} yr^{-1}, within the large errors comparable with the birth rate of white dwarfs.

Since asymptotic giant branch (AGB) stars (those that have completed core fusion and have contracting carbon–oxygen cores surrounded by fusing shells of hydrogen or helium) are losing their outer envelopes at fierce rates, and their luminosities are similar to those of planetary nuclei on the heating 'horizontal track', it is clear that they are the planetaries' predecessors. The planetary nebula nuclei are therefore essentially the spent carbon–oxygen cores that are still surrounded by hydrogen-burning shells and topped by thin hydrogen envelopes. The planetary nebulae therefore link the AGB stars directly to the white dwarfs.

Theory fits observation. The luminosity of a remnant core on a horizontal heating track increases with its mass, which in turn depends on initial mass. The cores run from about 0.55 solar masses for an initial mass of 0.8 solar to the Chandrasekhar limit for a 10 solar mass star. As the remnant outer envelope is thinned from the top by a fast hot wind and from the bottom by nuclear fusion, the radius

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of the core goes down and the effective temperature goes up, the star traversing the HR diagram to the left. The traversal time depends on a high power of the core mass. As a result, masses on the horizontal tracks are strongly concentrated toward an upper limit around 0.6 solar masses. Planetary nebulae thus become useful distance indicators for other galaxies. They are easy to find and the upper limit of their brightness distribution represents a standard candle for distances to tens of megaparsecs.

The turnaround point on an evolutionary track at specific mass is reached when the nuclear burning begins to shut down, the stars then cooling and dimming. The high-temperature maximum is proportional to the core mass, low-mass stars reaching only 80 000 K or so, high ones exceeding 200 000 K. The pace of evolution for different masses then changes, allowing the higher-mass cores to be observed. The ages of the nebulae can be found by comparing the positions of their stars with the calculated rates of evolution. However, this picture is complicated by the style of nuclear fusion, a large fraction (perhaps up to 40%) of the AGB stars becoming planetary nebulae while their inner shells are fusing helium instead of hydrogen, which slows the evolutionary pace. Evolutionary ages tend strongly to exceed the kinematic ages found from expansion velocities.

The chemical enrichments seen in the planetary nebulae are interpreted in terms of internal processes that take place in the predecessor giants before nebular ejection. While on the red giant branch (the first ascent), the star's convective envelope penetrates inward to the hydrogen-burning shell to dredge up the by-products of the carbon cycle, the process at least doubling the surface nitrogen content and altering carbon isotope ratios. A second dredge-up takes place in higher-mass stars beyond about 3–5 solar masses after the cessation of core helium burning, at the beginning of the AGB phase, when convection brings up helium and nitrogen created in what had been the hydrogen-burning shell. Third dredge-up occurs after the start of helium shell flashes, when convection enters the zone between the hydrogen- and helium-burning shells and lofts upward more helium and now carbon. Finally, in the 'hot bottom burning' stage, the carbon cycle operates at the base of the convection zone, causing yet more nitrogen to rise to the surface. The observations are qualitatively in accord with theory, although the nebulae can be more enriched than predictions allow. Only cores above about 0.7 solar masses, which come from higher initial masses, have highly enriched nitrogen, in rough accord with prediction. The carbon-rich nebulae are presumably the descendants of CARBON STARS.

Along with helium, nitrogen, carbon, planetaries must also eject vast amounts of elements created in the helium-burning shells by slow neutron capture (the s-process). Most of the galactic carbon and a great deal of nitrogen, as well as those elements made by the s-process, find their way into the interstellar medium—and into new stars—via the planetaries.

Structure, formation and evolution

Planetary nebulae exhibit a complex, sometimes bewildering, variety of structures that have elicited numerous classification schemes. The most general classification simply divides the nebulae into those with two lobes ('binebulous', now more commonly 'bipolar') and those without, the non-bipolar ranging from almost circular to quite elliptical. The more extreme bipolar nebulae have a tight 'waistband' that encircles the middle between two extended poles that fall along a prominent major axis. The majority of nebulae, bipolar or not, display double or even multiple shells that sometimes include vast extended outer haloes. A significant number are also 'point symmetric', in which each feature on one side of the nebula is reflected through the center almost exactly onto the other side.

The bipolar nebulae have distinctive common features. They tend to reside close to the plane of the Milky Way, suggesting that they are the progeny of higher-mass stars, which apparently eject their envelopes in a manner different from stars of lower mass. The bipolars also tend to have high enrichments of helium and nitrogen, in keeping with AGB dredge-up theory (although there are distinct exceptions). That is, highly enriched type I nebulae are population I and stick to the galactic plane. Moreover, bipolars are richer in molecular gas, the molecules strongly confined to the waistband. Waistband H_2 seems to be excited more by shocks rather than by radiation.

The nebulae are also filled with small 'microstructures' that are not well explained. Some planetaries have rod-like features that extend along the major axis. They can extend past the main nebula to form jug-handle 'ansae' and are often broken into pieces with complex substructures. Moving rapidly, they are called 'FLIERS' (from 'fast low ionization emission regions') and have very low excitations indicative of shock heating. Buried within the closest planetary nebula, the Helix (NGC 7293), are thousands of comet-like knots that point away from the central star, the knots filled with neutral gas, molecules and dust, their surfaces heated by starlight.

These structural features all somehow emerge from giant (AGB) stars. However, the process long remained mysterious because of limited resolution and imaging capability and because the AGB stars surround themselves in dusty cocoons, which rendered the birth process invisible until the advent of infrared capabilities. Understanding requires that we see the transition objects that cover the gap in the $\log L$–$\log T$ plane between the AGB stars and the planetaries. A number of such 'PROTOPLANETARY NEBULAE', nebulae in the developmental state, are now recognized. The Egg Nebula in Cygnus (figure 7), the paradigm, is a bipolar reflection nebula whose bright lobes have the spectrum of a class F supergiant apparently buried within a thick, dark, molecule-filled waistband. Shining through the poles are twin beams that illuminate dozens of rings of bright reflective dust. The rings show that the mass loss from the progenitor AGB star is episodic, with sudden

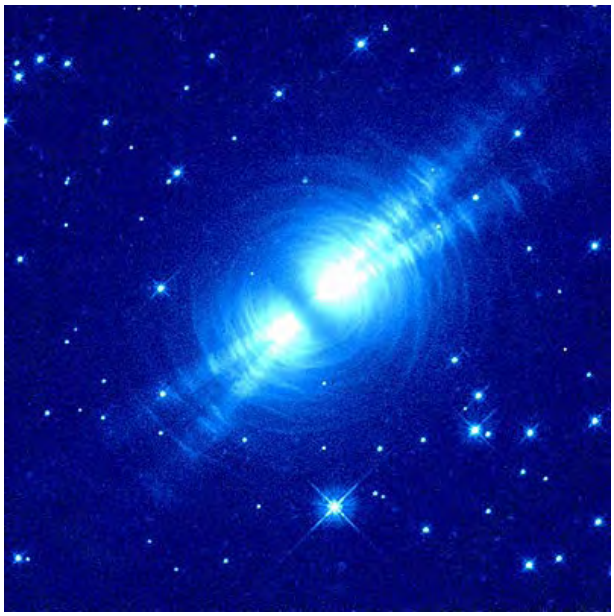

Figure 7. The Egg Nebula is the best-known protoplanetary nebula: a planetary nebula in the making. Outflowing columns of dusty gas, arranged in symmetrical rings, reflect the light of a class F supergiant that was probably once a Mira variable. The star is embedded in the dark thick central disk. H Bond (Space Telescope Science Institute) and the Hubble Heritage Team (AURA, Space Telescope Science Institute, and NASA). R Sahai and J Trauger (Jet Propulsion Laboratory), Space Telescope Science Institute and NASA.

increases every couple of hundred years, for reasons not understood. In other transition objects the star is hotter and the ionization of the interior just beginning. Very young nebulae clearly show oppositely directed flows from the buried stars that appear collimated by thick central disks. As the AGB star loses its envelope, the 'stellar' body that remains heats through the various spectral classes, from class M through F then to A to B as it loses ever more mass and the core is revealed. Finally, it is able to ionize the surrounding thick nebula.

The guiding principle to the formation of the visible nebular structures involves interacting winds (figure 8). As the hot core is revealed, the old, cool, slow wind of the AGB star is transformed into a fast hot wind that runs into the more slowly fleeing dusty gas and shovels it into a ring. When the star becomes hot enough, we then see a 'snowplowed' thick ring nested within a fainter outer structure that has not yet been shovelled up. The different structures are formed by the distribution of the mass that is lost by the AGB star and then magnified by the hot wind's interaction. If AGB mass is lost with great uniformity, the resulting planetary will be round. If the AGB wind is slightly axial symmetric, thicker at the equator than at the poles, the hot wind will blow more vigorously through the poles, and the nebula will take on an elliptical shape. If the slow wind is yet more concentrated into a waistband, the resulting nebula takes on a distinct bipolar structure as the hot wind creates huge bubbles that finally break through to interstellar space.

MIRA VARIABLES (AGB stars that will soon produce planetary nebulae) have been shown not to be round. How such asymmetries factor into shaping planetary nebulae, however, is unknown. Interactions with binary companions could produce latitude-dependent winds that give rise to elliptical and bipolar nebulae. As the giant expands, it approaches the tidal boundary between it and its companion, and may lose mass to it through the common LAGRANGIAN POINT. If the wind is strong enough, the giant can surround its companion in a common envelope that enhances mass loss in the orbital plane. When the envelope has been lost, revealing the white dwarf to be, and the fast wind begins, the result is a highly bipolar nebula, bipolar flows also being created in the interaction. Yet though some central stars are observed as binaries, most that inhabit bipolar planetaries appear to be single. The central stars, however, are so luminous that small companions could be lost. That binaries are indeed important is perhaps revealed by the point-symmetric nebulae, as one explanation is precession caused by orbiting companions.

At the extreme, the AGB wind loss pattern might be produced by interactions with planets still in orbit about the AGB star. The incorporation of planets into the growing giant may act to spin up the star, dust from their destruction adding to the dust formed in the giants' winds. Moreover, it has been suggested, on the basis that planets form from dusty disks and even from the remains of pulsar-ablated stars, that new planets might form within the dusty waistbands of protoplanetary nebulae.

As the star passes through the protoplanetary nebula stage, it finally reaches the critical 25 000 K mark and begins to ionize the inner edge of the snowplowed nebula, shocks helping in the heating of the gas. As the nebula continues to expand and the density decreases, radiation can penetrate ever deeper into the cloud, dissociating the surrounding molecules, and ionizing more of the gas until radiation leaks through to illuminate the unplowed portions of the structure and then the outer haloes, which include matter lost while the star was still in its earlier giant phases. Jets presumably formed by the star penetrate through to act somehow in supplying the FLIERS. As the nebula continues to expand, the surrounding molecular shells disappear. Nevertheless, knots of dense matter in the wind can survive, leaving packets of molecules and dust behind perhaps to make a variety of globules that can survive for nearly the life of the nebula. The nebulae eventually become so large and tenuous that they and their motions through space are affected by the interstellar medium with which they are gradually merging. Continuing to move, the parent stars leave their nebulae behind, the star of one old object actually leaving a wake. All is now over except for the dim, cooling white dwarfs that will orbit the Galaxy forever.

Yet a surprise may await. As the nascent white dwarf cools along its descending evolutionary track, the old

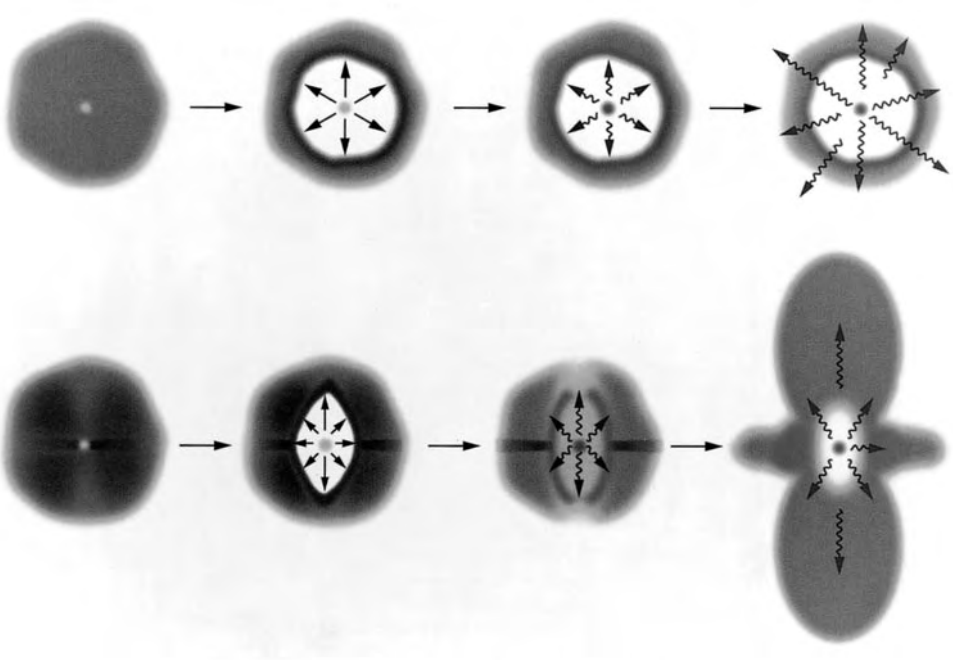

Figure 8. Planetary nebulae evolve with time. Each strip shows (1) a warming star in a protoplanetary nebula surrounded by a cloud of lost mass, (2) the development of a fast wind that shovels the matter into a shell, (3) the heating star radiating in the ultraviolet and illuminating the shell and (4) an advanced state in which the radiation penetrates the shell. The top strip shows the result of spherical mass loss that makes a spherical planetary; the bottom strip shows of mass preferentially lost in an equatorial waistband, the result a bipolar nebula. Art from Kaler J B 1997 *Cosmic Clouds (Scientific American Library)* (New York: Freeman).

helium-burning shell can reactivate itself in a final thermal pulse. The new energy source re-expands the star to giant proportions. New sets of thermonuclear reactions coupled with convection can dramatically change the chemical composition of the surface, enriching it with s-process elements. FG SAGITTAE, which has brightened and cooled over the past several decades, and whose spectrum has become increasingly bizarre, seems to be one of these.

The low surface gravity of such a 'born-again' giant allows more matter to be ejected to produce a planetary within a planetary, the star then approximately retracing its old path on the log L–log T plane. However, the star had already lost most of its hydrogen envelope before it produced its first planetary, so the new ejecta are ultra-rich in helium and carbon, a composition totally different from that of the old nebula. Fine examples are Abell 30 and Abell 78, which have knots of hydrogen-poor matter surrounding their nuclei, their stars now shrunken back to the usual dimensions. Such events may be responsible for a variety of other objects, including the rare R CORONAE BOREALIS STARS, giants with carbon-rich helium atmospheres.

Current research

Numerous problems involving both star and nebula remain. There are still no general methods that can unambiguously find distances to planetary nebulae. The best hope for now is to use nebulae in other galaxies, particularly in M31, where metallicity is no problem. Except in the Magellanic Clouds, however, extragalactic distances are too great to determine much of anything about morphologies. Chemical compositions of galactic nebulae also remain a problem. Abundances of carbon and oxygen found from recombination lines do not fit with those found from forbidden lines, perhaps because of temperature fluctuations.

Wind theory is still in a primitive state, and we cannot easily relate the initial main sequence mass of the star to that of the final product, rendering it difficult to trace the full path of evolution. Moreover, kinematical ages do not fit stellar evolutionary ages, the predicted sizes of the nebulae for a given point on the HR diagram being too large. Either evolutionary theory is wrong or we are not properly taking into account the accelerations and decelerations of the nebular gas.

The cause and the time of origins of the bipolar structures that so many of the nebulae assume are not known; neither are those of the bipolar flows. We are only beginning to penetrate into the mystery of the protoplanetaries. The degree to which binaries (including planets) are important is unknown. We do know, however, that Herschel's discovery eventually led to a fuller understanding of STELLAR EVOLUTION, of how stars meet their ends and of the processes of mass and chemical recycling in the Galaxy.

Planetary Rings

Planetary rings are common to all the giant planets of our solar system. They form a disk of particles following a nearly circular orbit in the equatorial plane of the central planet. Ring disks have various dimensions and radial structures. They have been discovered from both ground-based and spacecraft observations. SATURN'S RINGS were discovered by GALILEO GALILEI in 1610 but clearly identified as rings by CHRISTIAAN HUYGENS in 1659. The development of ring science has been tightly linked with the history of their observations during three centuries. The discovery of a new ring system around Uranus in 1977, during the ground-based observation of a stellar OCCULTATION by the planet (see URANUS: RINGS), boosted research in this area and a quest for new rings started. Suspected after the charge particle measurements of PIONEER MISSION 11 in 1974, the very faint JUPITER'S RINGS were finally detected by the VOYAGER spacecraft in 1979. The story of NEPTUNE'S RINGS started when ring 'arcs' were detected in 1984 with the same method of stellar occultation. The complete ring system was revealed by Voyager 2 cameras in 1989. The view of ring systems has been completely renewed in this 20 yr long 'golden age' period. Many theories have been developed to explain the huge amount of unexpected observations sent back by Voyager probes. Great progress has been made in our understanding of planetary rings but many questions remain on their origin and evolution. In the following sections the possible scenarios on their origin are discussed and the main questions raised after these discoveries are developed. Finally open questions and the main science objectives of the next CASSINI/HUYGENS MISSION to Saturn's rings are presented.

Origin

Rings are a common feature in the close vicinity of giant planets. They are located within the ROCHE LIMIT, an approximate distance below which any rock is expected to break up under the tidal effects exerted by the planet. Ring disks in the Roche limit are vertically very thin, a few hundred meters thick for a few ten or hundred thousand kilometers wide. This is the natural evolution of a cloud of particles which is losing energy in inelastic interparticle collisions while conserving angular momentum in the gravitational field of a central planet. An out-of-plane particle, when crossing the mean plane of the other particles, has its out-of-plane velocity component reduced in each collision and finally reaches the common plane. Meanwhile particle orbits are precessing in the equatorial plane if the planet is oblate.

Ring particles may have condensed from circumplanetary material when the planet formed and have collapsed into a thin disk. The creation of rings after the disruption of a parent body is another plausible scenario. The progenitor, a satellite or a captured comet or asteroid, would have drifted into the Roche limit and been disrupted by tidal effects or by a large impact. Observations tend to show that the lifetime of particles and the timescales of evolution of planetary rings are much shorter than the age of the solar system. Then primordial rings should have disappeared already or should be continuously replenished and destroyed over ages. The equivalent mass of a 200 km sized satellite should be reinjected into the Saturn's rings every 500 Myr. The less massive main rings of Neptune, Uranus and Jupiter might have found enough material in their nearby small satellites to be fed with. An alternative scenario of a recent and widespread ring formation would imply a hardly reconcilable anthropocentric viewpoint.

The origin of diffuse rings may be less uncertain. Their particles are typically micron sized and should be consequently removed very rapidly by drag forces. They are most probably replenished with the ejecta produced by the meteoroid bombardment of the surfaces of close satellites. The E ring of Saturn, which extends from 3 to 8 Saturn radii, may be the most illustrative example. Its peak density is correlated with the orbit of the icy satellite Enceladus. The ejected dust would be dispersed around its orbit and further dispersed at large scale under the action of electromagnetic forces. Recent Galileo observations of Jupiter's rings have shown direct evidence of very faint dusty rings associated with small satellites Amalthea and Thebe outside of the main ring system (see GALILEO MISSION TO JUPITER). Spectroscopic measurements tend to confirm the compositional link between Jupiter's rings and nearby satellites (see JUPITER: SATELLITES).

The chemical composition and bulk structure (density, porosity, ...) of ring particles may provide hints of possible scenarios of formation but relevant spectroscopic data are often lacking. Water ice has been identified as the main constituent on the surface of Saturn's ring particles. Impurities are also present but not yet identified. The compositions of the other ring systems are still unknown. Water ice has not been detected. Reaching conclusions about the origins of rings from their current composition remains, however, a tricky task as ring particle surfaces are eroded or polluted on relatively short timescales by meteoroid bombardment, high-energy particles sputtering or ejecta of nearby satellites. Clues to origin may be deeper under the surface of particles and therefore still hard to probe with current data.

Evolution

Interparticle collisions in the ring plane disperse particles radially even more. The final disk should be uniform with smooth edges. The most remarkable discovery in the past 30 yr has been the unexpected and extreme diversity of structures in planetary rings, such as divisions, sharp edges, spiral waves, narrow ringlets or azimuthal asymmetries such as arcs and clumps in narrow rings or spokes in Saturn's rings. Most of them are common to all ring systems. Any narrow ring should be dispersed radially because of collisions and differential motion (the orbital velocity decreases with increasing distance to the planet). Any longitudinal asymmetry should also be slowly stretched along the ring and erased on timescales

of a few years by this differential motion. The observed structures are therefore either very young or radially and azimuthally confined.

Among the processes proposed to explain the observed structures, the resonant gravitational interaction of ring particles with nearby satellites is certainly one of the most important. Theories of the radial confinement of a ring, or a 'shepherding' mechanism, proposed by Goldreich and Tremaine in the 1970s, estimate the torque exchange between colliding ring particles and a satellite. A transfer of angular momentum takes place at resonant locations where the orbital frequencies of the satellite and ring particle are commensurable, with mean motions in a ratio $m:m+1$ for example. The resonant perturbation of an outer satellite removes angular momentum from ring particles which drift inwards while an inner satellite adds angular momentum to outer ring particles which drift outwards. Both interacting bodies tend to move away from the resonant orbit. This interaction results in various structures depending on satellite mass and distance. A close or massive outer satellite creates a wake in the ring and repels particles along a sharp edge. The edge of Jupiter's main ring is maintained by the close 10 km sized satellite Adrastea. The outer edge of the B ring is located at the 2:1 resonance with 200 km sized Mimas and corresponds to the Huygens gap in the Cassini division. The massive Mimas is then able to remotely open a gap. The outer edge of Saturn's A ring is located at a 7:6 resonance with the coorbital 100 km sized satellite Janus (see SATURN: SATELLITES). Gaps with sharp edges can also be opened in rings by embedded moonlets. The Encke gap is carved out of Saturn's A ring by the 10 km sized moonlet Pan. The satellite was suspected because of wakes detected on gap edges and later discovered in Voyager images. Density waves or bending waves are driven by smaller and distant satellites at high-order (m) resonance locations. They provide useful information on the collective behavior of particles (or 'viscosity') in the densest parts of the rings. Waves a few kilometers wide driven by Prometheus, Pandora, Janus or Mimas are visible in Saturn's rings. Because of these interactions, the orbits of particles drift a few cm to 1 m per year. The outer A ring is expected to fall onto the Cassini division in few hundred million years.

Two shepherding moons on each side of a ring repel particles the same way and can confine the ring radially. The discovery of Saturn's F ring shepherds Prometheus and Pandora and of Uranus's ε ring shepherds Cordelia and Ophelia were the most spectacular success of the Goldreich and Tremaine theory. The singularity of URANUS'S RINGS at the time of their discovery was their extreme narrowness of a few kilometers. Dermott and Gold had proposed in 1977 another confinement theory involving a single small satellite. In a frame corotating with the moon, a ring particle of nearly the same semimajor axis describes a 'horse shoe' trajectory forming a narrow ring. However, this kind of orbit is not stable against collisions. No shepherding moons were discovered around or within the other eight narrow rings of Uranus. However, resonant relationships were found between the sharp edges of Uranus's δ, λ and γ rings and the satellites Cordelia and Ophelia. The radial confinement of the 6, 5, 4, α, β and η rings remains unexplained.

The discovery of Neptune's arcs set the new puzzling question of azimuthal confinement. From 1984 to 1989, a campaign of stellar occultation observations led to the conclusion that Neptune's 'rings' were in fact a family of longitudinally discontinuous rings, called 'arcs'. Lissauer in 1985 formulated a model where an arc could be confined at the Lagrangian L_4 or L_5 points of a 200 km sized satellite. An inner satellite was required to prevent the radial spreading due to collisions. Goldreich, Tremaine and Borderies in 1986 proposed that a single nearby inclined satellite would confine azimuthally the whole family of arcs in very specific sites. Voyager 2 images in 1989 showed that arcs were in fact the densest parts of one narrow ring, the Adams ring. No coorbital massive satellite was found but clumps, maybe embedded km-sized objects, were discovered in the arcs themselves. After ground-based observations and Voyager 2 data were compared, the arcs appeared to be stable over 5 yr despite differential motion. Porco detected in Voyager 2 images a wavy radial distortion in the Adams ring that she attributed to the excitation of the ring by a 42:43 resonance with the nearby satellite Galatea. Arcs would be confined in 4.2° long azimuthal sectors along the ring according to the theory of Goldreich and colleagues mentioned above. However, some arcs were not completely confined to these sites. Thanks to the recent first direct imaging of Neptune's arcs from Earth with the HUBBLE SPACE TELESCOPE, the mean motion of the arcs has been measured more accurately. The orbit is unambiguously outside the 42:43 resonance with Galatea. The role of this satellite and the azimuthal confinement of arcs therefore have to be studied again. Other arcs and clumps have been detected in the F ring, in the Encke gap ringlets around Saturn and in Uranus's λ ring. Their temporal evolution is still poorly known but recent ground-based and HST images of the F ring arcs obtained during Sun and Earth ring plane crossings in 1995 suggest that the structure of the F ring is evolving on a timescale of weeks. This result appears to be compatible with former Voyager observations. Observing heterogeneous rings is certainly a key towards the understanding of the close relationship between rings and satellites, the radial and azimuthal confinements of ring material and then the origin and evolution of rings.

Other processes at play in planetary rings can also severely reduce their lifetime. Erosion mechanisms due to interparticle collisions, meteoroid bombardment, sputtering by cosmic rays, etc supply new molecules to a gaseous ring atmosphere or new small particles in the ring system while removing others. The meteoroid bombardment appears to be the most efficient at eroding particle surfaces at a rate of about 10^{-3} cm yr^{-1}. These outstanding rates even for cm- to m-sized ring particles

still depend on poor data. The size distribution and number of particles are also changed by interparticle collisions but the surface erosion, fragmentation or accretion rates of particles are very uncertain as the restitution factor and bulk properties of particles are unknown and difficult to constrain. Ring particles immersed in the surrounding magnetospheric plasma are charged. Within the planetary magnetic field, sub-micron-sized grains can experience significant Lorentz force compared with gravity and be driven out of the ring plane. This process is certainly involved in the creation of Saturn's B ring spokes and of Jupiter's ring halo and in the spatial distribution of Saturn's E ring. Small particles are also sensitive to drag forces such as Poynting–Robertson or plasma drags. The POYNTING–ROBERTSON EFFECT due to solar radiation induces an orbital decay and reduces the lifetime of dusty particles in the system to less than 1 Myr. The plasma drag is due to collisions with electrons and ions or long-range charge interactions. Charged dust particles inside or outside the synchronous orbit (where particles and magnetic field rotation speeds are equal) will spiral inwards or outwards respectively. The related lifetime may be as short as few hundred years in Jupiter's and Saturn's systems.

Future

Planetary rings are complex systems. They apparently evolve on timescales much shorter than the age of the solar system but are also a common component around a planet. The different processes at play transfer angular momentum between rings and satellites, confine ring material at some places or push other material onto the planet, provide or remove particles. Rings are therefore marvellous laboratories for 'live' tests of theories of dynamical processes at work in disks, the same processes which have been certainly at work, at a larger scale, sometimes during the formation of planetary systems. Many important ring structures are still not understood. Timescales of evolution and lifetimes of particles have to be confirmed. The Cassini spacecraft will be placed into orbit around Saturn in 2004. Observations in a uniquely large spectral range will give decisive constraints on Saturn's ring particles properties and on the compositional relationship between ring and satellites. The temporal evolution of structures will be carefully followed during 4 yr to better understand confinement mechanisms or collective behavior of particles in dense disks. This mission will then allow major advances in answering the questions of the origin and evolution of Saturn's rings and of planetary rings in general. Meanwhile technical progress will provide always-richer ground-based data on the other ring systems to constrain their physical properties and any short-evolution timescales, until a new generation of spacecraft is sent to Uranus and Neptune.

Planetary Society

Carl Sagan, Bruce Murray and Louis Friedman founded the non-profit Planetary Society in 1979 to advance the exploration of the solar system and to continue the search for extraterrestrial life. The Society has its headquarters in Pasadena, California, but is international in scope, with 100 000 members worldwide, making it the largest space interest group in the world. The Society funds a variety of projects and programs, including Red Rover Goes to Mars (for students), the Mars Microphone on the Mars Polar Lander mission, SETI@home, the Gene Shoemaker Near Earth Object Grants, etc.

Planetary Surfaces

For most of the planets and satellites, the knowledge we have of their global properties comes from the observation of their surfaces. Indeed, the information used to characterize solar system objects derives essentially from the analysis of the light we receive from them. Only rarely does one have access to additional sources of data, such as *in situ* seismic or magnetic probing, or soil chemical analysis. When the objects are surrounded by a thick—and therefore opaque—atmosphere, as for VENUS or JUPITER, we cannot see the surface. In all other cases, including the inner and minor planets, as well as planetary satellites, the surface characteristics are used to decipher clues about the past and present properties of the objects as a whole.

Surface features do in general result from the complex interaction between internal processes, which initiated tectonic and volcanic activity, atmospheric phenomena and exogenic processes, due to the contact with the interplanetary medium, such as irradiation with solar particles and bombardment by meteorites. These processes control the evolution of planetary surfaces over a wide variety of time constants. Therefore, by studying their surfaces, one has the potential to trace back the history of planetary bodies, from seasonal variations to geological time scales.

Heavily cratered terrains

Some of the most widely observed surface features are impact CRATERS, as on the MOON and MERCURY. These craters are remnants of the very intense bombardment that affected all solar system bodies after their accretion. Actually, in the inner solar system, a huge number of bodies were formed, on trajectories leading to violent collisions. It took hundreds of millions years to clear up the solar cavity, largely by mutual destruction of the impacting bodies. These impacts constituted the dominant process in the early solar system. If pictures of the inner planets had been taken four billion years ago, they would essentially all look the same.

On the few remaining objects, records of this era remained in the form of impact craters of all sizes, covering their entire surface. Bodies that have not evolved much since still exhibit their impacted surface. ASTEROIDS, planetary satellites and planet areas are labeled 'old' when their surfaces appear heavily cratered, which only means that they have not been further remodeled by global activity.

As a general rule, the smaller the objects are, the less they have evolved after this early bombardment. Thus, by studying the Moon and Mercury, we have access to the first billion years of solar system evolution. MARS has a greater mass and has transformed about half its surface by more recent activity, while preserving heavily cratered highlands on its southern hemisphere. On the largest of the inner planets, the Earth, geology has erased the record of that early history. Attempts to identify impact craters from that era on the terrestrial crust continue.

Tectonic and volcanic features

Surface TECTONIC features have been produced in solid bodies with internal energies large enough to have sustained a mantle activity through the crust. For most planets and satellites, for which the energy source is dominated by the radioactivity of long-lived (U, Th and K) elements, the rise in temperature, and thus the level of internal activity, increases with the size. On the Moon, the only surface features associated with this internal activity come from the filling with lava flows of the largest—and thus the deeper—impact-produced basins, giving birth to the so-called 'MARE'. Predominantly made of Mg/Fe silicates (pyroxenes and olivines), they appear darker than the surrounding 'continents', rich in bright Al-rich feldspar (anorthosite). On larger bodies, internal activity induced the lifting of large areas, like THARSIS MONTES, on Mars, or ISHTAR TERRA on Venus, with MAXWELL MONTES dominating the surrounding plains from an altitude of 11 km. The rise of these features is sometimes associated with great faults or canyons, such as VALLES MARINERIS on Mars, 5000 km long, 6 km deep on average and up to tens of km wide.

Magmatic activity, restricted to mare production on the Moon, produced five impressive volcanoes on Mars, the largest in the solar system, with OLYMPUS MONS the highest, 27 km in altitude. Each of these volcanoes results from a process similar to the one responsible for volcanic chains on the Earth, the difference being the lack of plate tectonics on Mars: a 'hot spot' under the lithosphere generates distinct 'bubbles' of magma which, on Mars, contribute to the same volcano while, on the Earth, the moving lithosphere is 'pierced' through aligned blisters, building distinct volcanoes, as one can see for example with the Hawaiian islands.

In a very few cases, tidal effects initiate volcanic activity at a very high rate. The most striking example is Io, closest of Jupiter's four Galilean satellites, whose entire surface is remodeled by volcanic activity on time scales of only thousands of years (see IO: VOLCANISM AND GEOPHYSICS). The differences in surface properties of these four objects reflect the high degree of diversity of evolutionary patterns in the solar system. Formed almost at the same time from the same material, with about equal masses, they exhibit today totally different surfaces: the more distant one, CALLISTO, is very heavily cratered, and thus described as the 'oldest' one. On GANYMEDE, bright 'young' terrains contrast with darker cratered units. EUROPA is covered with a fractured but smooth and uncratered ice sheet, possibly floating on an underground water ocean; Io is the only planetary object, apart from the Earth, where active volcanoes have been observed (see also VOLCANISM IN THE SOLAR SYSTEM).

Impact craters and volcanoes constitute surface structures with elevations that can reach tens of kilometers. However, mountains similar to those on Earth are extremely rare. They result from continental drifts directly linked to plate tectonics.

Features induced by interaction with the atmosphere

Surface structures can also be driven by interactions with PLANETARY ATMOSPHERES. Polar caps and frosts are currently observed on Mars; liquid, icy and eolian erosion features are also spread over large areas of its surface. Some may have been formed billions of years ago, such as valley networks, while dunes are formed by dust transportation processes occurring on a seasonal basis, at present, when CO_2 condensation at the poles induces drastic changes in atmospheric pressure, giving rise to giant dust storms (see MARS: SURFACE).

Past and present: the surface records

Altogether, the variety of information one can derive from an in-depth study of surface features, in the framework of comparative PLANETOLOGY, has the potential to trace back the entire history of the solar system. This requires an extended coverage of the surface mapping, together with a high spatial resolution, a wide spectral range and a large spectral resolution. Indeed, one needs not only to distinguish extended geological areas, but also to identify structures at a much smaller scale, such as outflows, crater rims and stratified canyon slopes. Moreover, in order to determine the composition of the observed terrains, the observation in the visible has to be extended towards the infrared, where most materials have specific transition features enabling unambiguous characterization. When the atmosphere is opaque in the visible, as for Venus and, to a lesser extent, TITAN, one needs to image the surface at longer wavelengths. A new generation of instruments, imaging spectrometers operating in a variety of wavelength ranges, will provide a major source of information for the future space exploration of the solar system.

Planetary Theory from Eudoxus to Copernicus

By the term planetary theory, in its widest sense, is meant a method of representing, either qualitatively or quantitatively, the apparent geocentric motions of the Sun, Moon and planets. Prior to the development of modern celestial mechanics by Newton, planetary theory could be purely arithmetic, geometrical with or without computation, or physical, the last being an extension of geometrical planetary theory to mechanisms presumed to exist in the heavens and to produce the apparent motions of the Sun, Moon and planets. The principal arithmetic planetary theory is that of the Babylonians, considered in the article on BABYLONIAN ASTRONOMY. Here we shall consider primarily geometrical and secondarily physical planetary theory in Greek, Arabic and European astronomy up to the time of Copernicus.

The earliest geometrical and physical planetary theory is that of EUDOXUS OF CNIDUS (*c*. 350 BC), known only from rather imprecise descriptions by ARISTOTLE (384–322 BC) and Simplicius (sixth century AD), which has been reconstructed by SCHIAPARELLI and more elaborately by Yavetz. Eudoxus's theory, and its slightly later modification by CALLIPPUS (*c*. 330 BC), is composed exclusively of uniformly rotating spheres concentric to the Earth, perhaps on the analogy of the sphere of the fixed stars, which appears to rotate daily about a central Earth. The Sun and Moon each receive three spheres, the outermost, with poles at the celestial poles and equator in the plane of the celestial equator, produces the diurnal rotation from east to west, the second, with poles at the poles of the ecliptic and equator in the plane of the ecliptic, slowly shifts the inclined plane of the path of each body—it was assumed that the Sun had some small motion in latitude—from west to east for the Sun, from east to west for the Moon, and the third, with poles inclined slightly to the poles of the second, carries the Sun in its annual motion and the Moon in its monthly motion through the zodiac from west to east. The planets are more interesting. The outer sphere produces the daily rotation just as for the Sun and Moon, the second sphere, with poles at the poles of the ecliptic and equator in the plane of the ecliptic, produces the motion through the zodiac from west to east in the zodiacal period specific to each planet; then a third sphere with poles in the plane of the ecliptic and a fourth with poles slightly inclined to the third complete rotations in opposite directions, in principle in the planet's synodic period, the period between conjunctions with the Sun.

In Schiaparelli's reconstruction, the planet is at the equator of the fourth sphere and the combined motion of the third and fourth spheres produces a figure called by Simplicius a *hippopede* (horse-fetter), an elongated figure '8' lying on its side and bisected by the ecliptic, with the inclination of the two spheres determining both its length along the ecliptic and its width above and below the ecliptic. When carried about the ecliptic by the second sphere, this produces periodic and invariable retrograde arcs and deviations from the ecliptic in latitude for Saturn, Jupiter and Mercury, but fails badly for Mars and Venus, producing either no retrogradation, because their synodic periods are longer than their zodiacal periods, or enormous deviations in latitude if the inclinations are made large enough to produce a retrogradation. In Yavetz's reconstruction, the poles of the fourth sphere are not only inclined to those of the third, but are offset from the plane of the ecliptic, in which the poles of the third are located, and the planet itself is offset from the equator of the fourth sphere. This gives three degrees of freedom and allows a far better approximation to the apparent path of a planet. It is not incompatible with Simplicius's description, and can even produce a figure like the *hippopede*, but whether Eudoxus himself actually did something so complex, and so ingenious, is uncertain. The models were modified by Callippus by the addition of two spheres each to the Sun and Moon, to account for inequalities in their motions, and of one sphere each to Mars, Venus and Mercury, the reasons for which are not known. Both Schiaparelli and Yavetz have investigated such models, and Yavetz has shown that retrogradations of different shape can be produced, remarkably close to those of Mars, although they still remain invariable throughout the zodiac, contrary to the behavior of the planets.

Whatever the models of Eudoxus and Callippus, which were intended as physical mechanisms in the heavens, may have achieved as geometrical representations of the apparent motion of a planet, they could not be used for calculation of any kind; in this sense they were purely qualitative. There was another geometrical method of representing the motions of planets, by means of concentric circles, or spheres, surrounding the Earth and carrying epicycles, or of eccentric circles, or spheres, about the Earth with movable centers, which are equivalent. Since, as shown in figures 7 and 8 below, these are also geometrically equivalent to the heliocentric theory for, respectively, superior and inferior planets, proposed by ARISTARCHUS OF SAMOS (early third century BC), they must have been known by that time, as it is unthinkable that Aristarchus could have worked out the heliocentric theory without an understanding of these transformations and equivalencies; in the most interesting equivalence of such models, APOLLONIUS OF PERGA (late third century BC) showed how to find the stationary points between which the motion of the planet is retrograde. By the second century BC, there were computational planetary theories in Greek astronomy, but these were arithmetic rather than geometrical and based upon Babylonian methods, probably with no alteration except for adaptation to the Egyptian calendar and, late in the first century, to the Alexandrian calendar. HIPPARCHUS (mid second century BC) developed epicyclic and eccentric models for the Sun and Moon, and even derived parameters for them from observation. Nevertheless, it appears that for computation he too used Babylonian methods rather than geometrical models. Nearly 300 years elapse between Hipparchus and PTOLEMY (mid second century AD), and although it is probable that computation from geometrical

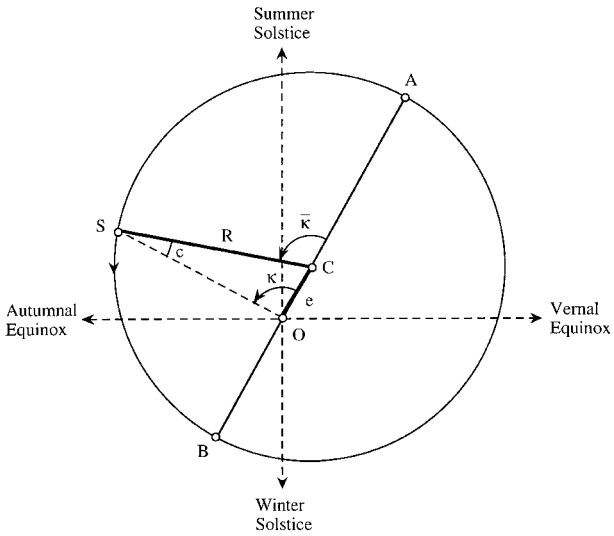

Figure 1.

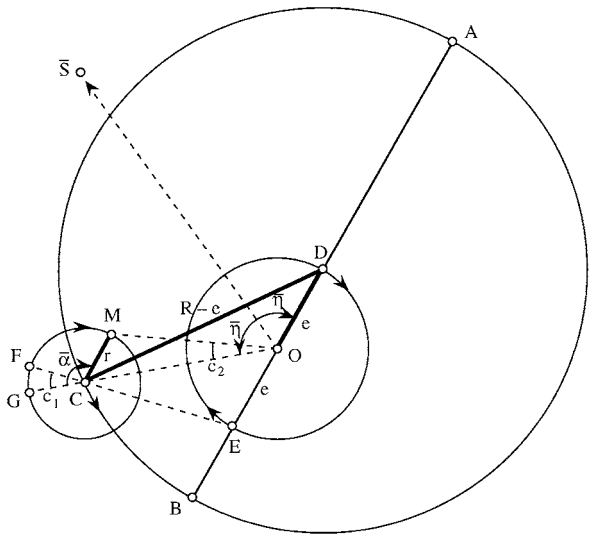

Figure 2.

models was developed during this period, as shown by survivals in Indian planetary theory, the earliest examples in Greek are in the works of Ptolemy, in particular, the *Almagest* and the *Handy Tables*. These remain central to mathematical astronomy for the next 1400 years, as does Ptolemy's *Planetary Hypotheses* to physical astronomy.

In what follows, we shall briefly go through the elements of Ptolemy's theories of the Sun, Moon and planets. Ptolemy's method may be characterized simply: it is rigorously empirical and rigorously mathematical. Every model is either derived or confirmed by observation, although not all the observations are presented in the text, and every numerical parameter is derived directly and uniquely from observation by strict mathematical procedures. There is, however, a large range of precision in his observations, from positions and times measured to within a few minutes for the derivation of parameters—although their accuracy is more variable and there are systematic errors—to rough, even qualitative, observations for demonstrating the properties of models.

In the case of the Sun there is a single inequality most evident in observations showing that the intervals of time between the equinoxes and solstices, although separated exactly by quadrants, are unequal, meaning that the apparent motion of the Sun is non-uniform. Ptolemy accounts for this inequality by letting the motion of the Sun take place on a circle eccentric to the Earth, a model earlier used by Hipparchus, and an equivalent epicyclic model may also be used. In figure 1, the equinoxes and solstices seen from the Earth at O are separated by quadrants, but the arcs of the Sun's motion on an eccentric circle about C are greater or less than quadrants. The motion of the Sun S may thus be considered as a uniform motion $\bar{\kappa}$ about C and a variable correction c, resulting in a non-uniform apparent motion $\kappa = \bar{\kappa} \pm c$ about O. The mean anomaly $\bar{\kappa}$, the eccentricity e as a fraction of the radius R of the eccentric, and the direction of the apogee A and perigee B may be derived from the very observations of intervals of time between the equinoxes and solstices that showed the Sun's inequality. Although later astronomers found improved values of these parameters, the solar model itself received no improvement prior to KEPLER.

The theory of the Moon is considerably more complex as Ptolemy found that it displayed two inequalities, the first with a period of the anomalistic month, in which the Moon returns to the same point in its (movable) orbit, already known to Hipparchus, and the second, which modifies the first, with a period of half a mean synodic month, in which the Moon returns to conjunction with or opposition to the 'mean Sun', that is, the Sun with only its mean motion ($\bar{\kappa}$ in figure 1). He accounted for the first inequality by placing the Moon on an epicycle with the period of the anomalistic month and for the second by placing the epicycle on an eccentric such that it completes a full revolution on the eccentric in half a synodic month. A related inequality, also with a period of half a mean synodic month, affects the mean anomaly, the motion of the moon on the epicycle. In figure 2, the Earth is at O, the mean Sun is at $\bar{S}$, from which the center of the epicycle C moves through the mean elongation $\bar{\eta}$, and the center of the eccentric D moves in the opposite direction through the same $\bar{\eta}$. The result is that C completes one revolution with respect to $\bar{S}$ in a mean synodic month, but two revolutions with respect to the apogee A and perigee B of the eccentric, the effect being to draw the epicycle closer to the Earth at quadrature than at conjunction and opposition, increasing the inequality due to the motion of the Moon on the epicycle. The Moon moves on the epicycle through the mean anomaly $\bar{\alpha}$, completing one revolution in an anomalistic month, measured from a direction FCE that has an 'inclination' to a point E that lies on the apsidal line AB exactly opposite D such that the distances OD

Dirac House, Temple Back, Bristol, BS1 6BE, UK

and OE are equal, the effect being to modify $\bar{\alpha}$ to the true anomaly $\bar{\alpha} \pm c_1$ measured from the direction GCO to the Earth. The true elongation of the Moon from the mean Sun is then $\bar{\eta} \pm c_2$, where c_2 is a function of $\bar{\alpha} \pm c_1$ and the variable distance OC. The parameters of the model are found from observation: the radius of the epicycle r, the mean anomaly $\bar{\alpha}$ and mean elongation $\bar{\eta}$ from lunar eclipses, the eccentricity e from observations of the Moon at quadrature and octants from the Sun. A peculiarity, really a defect, of Ptolemy's lunar model is that it produces a variation of the distance of the Moon from the Earth so large that it may be about half as distant at quadrature as at opposition and conjunction, which is directly contradicted by the small change in the Moon's apparent diameter and parallax.

The most impressive achievement in Ptolemy's astronomy is the theory of the planets, which provided the foundation of all later planetary theory, including that of Copernicus, and was not improved upon until Kepler. Ptolemy's criterion for ordering the planets in the *Almagest* is zodiacal period: in descending order from the fixed stars, Saturn, Jupiter, Mars, Sun, Venus, Mercury, Moon. The Sun, Venus and Mercury have the same period, one year, and Ptolemy places the Sun between the superior planets, Saturn, Jupiter and Mars, which reach opposition to the Sun, and the inferior planets, Venus and Mercury, which reach only a limited elongation. The Moon of course reaches opposition, but is placed lowest since it has the shortest period, may occult all the higher bodies, and has a large, measurable parallax showing that it is close to the Earth. In the *Planetary Hypotheses*, Ptolemy sets out a method of computing the distances of the planets which confirms that the Moon, Mercury and Venus are below the Sun, since there is adequate space only for them, and the remaining planets above.

The planets have two inequalities, the first a function of longitude, of location in the zodiac, the second a function of elongation from the Sun. It is the second inequality that produces the most obvious feature of planetary motion, a periodic retrogradation bounded by two stations, which occurs near opposition for the superior planets and near inferior conjunction for the inferior planets. The second inequality is produced by the motion of the planet on an epicycle and the first inequality by the motion of the center of the epicycle. For the superior planets, the motion of the center of the epicycle corresponds to the planet's own motion about the Sun in a heliocentric model, and the motion of the planet on the epicycle to the Earth's motion about the Sun; for the inferior planets the motion of the center of the epicycle corresponds to the Earth's motion about the Sun and the motion of the planet on the epicycle to the planet's own motion about the Sun. Ptolemy's model for both inequalities is shown in figure 3. The earth is at O and at an eccentricity e let M be the center of an eccentric circle of radius R with apogee A and perigee B. Symmetrically to M at the same eccentricity e let E be the center about which the epicycle moves uniformly,

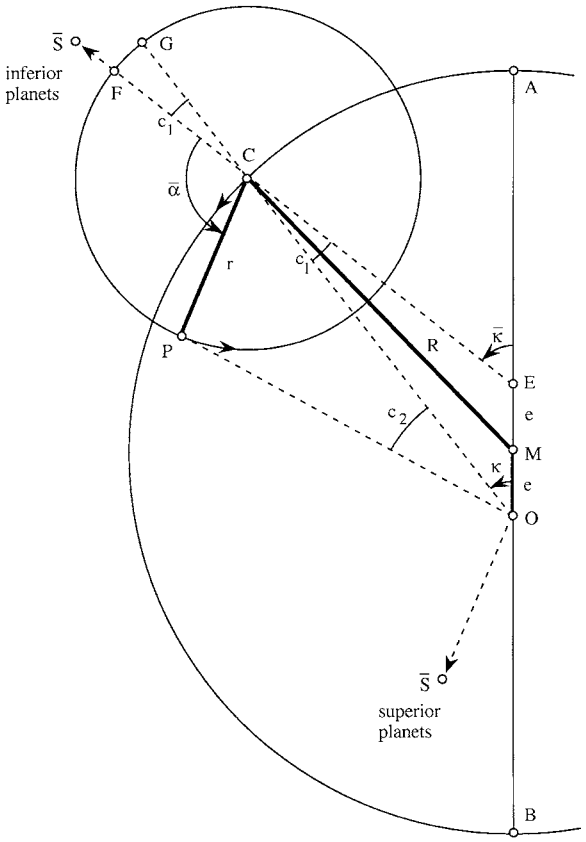

Figure 3.

often called the 'equant' point, and let the center of the epicycle C move on the circle about M uniformly about E through mean eccentric anomaly $\bar{\kappa}$. The effect of the separation of the center of constant distance M from the center of uniform motion E closely approximates motion according to Kepler's ellipse and area laws since the circle about M corresponds to the circle constructed on the major axis of the ellipse, to which for small eccentricity the ellipse very nearly coincides, and E corresponds to the empty focus of the ellipse, about which the angular motion of the planet is very nearly uniform. In principle, the models of Ptolemy and Kepler differ by only a few minutes of arc, although inaccuracies in Ptolemy's parameters and other approximations introduce greater errors.

The planet P moves on the epicycle of radius r though the mean anomaly $\bar{\alpha}$ measured from the direction EC extended to the mean apogee of the epicycle F such that for a superior planet CP is always parallel to the direction $O\bar{S}$ from the Earth to the mean Sun. For an inferior planet EC always lies in the direction of the mean Sun $\bar{S}$. The model produces variable corrections to two inequalities. The first, c_1, called the 'equation of center', corrects $\bar{\kappa}$ to the true eccentric anomaly $\kappa = \bar{\kappa} \pm c_1$ seen from O and $\bar{\alpha}$ to the true anomaly $\alpha = \bar{\alpha} \pm c_1$ measured from the direction OC extended to the true apogee of the epicycle G. The

Dirac House, Temple Back, Bristol, BS1 6BE, UK

equation of the anomaly c_2, subtended by the radius of the epicycle r, then corrects the direction of the center of the epicycle OC to the direction of the planet OP. Hence, where the longitude of the apogee A is λ_A, the true longitude of the planet is given by $\lambda_A + \bar{\kappa} \pm c_1 \pm c_2$. The parameters of the model are derived rigorously from observation. For the superior planets e, λ_A and $\bar{\kappa}$ are found from an iterative computation of considerable complexity using three oppositions of the planet to the mean Sun, and r and $\bar{\alpha}$ from two observations not at opposition. For the inferior planets e, λ_A and r are found through observations of greatest elongations from the mean Sun, and $\bar{\alpha}$ from an observation not at greatest elongation.

This is but a brief summary of Ptolemy's planetary theory in the *Almagest*, upon which the *Handy Tables* are based; there are additional complications for Mercury and rather complicated models for motion in latitude, due to errors in observations of extreme latitudes, in which the inclinations of the planes of the epicycles oscillate. The *Planetary Hypotheses* is notable both for the physical, spherical models that Ptolemy developed from the mathematical, circular models of the *Almagest*, and for a method of computing the distances and sizes of the planets (see DISTANCES (FROM ANTIQUITY TO 1900)). The two are related since the spherical models are contiguous, with no empty spaces, and the distances depend upon this contiguity. Figure 4 shows a cross section of the spherical model based upon the circles of figure 3. The epicycle, a complete sphere with the planet just inside it at P is carried by the eccentric sphere, the inner and outer surfaces of which are concentric to M. Within the eccentric sphere is an inner sphere with its outer surface concentric to M and its inner surface concentric to O. Outside the eccentric sphere is a corresponding outer sphere with its inner surface concentric to M and its outer surface concentric to O. The spheres of a lower planet lie inside the inner sphere and the spheres of a higher planet lie outside the outer sphere in the same way. The center of the eccentric sphere is M, but the sphere rotates such that the center of the epicycle C moves uniformly about the equant point E, and the epicycle rotates such that the planet moves uniformly with respect to the direction EC extended to the far side of the epicycle. But how can rigid, spherical bodies do this? For the spheres must be rigid in order to carry the epicycle and the planet, that is, the bodies are not moving through a fluid medium or empty space. This is the celebrated violation of uniform, circular motion in Ptolemy's models that was noted by Arabic astronomers and Copernicus, and both developed nearly identical alternative models to maintain uniform motion about the equant point strictly through the uniform rotation of spheres (see ISLAMIC ASTRONOMY, NICOLAUS COPERNICUS).

The original modifications of Ptolemy's models were the work of a number of astronomers associated with the observatory of Marāgha in north-western Persia in the second half of the thirteenth century, Naṣīr ad-Dīn aṭ-Ṭūsī, Mū'ayyad ad-Dīn al-'Urḍī, Quṭb ad-Dīn ash-Shīrazī, and in the following century in Damascus Ibn ash-Shāṭir. Their

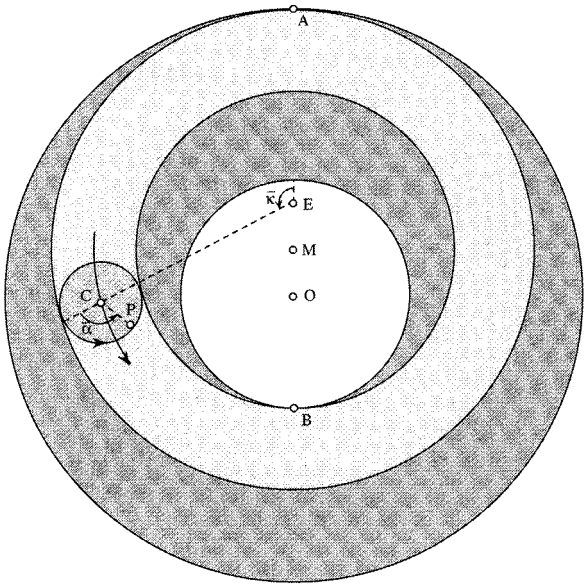

Figure 4.

models work on the principle of breaking up the equant motion in Ptolemy's model into two or more components of uniform circular motion that may be produced by the rotation of spheres. The models for the first inequality of the superior planets of al-'Urḍī and ash-Shīrazī, which are identical, and the model of Ibn ash-Shāṭir are shown superimposed on Ptolemy's model in figure 5. The center of the Earth is O, the center of the eccentric in Ptolemy's model is M, the center of the equant is E, and the two eccentricities $OM = ME = e$ are equal; the center C of the epicycle of the second inequality of figure 3, which is not shown here, moves in a circle of radius R about M such that its angular motion, the mean eccentric anomaly $\bar{\kappa}$, is uniform about E. In Ibn ash-Shāṭir's model the center C_1 of an epicycle of radius r_1 moves through $\bar{\kappa}$ in a circle of radius R about O, and the center C_2 of an epicycle of radius r_2 moves in the opposite direction through $\bar{\kappa}$ so that r_1 is always parallel to the apsidal line OA. The center C' of the epicycle of the second inequality moves in the same direction as C_1 through $2\bar{\kappa}$ such that r_2 coincides with r_1 when C_1 is in the apsidal line. Provided that $r_1 = 3/2e$ and $r_2 = 1/2e$, C' will lie on the line EC, thus moving uniformly about E, and the apparent directions OC and OC' will nearly coincide. In 'Urḍī's and Shīrazī's model, we let $OM' = r_1 = 3/2e$ and let C_2 move about M' through $\bar{\kappa}$ on a circle of radius R, so that the motion of C' measured from $M'C_2$ will be $\bar{\kappa}$, and the model is identical in effect to Ibn ash-Shāṭir's. Hence, both models preserve uniform motion about the equant and are observationally indistinguishable from Ptolemy's. We shall see that the same is true of Copernicus's model, to which the points $\bar{S}$ and P' in parentheses refer.

The Marāgha astronomers also devised notable modifications of Ptolemy's lunar model, both preserving

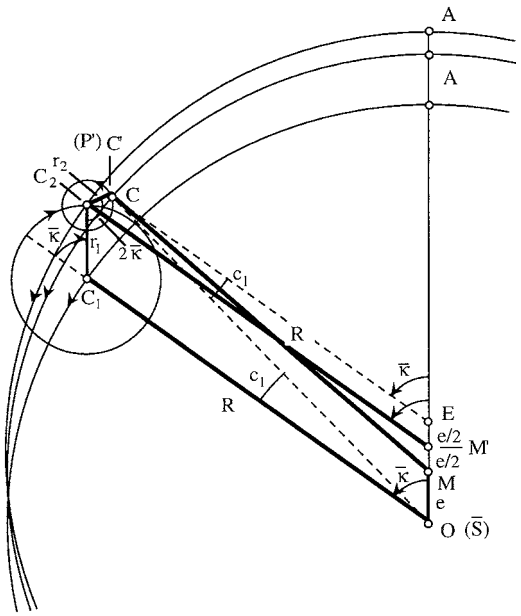

Figure 5.

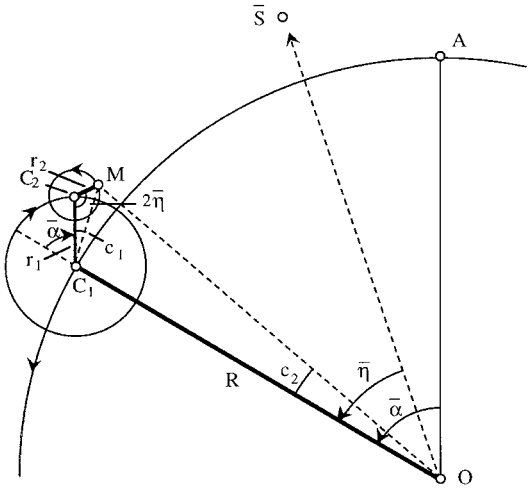

Figure 6.

uniform rotation of spheres and greatly reducing the variation of lunar distance. The model of Ibn ash-Shāṭir, to which Copernicus's model is identical, is shown here in figure 6. The Earth is at O, the apogee, which moves about $7'$ per day or 40° per year, is A, from which the center C_1 of a larger epicycle of radius r_1 moves through the mean anomaly $\bar{\alpha}$ and through the mean elongation $\bar{\eta}$ with respect to the mean Sun $\bar{S}$. The radius r_1 moves in the opposite direction through $\bar{\alpha}$, thus remaining parallel to OA, and the radius r_2 of a smaller epicycle, with center C_2, carries the Moon M in the same direction as C_1 through $2\bar{\eta}$, twice the elongation from the mean Sun. The effect of r_2 is to introduce a correction c_1 to the mean anomaly, and to vary the equation of the anomaly c_2 from a minimum at conjunction and opposition when $2\bar{\eta} = 0^\circ$ to a maximum at quadrature when $2\bar{\eta} = 180^\circ$. Both effects are also found in Ptolemy's model, but at the cost of a variation in lunar distance reaching about 1.9/1, which is here reduced to about 1.3/1, still more than twice as great as it should be; the correct variation was found by TYCHO BRAHE, whose lunar theory was a great improvement over all predecessors.

These innovations in planetary and lunar theory first appear in Europe in the sixteenth century in the work of Copernicus, although just how they were transmitted, perhaps by way of Italy, is uncertain. Ptolemaic astronomy itself only became known in the late twelfth century with the translation into Latin of the *Almagest* and of derivatives of the *Handy Tables*, first the *Toledan Tables* and then in the early fourteenth century the *Alfonsine Tables*. The most important exposition of Ptolemy's astronomy was the *Epitome of the Almagest* by GEORG PEURBACH (1423–61) and Johannes REGIOMONTANUS (1436–76), which first made Ptolemy's difficult book intelligible and was used along with, or even in place of, the *Almagest* until the beginning of the seventeenth century. In addition to Ptolemaic astronomy, the early sixteenth century saw a renewed interest in concentric-sphere models among Aristotelians, particularly at Padua, but these were little more successful than the models of Eudoxus and were never used for computation. The first serious innovation in planetary theory was that of Copernicus (1473–1543), built upon Ptolemy's and upon the models of the Marāgha astronomers. Copernicus's principal innovation is in accounting for the second inequality of the superior planets and the first inequality of the inferior planets by the annual motion of the Earth about the Sun. He arrived at his theory by way of transformations of Ptolemy's models explained by Regiomontanus in the *Epitome of the Almagest*, a work he used even in preference to the *Almagest* as his guide to Ptolemy's astronomy. He first explained his new theory in a short work known as the *Commentariolus*, written at some time between 1510 and 1514, in which the parameters of the models were merely extracted from the *Alfonsine Tables*. The original theory was modified and expanded greatly in *De Revolutionibus Orbium Coelestium* (On the Revolutions of the Heavenly Spheres), published in 1543, essentially a new *Almagest*, in which he derived new parameters from observation following Ptolemy's methods, again as explained by Regiomontanus.

The relation of Ptolemy's and Copernicus's models for the superior planets is shown in figure 7, in which we assume only circular motions. In Ptolemy's model, the Earth O is at rest, about it is described a circle of radius R', on which moves an epicycle with center C and radius r'. The planet P moves on the epicycle through the mean anomaly $\bar{\alpha}$ measured from the apogee of the epicycle A' such that the radius CP is parallel to the direction $O\bar{S}'$ from the Earth to the mean Sun, the Sun with only its uniform motion. The distance $O\bar{S}'$ is arbitrary in Ptolemy's model, but if a parallelogram $OCP\bar{S}$ is constructed and

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

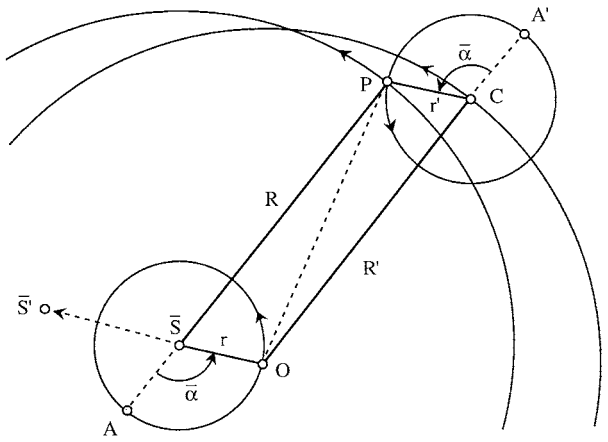

Figure 7.

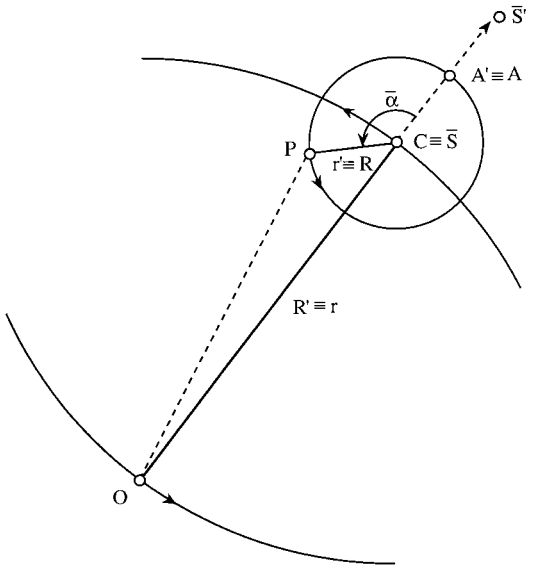

Figure 8.

it is assumed that the mean Sun is at $\bar{S}$, then both the Earth O and the planet P may be taken to move about $\bar{S}$ in circles of radii r and R where $r/R = r'/R'$, and the direction OP from the Earth to the planet, the diagonal of the parallelogram, is identical in both models. The relation of the models for the inferior planets is shown in figure 8, again assuming only circular motions. As before in Ptolemy's model, about the Earth O at rest is described a circle of radius R', on which is an epicycle with center C and radius r'. But now OC lies in the direction $O\bar{S}'$ from the Earth to the mean Sun, where the distance $O\bar{S}'$ is arbitrary, and the planet P again moves on the epicycle through the mean anomaly $\bar{\alpha}$ measured from the apogee of the epicycle A'. If it is assumed that the mean sun $\bar{S}$ coincides with C, is identical to $(\equiv)C$, then again both the Earth O and the planet P may be taken to move about $\bar{S}$ in circles of radii r and R, where $r/R = r'/R'$, and the direction OP from the Earth to the planet is identical in both models.

The essential advantage of the Copernican theory is concerned with the order and distances of the planets, the unification of the planetary models into a single system in which everything is determined and nothing arbitrary. In Ptolemy's models, the radii r' and R' are arbitrary for each planet, only the ratio r'/R' is determined by observation; thus there is no common measure of distances within the planetary system, and even the order of the planets is arbitrary without further assumptions. However, in Copernicus's models, the radii R of the orbits of all the planets are measured in terms of the unit r, the radius of the Earth's orbit, which is common to the model for every planet, so neither the distances nor the order of the planets are arbitrary, for they are fixed by the ratio r/R, which, as in Ptolemy's models, is determined by observation. There are also certain arbitrary rules governing Ptolemy's models that are explained when it is seen that geocentric planetary models are actually transformations of underlying heliocentric models. The most obvious in the figures are why the

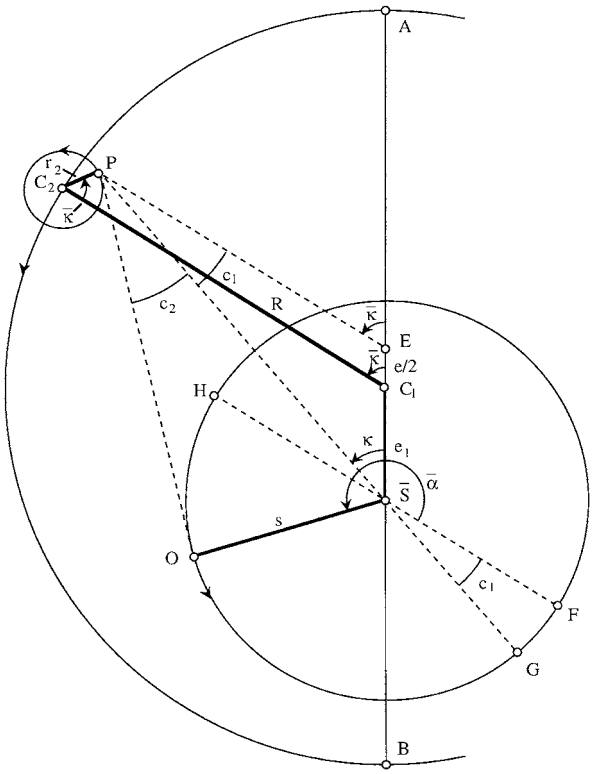

Figure 9.

radii of the epicycles of the superior planets are parallel to the direction from the Earth to the mean Sun, and why the centers of the epicycles of the inferior planets lie in the direction of the mean Sun, but there are many more properties of geocentric models, even as

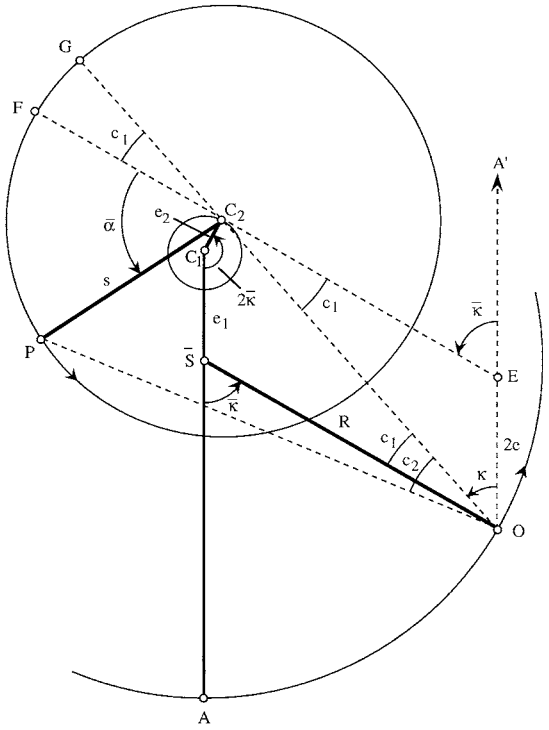

Figure 10.

basic as why the superior planets move in the same directions on their epicycles, that are only explained as transformations of heliocentric models. The most well-known consequence of the heliocentric theory is the explanation of retrogradation (see RETROGRADE MOTION), which takes place in Ptolemy's models near the perigee of the epicycle when the apparent backward motion of the planet on the epicycle exceeds the forward motion of the center of the epicycle, which happens to be near opposition for a superior planet and near inferior conjunction for an inferior. In Copernicus's models retrogradation occurs when the Earth passes a slower superior planet near opposition or is passed by a faster inferior planet near inferior conjunction, so the location of the retrogradation is also explained.

Copernicus's solar theory is the same as Ptolemy's, a simple eccentric, now with the Earth moving about the Sun, but, following medieval sources, he found a smaller solar eccentricity than did Ptolemy and he developed a model to produce a variation in the eccentricity, along with an inequality in the motion of the solar apsidal line, such that the eccentricity is near maximum at Ptolemy's time and near minimum at his own. Following the Marāgha astronomers, Copernicus objected to Ptolemy's lunar model on the grounds that it violates uniform, circular motion, since the center of the epicycle does not move uniformly about the center of the eccentric on which it is carried, and also that it produces a large variation in lunar distance contradicted by the small variation in the apparent size and parallax of the Moon. His own lunar model is identical to that of Ibn ash-Shāṭir shown in figure 6.

Copernicus's model for the first inequality of the planets in the *Commentariolus* is also that of Ibn ash-Shāṭir using two epicycles, shown above in figure 5, but with the mean Sun $\bar{S}$ in place of the Earth O and the planet itself P' in place of the center C' of the epicycle of the second inequality, as shown in parentheses in the figure. It thus preserves uniform motion about the equant E just as in Ptolemy's model. The model for the superior planets is altered in *De Revolutionibus* to that of al-'Urḍī and ash-Shīrazī, and is shown in figure 9, which shows both inequalities. As in figure 5, the larger epicycle is replaced by an equal eccentricity $e_1 = r_1 = 3/2e$, which has the same effect since r_1 is always parallel to e_1; r_2 is unchanged, although its motion, because it is measured from C_1C_2, is now $\bar{\kappa}$. Thus P still moves uniformly about E and, as in Ptolemy's model, the true eccentric anomaly $\kappa = \bar{\kappa} \pm c_1$. The second inequality is accounted for by the motion of the Earth O in a circle of radius s about the mean Sun $\bar{S}$ through the mean anomaly $\bar{\alpha}$, uniformly with respect to a line FH which is drawn parallel to EP; the true anomaly, from line $G\bar{S}$, is $\bar{\alpha} \pm c_1$. The true position of the planet as seen from the Earth is found through two corrections, c_1, the equation of center, the difference in direction between the uniform motion of the planet about the equant and the non-uniform motion about the mean Sun, and c_2, the equation of the anomaly, found from the true anomaly, which reduces the heliocentric direction of the planet $\bar{S}P$ to the geocentric direction OP. Given the longitude of the apogee λ_A, the longitude of the planet is $\lambda_A + \bar{\kappa} \pm c_1 \pm c_2$. The corrections are nearly identical to those used by Ptolemy, and Copernicus's tabulations of the corrections are also nearly identical to Ptolemy's. Likewise, Copernicus finds the parameters of the model for each planet by observation through exactly the same methods as used by Ptolemy, and except for the directions of the apsidal lines, his results are the same or quite close.

The model for the inferior planets, shown for Venus in figure 10, is somewhat different in that the equation of center depends, not upon the distance of the planet from its own apogee, but, remarkably, upon the distance of the Earth from the planet's apogee, due to a direct adaptation of Ptolemy's model. The Earth O moves through $\bar{\kappa}$ with respect to the planet's apsidal line while at the end of the fixed eccentricity $e_1 = 3/2e$ a movable eccentricity $e_2 = 1/2e$ rotates through $2\bar{\kappa}$. The result is that the equation of center c_1 is measured at the Earth, just as in Ptolemy's model, and the direction EC_2 from the equant to the center of the planet's orbit lies in the direction of $O\bar{S}$ from the Earth to the mean Sun, just as though C_2 moved uniformly through $\bar{\kappa}$ about E at a distance $2e$ from O in the direction of the geocentric apogee A', again as in Ptolemy's model. The equation of center c_1 and the equation of the anomaly c_2 are computed and tabulated as for the superior planets, and again the longitude of the planet is $\lambda_A + \bar{\kappa} \pm c_1 \pm c_2$. There are further complications for Mercury, which are identical

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

to those of Ibn ash-Shāṭir's model, most notably that the radius of the planet's orbit is itself variable as a function of $2\bar{\kappa}$, twice the Earth's distance $\bar{\kappa}$ from the apsidal line, the result being an excellent approximation of Ptolemy's model.

Copernicus's models for the latitudes of the planets are also direct adaptations of Ptolemy's, which require oscillations of orbital planes that Kepler found implausible and prompted his famous remark, 'Copernicus, ignorant of his own riches, took it upon himself for the most part to represent Ptolemy, not nature, to which he had nevertheless come the closest of all.' Kepler could not be more correct. Copernicus's astronomy was built upon Ptolemy's descriptions of the apparent motions of the heavens, upon Ptolemy's observations, upon transformations of Ptolemy's models, and upon Ptolemy's methods of deriving parameters from observation. Thus, he did, as Kepler said, represent Ptolemy rather than nature.

Planetesimal

In cosmogony, a planetesimal is one of numerous solid bodies of sub-planetary size orbiting the SUN (or another star), from which planets may accumulate. The term was coined near the beginning of the twentieth century by T C Chamberlin and F Moulton, who developed the 'planetesimal hypothesis' for the origin of the SOLAR SYSTEM. In their original concept, solid particles condensed from matter ejected from the Sun by tidal forces during a close encounter with another star. Collisions between objects in intersecting orbits caused them to accumulate into progressively larger bodies, forming the planets. Many features of the Chamberlin–Moulton theory have been rejected or superseded, but the concept of growth of planets from planetesimals has been adapted to the context of modern theories.

Formation of planetesimals

Both theory and observation indicate that a star forms by collapse of an interstellar cloud, composed mostly of hydrogen gas, when internal pressure cannot support it against its own gravity. If the cloud has some initial rotation, conservation of angular momentum ensures that some of its mass is left orbiting the star in a flattened, disk-shaped gaseous NEBULA. The nebula contains microscopic solid grains, a mixture of surviving interstellar grains and condensates from the cooling gas. Near the star, these consist of metals and silicate minerals; at larger distances organic compounds and ices are included. The small grains, with large area/mass ratios, are constrained by drag forces to move with the gas. They accumulate into planetesimals, which are sufficiently large to be in Keplerian motion about the star, controlled by gravity rather than gas drag. This is the case for objects of about kilometer size or larger.

The mechanism by which kilometer-sized bodies form from micrometer-sized grains has been a topic of much effort and some controversy. The idea of gravitational instability was suggested by K Edgeworth in 1949. In this concept, solid grains settle to form a thin layer in the central plane of the nebula. If this layer's density exceeds a critical value it becomes unstable, and localized regions collapse under their own gravitational attraction. This model was developed in quantitative form by V S Safronov in the Soviet Union, and independently by P Goldreich and W Ward in the United States. They showed that this process would tend to produce solid bodies a few kilometers in size in the inner solar system, and larger objects at greater distances from the Sun.

The simplicity and elegance of gravitational instability caused it to be widely accepted. The process was believed to be independent of the poorly defined properties of the grains themselves, requiring no sticking mechanism or force other than gravity. However, later investigations have cast doubt upon this concept. Microscopic grains would settle so slowly that the slightest degree of turbulence in the nebula would inhibit formation of the particle layer. Some non-gravitational coagulation mechanism is needed to produce larger aggregates of grains to allow their descent to the central plane of the nebula. Many possible sticking processes have been suggested, including electrostatic charging of grains, magnetic attraction of metallic grains, van der Waals surface forces, sticky coatings of organic material, physical interlocking of irregularly shaped particles, and condensation of ices upon grain surfaces. Some or all of these mechanisms may have dominated in different density–temperature regimes in various regions of the nebula, and are current topics of theoretical and experimental study. Because the rate of settling increases with particle size, larger particles can grow by overtaking and sweeping up smaller ones as they settle. If coagulation occurs, centimeter-sized aggregates of grains can grow in this manner on time scales of the order of a thousand orbital periods at any given distance from the star.

Coagulation during settling allows particles to become concentrated into a layer in the central plane of the nebula, but gravitational instability is inhibited by interactions of particles with the gas. The pressure in the nebula decreases with distance from the Sun. This radial gradient acts to support the gas against the central gravity, and causes the nebula to rotate at slightly less than the Keplerian orbital velocity. This velocity difference is less than one per cent for any plausible nebular structure, but has a typical magnitude of tens of meters per second. A solid body in the nebula lacks this pressure support, and as a consequence cannot be at rest with respect to the gas. Its motion occurs within one of two dynamical regimes that depend on its size. A small particle, coupled to the gas by a large area/mass ratio, moves with the nebula's angular velocity and drifts inward due to the residual radial component of gravity. The drift rate is proportional to the particle's size and density, with magnitude of order 100 times its diameter per second for a body of density one gram per cubic centimeter. A large body with low area/mass is less affected by drag, and pursues a Keplerian orbit. As it moves faster than the gas, it experiences a 'headwind', that causes its orbit to decay. In this regime, the orbital decay rate decreases with size and density, and has a magnitude of order $(100/D)$ m s^{-1}, where D is the diameter in meters. The radial velocity reaches a peak, equal to the difference between the Kepler velocity and gas velocity, at the transition between these regimes, at sizes of about a meter. Thus, solid bodies of all sizes move radially inward, while large bodies also have significant transverse velocities (tens of meters per second) relative to the gas.

If the particle layer becomes denser than the gas, as would be necessary for gravitational instability, collective effects become important. High mass loading allows the particles to become dominant, diminishing the pressure support of the gas within the layer, and causing its motion to be more nearly Keplerian, i.e. faster than the pressure-supported gas on either side. It can be demonstrated analytically that such a shear flow is

unstable and would become turbulent; this behavior has been confirmed with numerical fluid-dynamic simulations (see FLUID DYNAMICS). This self-generated turbulence is sufficient to prevent further settling of centimeter-sized particles. The layer cannot attain the critical density unless collisional coagulation produces meter-sized or larger bodies, which are unaffected by the turbulence. However, the critical density is necessary, but not sufficient, to allow gravitational instability. The particles must also have sufficiently low relative velocities to allow density perturbations in the layer to grow. The meter-sized bodies have radial and transverse motions induced by gas drag. As these velocities are size dependent, any system of non-identical bodies would have significant velocity dispersion, sufficient to prevent gravitational collapse.

The failure of gravitational instability seems to require that planetesimals grew gradually by collisional coagulation. The details of this evolution depend on their mechanical properties, such as impact strength and energy dissipation, which are unknown. However, collisions driven by nebular gas drag are relatively favorable for particle growth. The size dependence of radial and transverse motions induced by drag implies that for bodies of comparable size impact velocities would be low, so coagulation may be more likely than disruption. Objects of very different sizes would have more frequent collisions at higher speeds, in which the smaller projectile could be embedded in the larger target. Drag-induced velocities decrease with size, so collisions become more gentle as the planetesimals grow. When they reach sizes of the order of a kilometer, gravitational attraction increases their impact velocities. Thus, planetesimals built up in this manner may have a lumpy structure on scales from meters to hundreds of meters. Numerical simulations of collisional growth driven by drag produce kilometer-sized or larger bodies on time scales of a few thousand orbital periods at any given heliocentric distance. In these simulations, coagulation and settling is only moderately efficient, so a significant population of small grains remains after planetesimals have formed. This result is consistent with observations of DUSTY CIRCUMSTELLAR DISKS; the presence of dust does not mean that planetesimals have not yet formed. Some disks appear to have dust-free inner regions; such clearing probably is not a direct result of planetesimal formation, but is due to other processes operating on longer time scales.

Evolution of planetesimals to planets

After planetesimals reach sizes of a few kilometers, gravity becomes more important than gas drag, at least for short-term behavior, and their motions can be described as Keplerian orbits. As the planetesimals become larger, their mutual gravitational perturbations stir up random velocities, i.e. orbital eccentricities and inclinations. Analyses of this stirring process by kinetic theory show that the mean random velocity tends to be comparable to the escape velocity of the bodies that dominate the mass distribution in the planetesimal swarm. As the collisions are inelastic, gravitational binding ensures that the planetesimals experience net growth during this stage, regardless of their impact strength or mechanical properties.

The continuing evolution of the swarm of planetesimals is controlled by the interplay of stirring and collisions. V S Safronov developed an analytic solution to the coupled distributions of sizes and velocities, in which the mass distribution is assumed to be a power law. Its slope is such that it is dominated by the largest bodies. At any stage of the swarm's evolution, random velocities are comparable to the escape velocity of these bodies, increasing as they grow. This process, sometimes referred to as 'orderly growth', continues with collisions at larger scales and higher velocities until a few large bodies (PLANETS) survive in widely separated stable orbits that do not intersect.

Numerical simulations of planetesimal ACCRETION have revealed another possible path for the growth of planets. At low relative velocities, gravitational attraction deflects trajectories, allowing collisions between orbits that would otherwise not intersect. This enhancement of the collisional cross section increases as the square of the ratio of the mutual escape velocity of two planetesimals to their relative velocity. In a swarm containing bodies with some range of sizes, this factor tends to favor growth of the larger bodies due to their higher escape velocities. In the orderly growth model relative velocities are high enough to minimize this advantage. However, more recent models of velocity stirring include dynamical friction, a tendency for gravitational interactions to produce equipartition of the energy in random motions. More massive bodies tend to have lower velocities, giving them a greater advantage. In numerical simulations of accretion in such a system, a small fraction of planetesimals, the first to become larger than the average size, experience 'runaway growth'. The size distribution becomes bimodal, with a few large bodies (protoplanetary embryos) accreting while the mass distribution is still dominated by small planetesimals. This runaway growth is self-limiting, being halted by depletion of the small bodies in orbits near those of the embryos, when the latter have attained masses of the order of one per cent that of the Earth. Many such bodies must collide in order to produce a small number of widely spaced planets as found in our own solar system. Mutual perturbations among the embryos may cause their orbits to cross after the smaller planetesimals have been depleted. The final stage of planetary accretion probably involved very large impacts, like that which has been invoked to explain the formation of the Moon.

This scenario appears to account for the formation of the TERRESTRIAL PLANETS. The estimated time scale for their accretion, of the order of tens of millions of years, does not violate geophysical constraints on the age of the Earth–Moon system. However, it is less successful when applied to the outer planets. One widely accepted model for the origin of gas GIANT PLANETS, Jupiter and Saturn, is accumulation of planetesimals of mixed rock/ice

composition into cores with masses of the order of ten times that of Earth, which then accrete gas from the solar nebula. Despite the higher surface density of solids due to condensation of ice, the longer orbital periods at greater heliocentric distances yield slower growth of the cores. Current models do not produce cores of the requisite mass within the estimated age of the nebula. Models for accretion of Uranus and Neptune from icy planetesimals fare even worse, failing to produce those planets within the age of the solar system. Probably unmodeled phenomena, such as tidal interactions between massive planetary embryos and the nebula, were involved.

ASTEROIDS and COMETS represent populations of planetesimals that survive in the present solar system. The former have been greatly altered since their formation by collisional evolution; the smaller asteroids are not primordial, but are fragments of once larger bodies that have been disrupted. Comets in the Oort cloud and Kuiper belt have probably undergone little change since their formation. *In situ* examination by spacecraft may reveal structures elucidating their accretion in the solar nebula.

Planetology

Although created from the same solar nebula, the bodies residing in our solar system are all very different, each with its own distinct characteristics. The comparison of features and processes between different bodies can tell us about the evolution of those planets, or give us an idea of how things may have evolved if certain physical parameters were just slightly different. Comparing a particular process on two similar, but subtly different worlds allows us to isolate the contribution that just one or two physical parameters makes to the final form we see. Only in recent years, with the advent of spacecraft visiting other planets and taking detailed measurements of those systems, have we truly been able to compare one planet or satellite with another. But now, even superficial analysis reveals that the planets and satellites in our solar system are very different, each telling its own story and each able to tell us a little about our own past, present and perhaps even the future.

Comparison of surface processes

The surfaces of solid bodies can tell us much about its history. The different processes that can occur on the surface of a planet or satellite indicate properties of both its internal and external evolution. There are many processes that can act upon planets, satellites and asteroids, some affecting all, and others operating on only one or two. Here we look at the main processes that have acted to shape the PLANETARY SURFACES we see, revealing their differences and what those differences can tell us about the bodies themselves.

Impact cratering

Impact cratering is the most important process acting upon the surface of solid bodies in the solar system. Without exception, every planet, satellite and small body is subject to the effects of impacts, both large and small, past and present. The impact cratering process can tell us much about the history of a body as well as its present state; it can highlight the differences found between worlds and tell us something about the characteristics of the solar system itself. Without impact CRATERS, our knowledge of the solar system and the planets within it would be much poorer.

While every planet in the solar system has impact craters on its surface (figure 1), some have more than others or one region of a planet may have a higher density of craters than another area on the same planet. The MOON, for example, is completely saturated with impact craters on its highland surface—in other words, every new impact crater obliterates an older one, so that the crater density observed is constant in the highlands. On the dark maria (solidified ancient lava flows) however, the number of craters per unit area is much lower. The reason for this is quite logical—the maria have been exposed to space for less time than the highlands, and hence have had less time to accumulate impact craters. Therefore, the simple observation that the maria have less craters immediately tells us that they are younger than the highlands. This is true for any solid planetary body in the solar system although it starts to get more complicated when trying to compare the age of one planetary surface with another purely by counting craters. Firstly, the cratering flux through time is not constant. We can tell this by looking at the Moon. The highlands are known to be 4 Gyr or older and the maria are between 3.1 and 3.8 Gyr old. Yet the difference in the number of impact craters gives the appearance that the maria are very much younger. This implies that in the very earliest times, before the maria were emplaced, the impact cratering flux was much higher, and this has now become known as the period of heavy bombardment. The cratering flux dropped off dramatically after that time, and is now believed to be quite low. As the Earth is in close proximity to the Moon, it can be assumed that our planet underwent the same bombardment as the Moon. In fact, we may have had a slightly higher flux due to our greater gravitational attraction compared to the Moon. Therefore, the study of impact craters on the Moon can tell us something about the conditions on Earth about 4 Gyr ago—a period where terrestrial records have long been wiped out. While it is logical to believe that the whole solar system underwent a similar period of bombardment, the intensity of the flux may have varied quite considerably through space. It is possible that the immense gravitational pull of Jupiter may have caused more impacts to occur on the surfaces of its satellites than on the inner planets, for example. Or perhaps large impact events in the inner solar system threw off more debris destined to impact on the terrestrial planets. There may be many factors affecting the cratering flux through time and space, and hence to use the crater density on a planetary surface as an age indicator can give a great error on the value obtained. However, at the present time, counting craters is the only way we can estimate the age of a surface for which we have no sample, and this means every surface except the few areas for which we had rocks brought back from the Moon. Nevertheless, we are able to obtain crude estimates for relative ages, and in some cases this can tell us much about a planet's history. For example, on VENUS, the crater density is very low. Although Venus is relatively large (approximately the same size as the Earth) it has less than 1000 craters across its entire surface, distributed in a random fashion. This number is far less than would be expected if the surface had been exposed for the length of time that the lunar highlands have. Therefore the surface of Venus must be relatively young, with some scientists believing that Venus underwent a global resurfacing event only 500 million years ago, effectively resetting its age to zero.

Similarly, MARS also must have undergone some kind of resurfacing event, this time across only one half of the planet. Mars can be split into two hemispheres; the south, which is higher and has a high crater density; and the north, which is lower and has a low crater density. Lava flows can be seen across the northern plains, and it is believed that widespread volcanism is one of the reasons

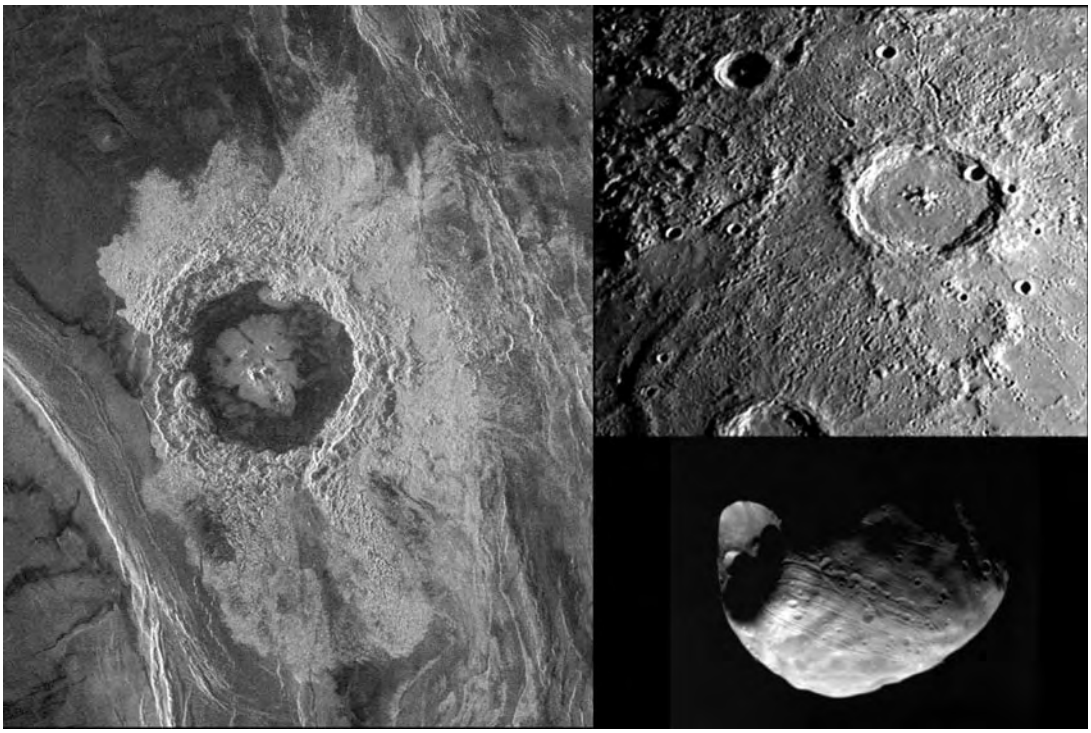

Figure 1. Impact craters on selected bodies. Left: a Magellan radar image of the 43 km diameter crater Dickinson, showing a complex structure with a central peak, terraced walls and flat floor. (Courtesy of NASA JPL/Caltech.) Top right: a large crater on Mercury, 140 km in diameter again showing a complex shape. Note the many smaller impact craters also in the image. (Courtesy of NASA JPL/Caltech.) Bottom right: Mars' moon Phobos has a large impact crater almost as large as the moon itself. Phobos is only 28 km by 20 km but still suffers from the effects of impact cratering. (Courtesy of NASA.)

for the dearth of impact craters across this hemisphere of the planet. MERCURY, the closest planet to the Sun, is very Moon-like. It is a small planet, rocky with no atmosphere and therefore no weathering process to destroy the record of impacts across its surface. We would therefore expect to see a similar cratering record on Mercury as we do in the highlands of the Moon, but we do not. Although Mercury's surface is heavily cratered, most of the surface is not saturated, and once again, it is believed that some kind of resurfacing event occurred early in Mercury's past. The satellites of the outer planets do not escape this kind of analysis either, and we find some very interesting results. Many of the larger satellites of, for example, JUPITER, show very few impact craters, indicating that their surfaces are young. IO, one of Jupiter's moons, is the only solid body that does not have impact craters on its surface (at least not at the resolution of our images). This does not mean that Io has never experienced an impact, it instead shows that the surface is extremely young in geological terms, some say as young as 10 000 years. This is not difficult to imagine, as we know that the surface of Io is constantly being renewed by volcanism (see later). Another satellite of Jupiter, EUROPA, has a low crater density. Its surface is known to be covered in a layer of thick water ice, and it is possible that water from beneath the icy crust is periodically brought to the surface covering the previous record of craters upon freezing. To obtain absolute ages it is necessary to get samples from areas of different crater densities and date them in the laboratory. Therefore, it is our Moon that provides the only key to this technique at the moment, because we have those samples to work with. We can infer much about the conditions in the solar system during its very earliest times as the Moon's surface does not have any significant weathering processes to degrade the impacts on its surface. The impact craters that we see there today (along with the footprints and tyre tracks left by the Apollo astronauts) will still be there in a billion years' time.

The Earth has a very young surface, as evidenced by the relatively few impact craters we have found here. The volcanic and tectonic activity that is still going on today are constantly renewing the Earth's surface, and the weathering caused by the action of wind and rain quickly degrade those craters we do see. Weathering also occurs on planets such as Mars and Venus, as these worlds both have atmospheres. In fact some craters may appear to be older than they truly are where weathering is particularly efficient. Other factors may also influence the shape of the impact craters, such as the angle at which the projectile hits the surface, the atmospheric density and, perhaps most importantly, the volatile content of the surface at the time of impact. For example, we can use impact craters to tell

us about the distribution of water across the surface of Mars through time by looking for distinct crater patterns. When an impact crater forms, material is ejected from the crater and thrown out onto the surrounding surface. When volatiles (i.e. water) are present, the ejecta takes on a mud-like appearance, as though it flowed as it hit the surface. The presence of a crater with this feature indicates that some water must have been present in the area (probably as a permafrost layer) at the time of the impact. Mapping the distribution of these craters across Mars gives an idea of where water has existed in the past, and hence may give us an idea of where life may have existed on the planet, if it did at all. These fluid patterns are unique to Mars and show how a single factor (in this case volatiles) can have a significant effect on the appearance of a crater. Similarly, by comparing the Moon and Mercury (both small worlds with no atmosphere and no current day activity), we can directly study the effects of gravity in the impact cratering process (Mercury has a higher gravitational pull than the Moon).

Of course, it is not only solid bodies that attract projectiles. The giant planets, Jupiter, Saturn, Uranus and Neptune, also suffer from the impact of large and small bodies, but as they have no solid surface, they hold no record of impact events of the past. Scientists were recently privileged to witness such an impact. The comet Shoemaker-Levy 9 was captured by the gravitational influence of Jupiter, the largest planet in the solar system, and was subsequently torn apart before being dragged into the atmosphere of the planet. Scientists watched each explosion as the comet pieces were consumed, and found that traces of each impact were visible for some time before finally disappearing. This was the first large impact event observed by modern-day scientists and their instruments. If nothing else, it brought home the fact that these impacting bodies are still out there and can still collide with any body in its way, even the Earth. By studying these impacts we can learn about how they may have affected the history of our own planet. It was the impact of an asteroid in the Yucatan Peninsula 65 million years ago that is believed to have caused the extinction of the dinosaurs. Such an impact today would cause world-wide devastation, and while we would hope that technological advances would allow some people to survive, the majority of Earth's human population and that of the large animals would certainly perish. It is a sobering thought that less than 100 years ago, a comet exploded in the Earth's atmosphere above Siberia flattening trees for many kilometers. Even a cometary explosion like this would kill thousands if located over a densely populated city. It is therefore very important to study the impact process and to identify precisely how many impacts we can expect over the next few hundred years—our lives may depend on it.

Volcanism

Volcanism, although not obvious on all planets, does occur, or at least has occurred, on many of the bodies we can see. Volcanism clearly still plays a role in the evolution of the Earth today and there are many instances of volcanic eruptions causing disruption to populations over recorded history. Volcanism was once far more extensive in the distant past however, with vast areas of the planet being covered with lava. These flood lavas, as they are known, are not active on Earth today, but it is the most common form of volcanism that has occurred on other planets. The dark maria on the Moon are composed of basaltic lava of low viscosity, erupted from large fissures (cracks) in its crust. The volcanism on the Moon occurred over a relatively short period of time (3.1–3.8 Gyr ago) and has remained dormant since that time, apart from the possibility of minor outbreaks of volcanic activity up to 2.5 Gyr ago. Mercury, on the other hand, is somewhat enigmatic when it comes to working out whether volcanism has occurred on this planet. We have photographs of only 45% of its surface and it is not conclusive from those alone whether volcanic activity has shaped the planet in any way. It seems likely that some of the plains regions are volcanic, and recent re-analysis of Mariner 10 data, taken through ultraviolet and orange filters, suggests that this is the case. One thing that does remain clear is that further study of Mercury is essential if we are to understand more of the role volcanism has played in its past.

From a world where volcanism has played an unknown role, we move to a world where there is little doubt that volcanism has significantly shaped the evolution of its surface. Across the entire planet of Venus, volcanic features can be seen. There are estimated to be over a million small volcanoes (<20 km diameter) across the planet, with a significant number of larger volcanoes to be found also. The volcanoes take on different shapes, which may be attributable to differences in the viscosity and perhaps composition of the lavas extruded. A similar situation occurs on Earth, with volcanoes at different locations erupting lavas of a different composition. Lava channels on Venus may extend for several hundred kilometers, which indicates that the lava was molten for a significant length of time, far longer than would be the case on Earth. It is highly likely that the elevated surface temperatures on Venus contributed to the ability of the lava to remain molten long enough to create these features. As we saw in the section on impact cratering above, the cratering record implies that Venus underwent a global resurfacing event a relatively short time ago. This event would have been volcanic, with the release of huge quantities of lava onto the surface covering the previous record of Venus' past. There is still a debate as to whether this event happened simultaneously (in geological time) across the whole surface or as a continuous set of discrete eruptions occurring over a longer period of time. Whichever theory is correct, the planet Venus obviously underwent a massive change, which effectively prevents us from learning about the very early stages of Venus' evolution.

Mars is very much easier to study than Venus. For one, it does not have a thick optically opaque atmosphere

like Venus. This means we can use standard photographic and multispectral remote sensing data to observe the surface and deduce its volcanic past. Mars has had an interesting history in volcanic terms. Although half the diameter of the Earth, it is home to the largest volcano in the solar system, Olympus Mons (figure 2). With a basal diameter of 600 km, and rising more than 24 km above its surroundings, it is many times larger than the largest volcano on the Earth, Mauna Loa, Hawaii (120 km diameter, 9 km above the sea-floor). The type of volcanism forming Olympus Mons and Mauna Loa appears to be the same. They are both shield volcanoes with Olympus Mons likely to be formed by the non-explosive eruption of basalts over a long period of time, as in the case of Mauna Loa. The main difference between them is the size. This is most likely due to the fact that Mars is a one-plate planet and does not experience motion of plates as the Earth does. The size of the Hawaiian volcanoes is limited by the fact that the plate on which they stand constantly moves. Once the volcano is no longer connected to the magma source, activity stops and a new volcano forms in the chain. On Mars this cannot happen and the volcano remains over the magma source and hence is active for as long as magma is available. The outermost flows on Olympus Mons appear to be very young, judging by the lack of large impact craters on its surface. However, while the youngest flows may have erupted only a few hundred million years ago, the volcano as a whole is likely to be much older. Olympus Mons is located just off the edge of a region known as the Tharsis bulge, a huge area uplifted relative to the surrounding terrain and which contains three very large shield volcanoes. Another volcanic area of uplift on Mars is the Elysium region, again containing large shield volcanoes. These regions and the long lava flows seen across the northern hemisphere indicate that volcanism has played an important role in the evolution of Mars.

But do any of these planets have active volcanism today? We cannot be sure. We are reasonably confident that no volcanism occurs on the Moon today. There is no image-based evidence for volcanism occurring on Venus or Mars, but Venus does seem to have an excess of SO_2 in its atmosphere. Chemical reactions with the surface should quickly deplete the atmosphere of sulfur, so there must be a continual replenishment of this element into the atmosphere. The most likely explanation is volcanism, but we cannot be certain until we get direct evidence of eruptions taking place there. The only other body where we are certain that present day volcanism is occurring is on Io, the third largest satellite of Jupiter. The tidal forces from Jupiter and the surrounding satellites maintain a high temperature within Io, which in turn drives the volcanism we see today (figure 3). Evidence for active volcanism on Io was first found by one of the Voyager craft as it flew past the Jovian system. A large plume of material was seen on the limb of the satellite being erupted from a volcano. Subsequent analysis of Voyager data showed Io to have many volcanoes across its surface and it is the most volcanically active body in the solar system today. The Galileo mission to Jupiter has returned stunning pictures of eruptions in action, revealing changes visible over only a few days. But, how does the volcanism on Io compare with that of the Earth? Firstly, Io's eruptions are likely to be more similar to terrestrial geysers. In addition, the type of volcanism occurring has become

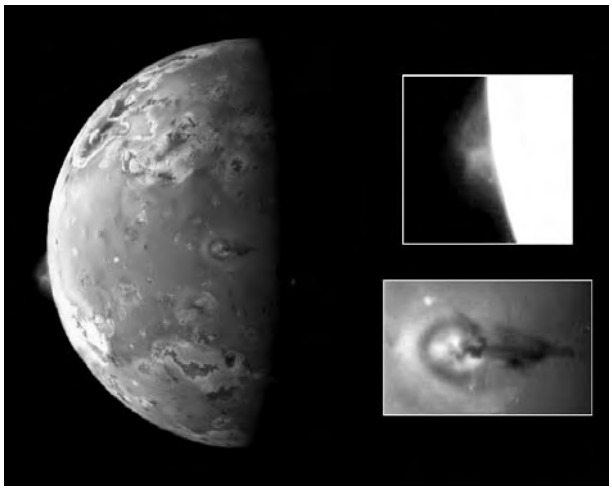

Figure 3. Images from the Galileo Orbiter showing volcanic activity on Io. The plume seen on the limb of Io in the main image (and enhanced in the top right insert) is 140 km high. The bottom right insert shows another area of activity with a 75 km high plume erupting from the surface. The shadow of this plume is clearly seen to the right of the main center of activity. (Courtesy of NASA JPL/Caltech.)

a matter of debate. On Earth, most of the volcanism is silicate based with some sulfur gases being released when the magma rises and lava erupts. For some time it was suggested that Io had sulfur based eruptions, due to the orange and brown colors of Io. These are similar to allotropes of sulfur with the different colors representing sulfur at various temperatures. In addition, spectroscopy of the surface and tenuous Ionian atmosphere revealed the presence of substantial amounts of sulfur being present. However, the density of Io ($\sim$3.5 g cm^{-3}) is more consistent with silicate rocks, and the crust has to be made of a strong material such as silicate in order to support the mountains of Io, some of which reach heights of 5–10 km. Finally, some of the 'hotspots' on Io reach temperatures of 1000 K or more, far too hot for sulfur. So it seems that Io, like the Earth, does have silicate volcanism, but also has an added contribution from sulfur (see also VOLCANISM IN THE SOLAR SYSTEM).

Tectonism

The Earth is today a tectonically active world, and has likely always been that way. The other planets and satellites in the solar system also show evidence of TECTONIC activity, but not like that of the Earth (figure 4). Without plate tectonics, the Earth would have been a very different world. Neither Mercury nor Venus nor Mars show any evidence for having multiple plates, and hence plate tectonics. On Mars, this means that huge volcanoes such as Olympus Mons could form. Mars' huge canyon, Valles Marineris, is likely to be at least partly formed by tectonic activity and forms a scar approximately 4000 km long. On Venus, global tectonism could have provided the vents through which the magma rose to completely resurface the planet. If true, evidence for this is now buried, but Venus still shows complex tectonic forms covering much of the planet. Tectonism is not limited just to the larger bodies. Smaller worlds like the Moon, Mercury and some satellites also show evidence for tectonism. Mercury in particular is another world where global events may have shaped the surface. Long lobate scarps are to be found all over the photographed hemisphere. These are contractional features, but have no associated extensional tectonism to compensate. This implies that at some point Mercury's crust must have undergone a global contraction by a few kilometers to produce the features seen. Looking just at the four terrestrial planets, we get very different views of how tectonism has shaped their evolution and provides a convincing argument that the Earth would indeed have been very different without the action of plate tectonics.

Comparison of planetary atmospheres

The PLANETARY ATMOSPHERES in our solar system should be able to tell us much about the evolution of the planets themselves. After all, each atmosphere came from the same nebula that made up the planets and all their atmospheres, so we would think that to a first approximation all the atmospheres would be of a similar composition. It is now obvious that they are not, and this is likely to be the result of the differences in the formation and evolution through time of the host planet. There is an obvious dichotomy between atmospheres in different parts of the solar system. Close in to the Sun we have the terrestrial planets with their sometimes tenuous, sometimes thick atmospheres enveloping the solid rocky body beneath. Once we get past the orbits of Mars and the main asteroid belt, we come to the gas giants, which are composed entirely of gases and have no solid surface beneath. The difference between these two kinds of world are quite dramatic, with the gas giants showing spectacular 'weather' systems and storms which, in the case of Jupiter, are larger than the planet Earth itself. However, we can learn most about our own planet by looking at the atmospheres of the terrestrial planets. The gas giants have undergone different evolutionary processes due to their nature, whereas the terrestrial planets share the same region of space and will have had initial starting conditions closer to that of the Earth.

Venus is often referred to as 'Earth's twin' due to its similar size and density. We would perhaps expect its atmosphere also to be similar to Earth, but we now know that Venus' atmosphere is very different. The atmosphere of Venus is composed mainly of CO_2, whereas the Earth has an atmosphere dominated by N_2 and O_2. Also, the atmosphere of Venus is very much denser than the Earth's. It has a surface pressure 90 times greater than that at our sea-level, and contains 100 times the amount of gas as our atmosphere. If Venus' atmosphere was once similar to our own, something quite dramatic happened to change it in this way. Venus is known to have a runaway GREENHOUSE EFFECT that has raised its temperatures to far in excess of

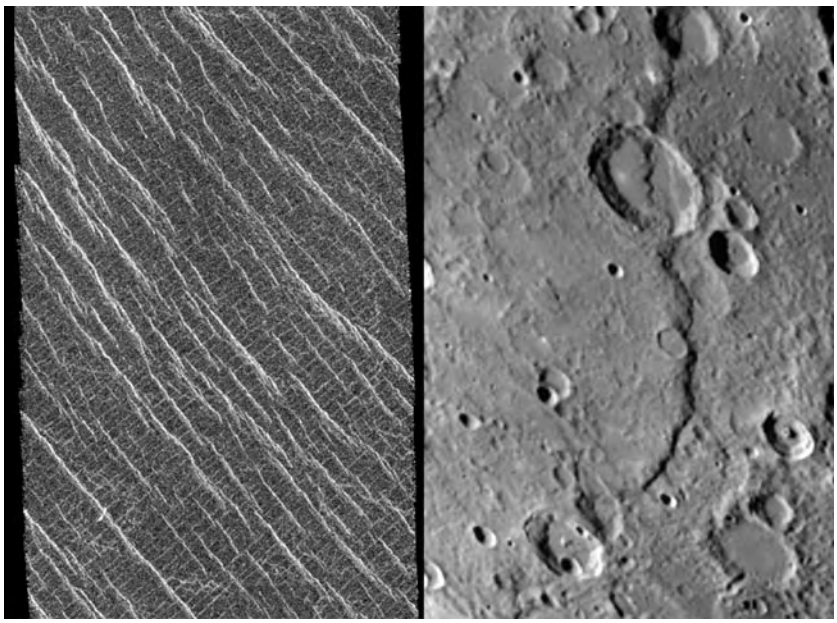

Figure 4. Two examples of tectonism on different planets. Left: lineated plains in Lakshmi Region on Venus. It is not known whether the two sets of intersecting lineations are faults or fractures, but this kind of terrain is unique to Venus. The image is 37 km wide, and 80 km long. (Courtesy of NASA JPL/Caltech.) Right: Mariner 10 image of part of the surface of Mercury. The long fault running through the center of the image is called Discovery scarp and is 350 km long. The large crater it intersects is 55 km in diameter and the maximum height of the scarp just below this crater is 3 km. (Courtesy of NASA JPL/Caltech.)

those it would have if it had an Earth-like atmosphere. In fact, this effect raises the surface temperature on Venus to approximately 750 K—hotter even than the surface of Mercury, which is closer to the Sun. The abundant CO_2 in Venus' atmosphere acts as an excellent greenhouse gas. One reason why the Earth's atmosphere has so little CO_2 compared to Venus is that CO_2 is easily dissolved into the Earth's oceans where it ends up being converted into carbonates, such as limestone. If you look at the total amount of CO_2 Earth and Venus have, including that locked into carbonates, we find that the amount on each planet is rather similar, but distributed in a very different way.

The water content in the atmospheres of Earth, Venus and Mars are all very low. Overall, the total volatile content as a percentage of the mass of the planet is not very high either. However, water plays an important role where Earth is concerned—it supports the life on the planet. We also know that water played a role in Mars' past, due to the numerous features on the surface that must have been cut by the action of running water or glacial action. For this to be the case though, the atmosphere of Mars must have been very different to what it is today. Under today's atmospheric conditions, water is not stable at the surface of Mars. There is a small amount to be found in the north polar region as water ice, and it is likely that some water ice exists beneath the surface as a permafrost layer. As mentioned earlier, impact craters can be used to trace the past presence of ice beneath the surface, but it is difficult to say whether that ice layer still exists in those regions today. It is clear, however, that Mars lost a lot of its atmosphere some time in the past, and its surface water along with it.

Why did the atmospheres of Mars and Venus change so dramatically over time? While this is still a matter of debate, Mars may have lost its atmosphere for a variety of reasons, including stripping of the atmosphere due to the solar wind, or erosion caused by impacts ejecting atmospheric gas into space. Venus, on the other hand, may have had a more hospitable atmosphere in the early solar system while the Sun was less luminous. As the Sun output more energy, Venus heated up, starting its runaway greenhouse effect and leaving the planet as it is today. Could this happen to the Earth? Conceivably, yes, but it would require a substantial heating of the Earth's atmosphere and the appropriate levels of greenhouse gases to cause it. Venus does, however, give us an insight into what Earth may have been like if we were formed as close to the Sun as our twin.

The rubble of the solar system: asteroids, comets and other small bodies

While most of our comparative planetology concentrates on the planets and satellites of the solar system, we must not forget the smallest bodies, as they can tell us much about the characteristics of the young solar system. METEORITES are pieces of ASTEROIDS and other bodies, broken apart from their parent body, probably by an impact and sent on a course that sees it captured by the Earth's gravity and fall to the surface. These give us the chance to study other bodies without the expense of sending a

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

spacecraft to it, although with meteorites, there is the problem of coping with terrestrial contamination in the results. Some meteorites have been found to contain material that dates back to the start of the solar system, and hence we can get an idea of the initial makeup of the solar nebula. Meteorites give us clues as to the nature of asteroids too. Asteroids are larger bodies, most of which reside in a belt between the orbit of Mars and Jupiter. The compositions of the asteroids vary, as evidenced by meteoritic compositions. In fact, there are a rare few with properties which indicate that the parent body underwent melting. The sizes of the asteroids today are too small for this to have happened, and so it is likely that the asteroids we see were once part of a larger body or bodies. The gravitational perturbations of Jupiter probably prevented this body from reaching planetary proportions.

Further out in the solar system, beyond the orbit of Pluto are the KUIPER BELT objects. These again are large lumps of rock, left over from the formation of the solar system. Although we do not have any samples of these objects (or at least we do not know if we have a sample in a meteorite on Earth) scientists are discovering more and more Kuiper belt members. Being able to get a sample of one of these, or at least to be able to determine its composition remotely will tell us much about what we were made of. This region of space may also be the home of some of the comets we see on a regular basis. COMETS are made mostly of ice and rock. They can make spectacular displays when close to the Earth, but more importantly it may have been the comets that were responsible for the delivery of a substantial amount of the volatiles to be found on Earth today. By studying the complete composition of these bodies, we may get a better understanding of what the comets delivered to us.

There is much to learn by comparing one world with another. Some may be able to tell us more about our own planet and what will or may have happened to it. In other cases, we can learn more about an individual process that occurs on many bodies. Comparative planetology was not possible a few decades ago, and we are now in a phase where our knowledge of other worlds is expanding at a fantastic rate. The more we learn about the differences between planets and why those differences occur, the more we will understand about the evolution of the entire solar system and perhaps even that of the planetary systems we are discovering around other stars (EXOPLANETS).

Planisphere

A simple device that displays the stars visible from a particular place at a particular time and date. It consists of a disk-shaped chart of all of that part of the celestial sphere that can potentially be seen from a particular latitude, overlaid by a rotatable disk-shaped mask in which an aperture has been cut. Using graduated scales around the perimeters of the two disks, the mask may be rotated so that the aperture reveals the stars that are visible on any selected date or time. The principle of the planisphere is broadly similar to that of the astrolabe, an ancient astronomical and navigational device.

Plaskett, John Stanley (1865–1941)

Astronomer and spectroscopist, born in Woodstock, Ontario, worked as a mechanic. He was a member of the original staff of the Dominion Observatory, Ottawa, where he became director and designed and constructed the 72 in telescope there. He worked on stellar radial velocities and spectroscopic binaries, and studied spectra of O- and B-type stars, and the interstellar calcium that showed on their spectra, mapping galactic structure. *Plaskett's star* HD47129 is the most massive known star, in fact a pair of O-type stars in a binary system, each 55 solar masses, and close to the maximum permissible for a star, beyond which radiation pressure disrupts the star.

Plaskett's Star

A spectroscopic binary in Monoceros, discovered in 1922 by the Canadian astronomer J S Plaskett (1865–1941) using a spectrograph he had designed specifically for the measurement of stellar radial velocities, attached to the 72 inch reflector of the Dominion Astrophysical Observatory in Victoria, British Columbia. The telescope was also largely of Plaskett's design, and is now known as the 'Plaskett telescope'.

Plaskett's Star, also designated V640 Mon, is in the region between *Betelgeuse* and *Procyon*, about 10° south of the star γ Geminorum. It is a member of a major cluster of hot, young stars associated with the Rosette Nebula, NGC 2244. Its apparent magnitude varies between 6.04 and 6.08 in a period of 14.396 days. The system, believed to be one of the most massive pairs of stars in the Galaxy, comprises two blue supergiants of spectral class O8e which may be separated by as little as 80 million kilometers. There must therefore be a turbulent mass of gas surrounding, and flowing between, the components. The latest determinations indicate that the mass of each of the components is of the order of 50 solar masses.

Sir James Jeans (1877–1946) described Plaskett's Star as 'the most massive and absolutely the brightest star whose elements are known with fair certainty. Temperature 28 000 °C. Every square centimeter of surface emits sufficient energy to run a locomotive at full speed for millions of years.'

Plasma

An almost completely ionized gas that contains equal numbers of electrons and positive ions moving freely and independently of each other. Although a plasma is electrically neutral, because it contains equal numbers of positively and negatively charged particles, it is highly conductive. Plasmas, which normally have very high temperatures, are found in a wide variety of astrophysical contexts, for example deep inside stars, where matter is very highly ionized, or in the high-temperature outer atmospheres of stars (coronas). The solar corona and the solar wind are both examples of plasmas that consist predominantly of electrons and protons (hydrogen nuclei).

Magnetic fields and plasmas interact in interesting and important ways. Because a charged particle moving in a magnetic field is subject to an accelerating force acting at right angles to the direction in which it is traveling, it is compelled to trace out a circle around the field line. If it also has a component of motion along the direction of the field, the combination of the two motions will cause it to follow a helical path along the direction of the magnetic field and prevent it traveling for any distance at right angles to the field. Therefore, provided the density is not so high that frequent collisions between particles break the ties between particles and field lines and thereby enable charged particles to diffuse across the direction of the magnetic field, plasma can flow along the direction of a magnetic field but not at right angles to it. In these circumstances, magnetic field and plasma are closely tied together, and the field is said to be 'frozen in' to the plasma. Where the pressure of the plasma exceeds the pressure of the magnetic field, moving plasma pushes the field lines around; conversely, where the magnetic pressure exceeds the plasma pressure, moving magnetic field structures push the plasma around. In the case of the Sun, closed magnetic structures (field lines that curve out from, and back into, its surface) confine the hot coronal plasma and prevent it escaping into space, whereas open field lines (which lead out into interplanetary space) allow plasma to flow out into the solar wind. The interplay between magnetic fields and plasmas underlies practically all aspects of solar activity.

Plate-Measuring Machine

A device that enables the positions of images on a photographic plate to be measured to a high degree of accuracy. The plate is mounted on a flat table that may be moved in two perpendicular directions ('x' and 'y'). In traditional machines the plate is moved manually in the x- and y-directions by means of two fine screws until the star image of interest is centered on crosswires in a microscope eyepiece. The amount of movement is registered on a finely graduated drum or vernier, typically to an accuracy of about a micron (μm). The plate may then be reversed (and, if necessary, inverted) and re-measured to minimize positional errors. This is a tedious and time-consuming process. Automatic plate-measuring machines have speeded up the process by many orders of magnitude. Usually, in a machine of this kind, the plate is mounted on a table that moves slowly, or in very small steps, in one direction while a spot of light (produced, for example by a cathode ray tube or a laser) scans rapidly across the plate in the other, images being identified by measuring the amount of light transmitted through the plate. In addition to measuring position, some machines can also measure brightness and distinguish between different kinds of objects (for example stars and galaxies). The machines are usually computer controlled and the computer carries out much of the data analysis. The SuperCOSMOS machine at the Royal Observatory, Edinburgh, which uses a linear CCD array to scan successive strips of a plate, can scan a complete Schmidt plate (which covers an area of sky 6° square and typically contains about a million star images) in two hours.

Plato (428–347 BC)

Philosopher, real name said to be Aristocles, with 'Plato' a nickname ('broad') derived either from the breadth of his knowledge, shoulders, or forehead, born in Athens, Greece, taught by Socrates, and travelled in Egypt, Sicily and Italy. Back in Athens, he founded, in 387 BC, a school of learning called the Academy, devoted to research and instruction in philosophy and the sciences, particularly to the development of mathematical models of natural phenomena. The Platonic solids are the cube, tetrahedron, octahedron and icosahedron, envisaged as the shapes of the atoms of the four elements, earth, fire, air and water, with the fifth Platonic solid, the dodecahedron, a model for the whole universe (see KEPLER). Plato envisaged the universe as a series of shells of crystalline spheres on which the stars, planets, Sun and Moon move round the Earth. He believed that the Moon shines by reflected sunlight and that astronomers were the wisest people. Plato's Academy was deemed a pagan establishment and closed in AD 529 by the Christian Emperor Justinian, but at 900 years of age it was the longest surviving university.

Plough

A well-known asterism, being the most readily recognizable part of the rather disjointed constellation of Ursa Major; it comprises the seven stars α, β, γ, δ, ε, ζ and η UMa. The arrangement resembles the outline of the old-style, hand-steered plough drawn by a horse or ox. The stars α and β UMa are also termed 'the Pointers', as they indicate of the direction of Polaris, the pole star. The star ζ Uma (Mizar), is a well-known binary system which has a fourth-magnitude naked-eye companion, Alcor (80 UMa).

Five of the stars (β, γ, δ, ε and ζ UMa) are members of the Ursa Major open cluster and have very similar proper motions. As the proper motions of the other two stars (α and η UMa) are in an opposing direction, the present familiar appearance of the Plough is temporary; thousands of years ago its shape was entirely different, and will be different again thousands of years hence.

Plutino

Any of the Kuiper Belt objects in or near the 3:2 mean motion orbital resonance with Neptune. This means that they complete two orbits around the Sun in the time it takes Neptune to complete three orbits. The 3:2 resonance acts to stabilize the Plutinos against gravitational perturbations by Neptune.The same resonance is also occupied by Pluto. 'Plutino' means 'little Pluto'. Approximately 35% of the known trans-Neptunian objects are Plutinos, and there are approximately 25 000 larger than 100 km diameter. Pluto is considered by some astronomers as by far the largest Plutino.

Pluto and Charon

Pluto is an unusual planet in many respects. It is the smallest and the most distant from the Sun of all nine planets. Its orbit is unusually eccentric and inclined to the ecliptic. It is accompanied in this orbit by a satellite, Charon, whose radius is half of Pluto's. Its surface is among the coldest and, except for IAPETUS, the most contrasted of all PLANETARY SURFACES. Although Pluto is the only planet never visited by a space probe (but see PLUTO–KUIPER EXPRESS), a series of breakthrough discoveries made since about 1975 have now provided us with a relatively detailed picture of the Pluto–Charon system, which is reviewed here.

Pluto's heliocentric orbit

Although Pluto was discovered in 1930, prediscovery photographs establish its position back to 1914. Pluto has thus been observed for about 85 years, i.e. slightly over one third of its orbital period of 248 years. Pluto's mean distance from the Sun is about 40 Astronomical Units (semi-major axis of the orbit, a = 39.54 AU), i.e. about 6 billion kilometers. However, due to its strongly elliptical orbit (eccentricity, $e = 0.249$), its distance from the Sun varies by 20 AU between PERIHELION (q = 29.7 AU) and APHELION (Q = 49.85 AU). Pluto's orbit is therefore 'Neptune-crossing' in the sense that during approximately two decades within its orbital period, it can get closer to the Sun than NEPTUNE, whose perihelion distance is 29.8 AU. However, due to its orbit high-inclination ($i = 17.1^\circ$), Pluto, unlike any other planet, makes large excursions of 8 AU above and 13 AU below the plane of the ecliptic and, despite the fact that the orbits of Pluto and Neptune appear to cross when projected onto the ecliptic plane, Pluto never gets very close to Neptune (never closer than 17 AU). Pluto in fact makes closer (12 AU) and more frequency approaches to URANUS than to Neptune. The reason for this interesting situation lies in the so-called 3:2 mean motion resonance between Pluto and Neptune. Over a period of 495 years, Pluto orbits the Sun twice while Neptune orbits three times (figure 1). As a consequence, the relative orbital phases of Pluto and Neptune recur periodically, so that the perturbative forces of Neptune on Pluto act in nearly the same phase at each repetition. Numerical integrations of the motion of the five outer planets over time scales of more than a million years indicate that Pluto's conjunctions with Neptune (i.e. the configurations when the two planets have the same heliocentric longitude) occur when Pluto is near aphelion. More specifically, calculations show that the 'resonance argument', defined as $\Phi = 3\lambda_P - 2\lambda_N - \varpi$, where λ_P and λ_N are the longitudes of Pluto and Neptune, and ϖ is the longitude of Pluto's perihelion, varies ('librates') about a mean value of 180° with an amplitude of 82° over a libration period of 19 912 years. Therefore, the 3:2 resonance has a strong stabilizing influence on Pluto's orbit. In addition, Pluto's perihelion and aphelion cannot occur at any position on the orbit and, in particular, they never cross Neptune's orbital plane, further helping to keep the two planets apart. Finally, it is important to note that most modern observations of Pluto occurred near the last perihelion (1989). Thus, the vision of the planet (in particular the surface and atmospheric properties) described below essentially refers to perihelion and would be drastically different at aphelion.

Charon's orbit and Pluto–Charon self-rotation

Charon, discovered in 1978, orbits about Pluto at a mean distance of 19 640 km (corresponding to about 17 Pluto radii, or an apparent separation on the sky of 0.9″ at 30 AU). (Because the masses of the two objects are not very different (see below), it is more correct to state that Pluto and Charon orbit about their common center-of-mass.) Charon is the only satellite of Pluto known to date, with a visible magnitude of $m_v = 17.25$ at opposition. Searches for additional satellites, motivated by the fact that the volume of space around Pluto that is stable against solar perturbation (i.e. in which other satellites could exist) extends to about 100 Charon orbit radii, have concluded to the absence of any object brighter than $m_v = 20.6$ in the region from 6 to 10 arcsec and $m_v = 22.6$ beyond that. The orbital period of the Pluto–Charon system is 6.387 223±0.000 017 days. The rotational period of Pluto, as determined from its photometric lightcurve (see below), is 6.387 260 ± 0.000 070 days, The two numbers are consistent within error bars, implying that Pluto's spin is tidally locked to Charon's orbital motion. Charon's rotational period is not well constrained but consistent with SYNCHRONOUS ROTATION. In addition, theoretical arguments indicate that Charon's rotational motion must also be locked to the orbital motion, because the timescale over which the satellite's self-rotation is slowed by frictional effects (called the tidal damping time) is much shorter than for Pluto. Therefore, just as the Moon always turns the same face to the Earth, each body (not only the satellite) keeps the same hemisphere turned towards the other. In addition, as seen from the surface of one of the two bodies, the other body is either invisible or always at the same position in the sky. This situation of mutual synchronism is the stable end of tidal evolution and Pluto–Charon is the only known example of such a case.

The orientation of Charon's orbit with respect to Pluto's orbital motion gives rise to so-called 'mutual events'. Every 124 years (i.e. every half-orbit of Pluto), and for a period of approximately 5 years, Charon's orbit is seen edge-on from the Earth (and the Sun), allowing observers to view Pluto and Charon passing directly in front of and behind one another. By unusual chance, this 'mutual events season' started in 1985, i.e. only seven years after the discovery of Charon. The scientific return of the mutual events was enormous, not only because they allowed an improved knowledge of Charon's orbit (thereby providing the total mass of the Pluto–Charon system by virtue of Kepler's third law) but more importantly because they provided the first resolved view of the two bodies, with estimates for their individual

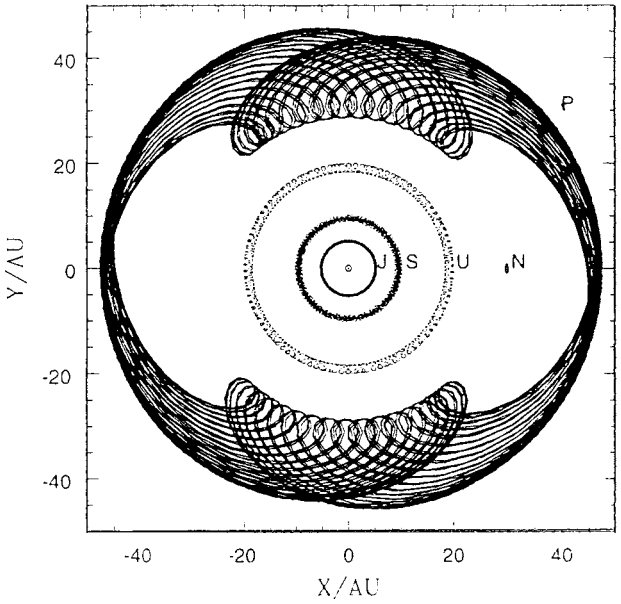

Figure 1. The orbits of the outer planets for 40 000 years in a reference frame corotating with the mean motion of Neptune. In this reference frame, two revolutions of Pluto trace a complete loop in 495 years. It can be seen that Pluto's perihelion librates 90° away from Neptune (with a period of about 19 900 years). From Malhotra and Williams (1997).

diameters (thus the average density of the system), their surface composition and their albedo distribution (see below). The best determination of Charon's orbit now relies on direct HST imaging. These observations yield a semi-major axis of 19 636 ± 8 km and a small but significantly non-zero eccentricity of 0.0076 for Charon's orbit. This result is surprising given that tidal effects can damp out such an orbital eccentricity on a time scale of 1-10 million years, and may suggest that the system was disturbed relatively recently. The orientation of Charon's orbit is such that its orbital angular momentum vector is inclined by 119.6° with respect to Pluto's orbital plane. Again for tidal effect reasons, Pluto's and Charon's polar axes must be parallel to Charon's angular momentum. Thus, with an obliquity of ∼120°, the latitude of the subsolar point varies between −60° and +60° over a Pluto year. This excursion, which dictates the annual variation of the insolation for a given point on Pluto's surface, is the largest experienced by any planet except Uranus. Due to the torques exerted by the Sun over the Pluto–Charon system, Pluto's equatorial plane precesses about the plane of its heliocentric orbit, so that Pluto's obliquity varies between 103° and 128° with a period of about 3 million years.

Bulk properties: radius, mass, density

Determinations of Pluto and Charon radii are based primarily on mutual event photometry, stellar occultations, and recently, from direct HST imaging. Radius values from mutual events and direct imaging tend to converge towards radii of about 1160 km for Pluto and 600 km for Charon, but the absolute accuracy, limited by the uncertain effects of limb darkening, is probably not better than 10-20 km. Stellar OCCULTATIONS by planets are a powerful means for measuring diameters (and possibly oblatenesses) but in Pluto's case, the small size and slow motion of the planet make these events rare and difficult to predict. To date, only occultation (June 1988) has provided good-quality data. Unfortunately, the uncertain structure of Pluto's atmosphere (see below) makes the radius determination ambiguous. Nominal values are 1180-1195 km which, at face value, are inconsistent with the above numbers; however, whether the occultation has probed Pluto's atmosphere down to the surface is actually not certain (see below).

The total mass of the Pluto–Charon system is straightforwardly determined from the orbit parameters of Charon to be equal to 0.002 433 terrestrial masses. (Incidentally, this value is 1/4000 of the mass deduced by Lowell in 1915 to account for the then believed perturbations in the orbit of Uranus. Therefore although Pluto was indeed discovered somewhere near the position predicted by Lowell, this appears to be a mere coincidence.) The individual masses of Pluto and Charon are much harder to determine, as this requires examination of the motion of Pluto with respect to the barycenter of the system, which is about an order of magnitude smaller than Charon's. Nonetheless, and in spite of remaining divergences, the current 'consensus' value for the Charon/Pluto mass ratio is about 0.119. This gives individual masses of 1.30×10^{25}g for Pluto and 0.15×10^{25}g for Charon. Adopting radii of 1151-1178 km for Pluto and 591-628 km for Charon, based on the various modern measurements, the average mass density of the Pluto–Charon system is 1.87-2.03 g cm^{-3}; individual densities are 1.92-2.06 g cm^{-3} for Pluto and 1.51-1.81 g cm^{-3} for Charon.

Surface properties

Visual appearance

One of the earliest findings (1955) about Pluto is that its brightness varies by about ±0.15 magnitudes (about ±15%) around a mean magnitude of 15.9 with a period of 6.3872 days. At that time, this result, called the 'Pluto visible lightcurve', actually pertained to the 'Pluto+undiscovered Charon' system. HST observations, which separate Pluto from Charon, prove that the variation is essentially entirely due to Pluto, with Charon having a very weakly marked lightcurve of ±0.04 magnitude (figure 2). The existence of the lightcurve indicates that Pluto's surface is not uniformly bright, but has bright and dark regions. Observations of the mutual events and now direct imaging, in combination with lightcurve information, indicate the gross structure of Pluto's surface. It includes a large bright southern polar cap, a broad dark equatorial band, and a large region of intermediate brightness in the Northern hemisphere (figure 3). The equatorial and mid-latitude regions appear

Figure 2. Pluto and Charon separate lightcurves. These curves give the visual magnitude (for a mean opposition) as a function of longitude on the planet and satellite. From Buie *et al* (1997).

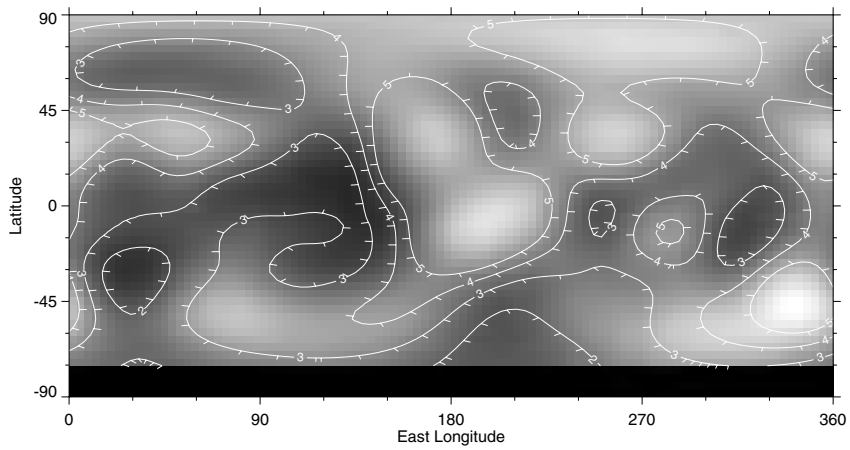

Figure 3. Surface appearance of Pluto, from HST imaging. Albedo contrasts reach values of 6:1. From Stern *et al* (1997).

very variegated. Brightness contrast ratios over the planet can reach values of 6:1, nearly as high as on Iapetus. Brightness variations probably result from the effect of volatile condensation/sublimation cycles and transport over very many seasons (see below). Charon's surface is not so well known but does not seem to show any strong spatial variations. Its average geometric albedo is 0.36-0.39, substantially less than the average Pluto value (0.58), suggesting that its surface is not as frost-rich.

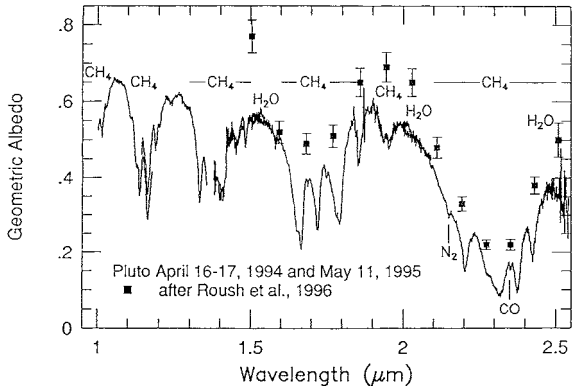

Figure 4. The near-infrared spectrum of Pluto at 1-2.5 μm, showing absorption bands due to CH_4, N_2, CO and tentatively H_2O. From Cruikshank *et al* (1997).

Composition

Spectroscopic studies at 0.7-2.5 μm indicate that Pluto's surface is dominantly covered by volatile ices. Ices of N_2, CH_4, CO and tentatively H_2O have been detected (figure 4). N_2 appears to be the dominant species, with CO and CH_4 ices constituting less than 2% by mass of the surface materials. In the case of CH_4, there appear to be at least two components: one corresponds to CH_4 ice intimately mixed at small concentrations with N_2 ice (e.g. N_2:CH_4 in ratios 100:1), and the other corresponds to a fraction of the surface covered by a thick layer of pure CH_4. Some models also suggest that the N_2:CH_4 layer is actually overlain by a thin CH_4-enriched layer. The methane bands appear to vary in intensity with the phase, with generally weaker bands near the minimum of the visible lightcurve (i.e. when the largest fraction of dark regions are in view). The interpretation of this variation is, however, not clear. Variations in methane depth can be due, for example, to variations in the spatial coverage of the CH_4 ice deposits, in the abundance of CH_4 in the N_2-CH_4-CO mixture, or in the size of the icy grains. It also appears that the overall spectrum of Pluto at visible wavelengths is somewhat 'red', i.e. that the reflectance of the surface increases with the wavelength between 0.4 and 1 μm. This may be related to a compositional effect, but the reddening agent remains to be identified. On Charon, H_2O ice has been clearly identified. It dominates the infrared spectrum at all longitudes. The visible spectrum of Charon, unlike Pluto's, is spectrally neutral.

Temperature

Pluto's and Charon's surface temperatures remain uncertain. At 30 AU from the Sun, the maximum temperature of any point of their surfaces is 72 K (the value corresponding to instantaneous equilibrium with the solar insolation). Observationally, the surface temperature of a planet with no atmosphere or a tenuous atmosphere is mostly determined by the thermal flux emitted by the object. In the Pluto–Charon system case, measurements have been performed at far-infrared (60-200 μm) and millimeter/submillimeter (0.8-1.3 mm) wavelengths. Note that these measurements cannot separate Pluto from Charon, so they primarily sample Pluto, which contributes ~80% of the total flux. The two techniques give apparently discrepant results, with an average surface temperature on the visible disk (i.e. on the dayside) of 47-58 K from the far-IR data and 30-44 K from the mm/submm. The far-IR values are thought to be the most representative of the true surface temperature, because the flux emitted at the longest wavelengths can be significantly lowered by non-unity surface emissivities, leading to an apparently lower temperature. However, studies of the shape of the N_2 absorption band at 2.15 μm on Pluto suggest that the N_2 ice temperature is about 40 ± 2 K. This suggests that Pluto's surface is not isothermal. This situation is also expected given the existence of Pluto's visible lightcurve (dark regions reflect less energy than bright regions and therefore must be warmer) and given the atmospheric composition (see below). A direct proof that Pluto's surface is not isothermal is provided by recent IR observations which indicate that the thermal flux emitted by the Pluto–Charon system varies with orbital longitude, with, as expected, more flux (i.e. a higher average temperature) when Pluto is darker. In summary, the current paradigm is that Pluto possesses cold (40 K) regions dominated by N_2 ice and warmer regions at temperatures well above 50 K. No information is available on Charon.

Pluto's atmosphere and interaction with the surface

The existence of an atmosphere around Pluto was demonstrated by the observation of a stellar occultation in June 1988 (figure 5). It is not surprising in the presence of volatile species on its surface, which can sustain an atmosphere by sublimation equilibrium. The observations indicates a pressure of a few μbar, but the full interpretation of the occultation data requires a knowledge of the main atmospheric chemical composition (which in fact was obtained later).

Chemical composition

Methane is the only gas to have been spectroscopically detected in Pluto's atmosphere. However, N_2 must dominate the composition of Pluto's atmosphere, because it is the most volatile of the various ices detected on Pluto's surface, and because its abundance at the surface is also the largest. Based on the relative abundance of ices, estimates of the surface temperature and direct abundance measurement of CH_4, Pluto's atmosphere can be estimated to consist primarily of ~99% of N_2, ~1% of CH_4 and ~0.1% of CO (the latter two numbers being uncertain by factors of a few).

Atmospheric structure and surface pressure

The occultation lightcurve (figure 5) is very unusual in that it exhibits a break in slope. This break occurs when the stellar rays cross Pluto's atmosphere at 1215 km from

Copyright © Nature Publishing Group 2001

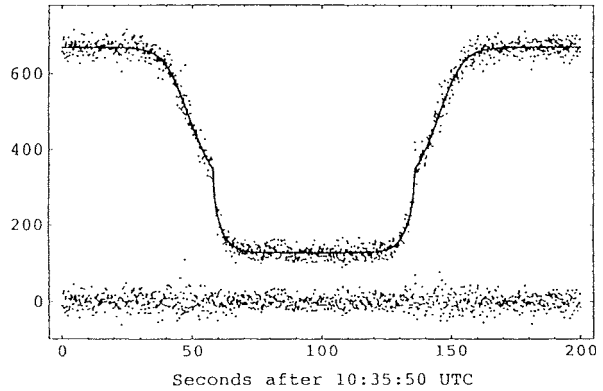

Figure 5. The occultation lightcurve for the stellar occultation by Pluto of 9 June 1988. The dots represent the stellar signal as the star is progressively extinguished by Pluto's atmosphere. Note the 'breaks' in the lightcurve. They occurred when the image of the star was 1215 km away from Pluto's center. Above this level, the lightcurve can be fitted by an isothermal atmosphere. Below this level, the data can be interpreted as due to a haze layer or to a strong temperature gradient. From Elliot and Young (1992).

Pluto's center, at a pressure level of 2.3 μbar. Above this level, Pluto's atmosphere is vertically isothermal with a temperature of about 102 K. Below this level, the shape of the occultation curve can be explained by either (i) a very strong temperature gradient (i.e. the temperature decreases towards the surface at a rate of 5-10 K km^{-1}) or (ii) an extinction layer due to a relatively thick haze, with an opacity of about 0.15. A temperature of ∼100 K for the upper atmosphere while the surface temperature is only 40-60 K is quantitatively explained by the fact that gaseous methane is an efficient heating agent, from absorption of solar insolation in its near-infrared bands. Models indicate that an atmospheric abundance of ∼1% for methane may also be capable of sustaining a strong temperature gradient near the surface. On the other hand, the 'haze' interpretation of the shape of the occultation curve is more difficult to justify physically. In addition, both interpretations imply a surface radius in the range 1180-1195 km, which is inconsistent with the values inferred from the mutual events and direct imaging. A way to resolve this discrepancy is to postulate that the occultation has not probed Pluto down to the surface itself but that the atmosphere extends 20-40 km below the strong thermal gradient layer. Specifically it has been proposed that Pluto possesses a 'hidden' 40 km deep troposphere. The uncertainty in the structure of the lower atmosphere reflects on the surface pressure. The occultation probes the atmosphere down to pressures of 3-5 μbar but the surface pressure could be significantly higher: for example with a 40 km troposphere at ∼40 K the surface pressure would be about 30 μbar.

Interaction with the surface

Pluto's atmosphere is primarily produced by the sublimation of the surface ices. At a temperature of 38-42 K, the surface pressure of nitrogen ice is 19- 159 μbar. To first order, this is in agreement with (although possibly somewhat higher than) the observed surface pressure. The equilibrium between frost and gas implies that the frost must be isothermal. Indeed, on a planet covered by frost, the frosts in the two hemispheres are at a uniform temperature if about half of the solar energy received by the summer hemisphere is transported to the winter hemisphere in the form of latent heat across the equator. This can be expressed by the following equation:

$$\tfrac{1}{2}S(1-A)\pi R^2 = 2\pi RL\Phi$$

where S is the solar constant, A is the surface albedo, R is the planetary radius, L is the latent heat per unit of mass and Φ is the mass flux across the equator (g cm^{-1}s^{-1}). Φ is equal to the product of the mass density (ρ) by the meridional flow velocity (υ) and the vertical height (d) of the flow. One can solve this equation for the flow velocity. Taking d = 1 km, one finds $\upsilon \sim 3$ m s^{-1}. Thus, modest meridional winds are able to equalize the N_2 frost temperature and surface pressure over the globe. The situation is similar to MARS but with the important difference that on Mars the temperature of the CO_2 polar caps is determined by the annually averaged insolation. On Pluto, the characteristic time of hemisphere transport is of the order of a few planetary days only. Thus the frosts are in instantaneous equilibrium with the diurnally averaged insolation. As a consequence, the seasonal variations in surface pressure and frost temperature are expected to be much larger than on Mars. Over the 21st century, when Pluto recedes from perihelion, the atmospheric pressure is expected to decrease by about two orders of magnitude. Seasonal variations are accompanied by a redistribution of volatiles, thereby modifying the visual appearance of the planet. Note that the above discussion applies as well to TRITON, which exhibits a 14 μbar N_2 atmosphere in equilibrium with N_2 frost at 38 K.

This simple picture does not work for methane, whose atmospheric abundance (∼1%) is orders of magnitude higher than expected from thermodynamical equilibrium. This methane enrichment is explained by postulating the existence either of a thin CH_4-enriched layer at the surface, or of thick and warmer isolated patches of pure CH_4 ice. Both scenarios could result from the known fact that in a CH_4-N_2 solid mixture, N_2 preferentially sublimes because of this higher volatility. Remarkably, both of them are supported by the most recent analyses of the near-IR spectra (see above). The presence of a thin CH_4-enriched layer is also expected to somewhat decrease the equilibrium atmospheric pressure of N_2.

Atmospheric escape

Reaching 100 K within a few kilometers from the surface, Pluto's atmosphere is much warmer than Triton's, where the 100 K upper atmosphere temperature is not attained before several hundreds of kilometers. As a consequence,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Pluto's atmosphere is very extended, with an exobase (i.e. the level where the mean free path of the molecules is comparable to the scale height) near 4000 km altitude (750 km for Triton). Given the low gravity field, Pluto's atmosphere escapes very significantly, with an estimated escape flux of a few 10^{27} N_2 molecules/s (and about 10 times less of CH_4). In fact, Pluto's atmosphere is so weakly bound that escape occurs hydrodynamically (i.e. vertically 'blowing off') rather than thermally (i.e. from the fact that a fraction of the molecules has a velocity exceeding the escape velocity). Note, however, that Pluto's escape flux is expected to drastically decrease towards aphelion, not only because of the expected collapse in surface pressure, but, more importantly, because the atmospheric temperature and extent, controlled by the atmospheric abundance of methane, will strongly decrease with increasing heliocentric distance. Pluto's present averaged escape flux, if maintained over the age of the Solar System, represents a loss of a volatile (N_2, CH_4 . . .) ice layer at least several kilometers thick.

Possible internal structure

The internal structure of any planet is necessarily uncertain to some degree, as it escapes direct observation and is primarily based on models. The philosophy of structural modeling can be summarized as follows: a set of components (e.g. water ice, other volatile ices, rock) for the interior of the planet is selected based on observational (surface data) and theoretical (cosmogonic) considerations, an internal arrangement of these components is guessed (for example, is the planet differentiated or undifferentiated, i.e. are the ice and rock vertically statigraphed or homogeneously mixed?), and using the equation of state of the components and hydrostatic equilibrium, the equation of state is computed throughout the body. Parameters are adjusted until the model predicts correct values of the observables (mass, radius, quadrupolar moments of the gravity field, etc). In the case of Pluto and Charon, the internal models are particularly uncertain because only the individual masses and radii are known as constraints to the models, and still with a considerably uncertainty (see above). Nonetheless, internal models are useful because they allow the estimation of parameters such as the rock-to-ice ratio and the bulk chemistry, which are of key importance for understanding the origin of the bodies.

Constraints to the models

As discussed above, the most recently determined masses and radii provide values for the mass densities of 1.92-2.06 g cm^{-3} for Pluto and 1.51- 1.81 g cm^{-3} for Charon. This clearly indicates that Pluto and Charon are some mixtures of ice and rock. The dominant ice must be water ice because oxygen is the most abundant of the ice-forming elements (C, N, O). Given the temperature and pressure range in Pluto's and Charon interiors, H_2O ices I, II, III, V and IV may be present. Like Pluto's surface, Pluto's interior may contain other volatile ices. However, they are probably concentrated near Pluto's surface so that the present mantle structure and rheology must be dominated by water ice. The exact composition of the rock component is unknown but it is almost certainly at least partially hydrated. Finally, refractory organic compounds may represent an important fraction of Pluto and Charon interiors. This consideration is based on chemical evidence from COMET HALLEY in which CHON (carbon-hydrogen-oxygen-nitrogen) particles contained in a diversity of refractory organic materials represent as much as 10% of the mass.

Pluto's interior is probably differentiated. This stems from arguments based on Pluto's thermal history and the current presence of volatiles. Radiogenic heating release is more than sufficient to allow solid state flow of water ice. In addition, the accretional heating of Pluto may be important, especially considering the fact that the collision that probably formed Charon could have triggered water ice melting, followed by DIFFERENTIATION. Moreover, surface volatiles, as the source of Pluto's atmosphere, are subject to escape. Therefore, their continued existence implies either an initially substantial reservoir at the surface, which would suggest differentiation, or continual resupply. On the other hand, Charon's differentiation state remains ambiguous, due primarily to the large remaining uncertainty on its density and surface frost coverage.

Interior models

Based on the previous arguments, the most likely internal structure for Pluto includes a ∼300 km thick water ice layer (either pure ice I or a combination of ices I and II) and a ∼850 km thick layer of partially hydrogenated rock. The deeper part of the ice layer probably undergoes solid-state convection. The boundary occurs at a typical pressure of 0.2 gigapascals (GPa) and a temperature of 250 K. Conditions at the center are a pressure of 1.30 GPa and a temperature in excess of 1000 K. This model corresponds to a rock fraction of 0.65. If Pluto is organic-rich (say organic/rock mass ratio= 0.2), it may contain a separate ∼100 km thick layer of organics. For Charon, both differentiated structures, similar to Pluto, and undifferentiated (in this case the interior is a mixture of water ice I and II and hydrated rock) are possible, and the pressure at the center is about 0.2 GPa.

Origin of Pluto and Charon

Our understanding of the origin of the Pluto–Charon system has enormously improved in recent years, especially as the true nature of the dynamical link between Pluto and Neptune became apparent and as new objects were discovered in the Kuiper-Edgeworth disk. The most popular early hypothesis, based on the fact that Pluto's orbit is 'Neptune-crossing', was that Pluto was formerly a satellite of Neptune, which had been ejected to its present orbit by a collision with Triton (reversing, by the same mechanism, Triton's orbit). In fact, Pluto's 3:2 orbit resonance with Neptune, by preventing close approaches between Neptune and Pluto, implies that no Neptune

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

ejection event could have placed Pluto on its present orbit. In addition, the high rock-to-ice ratio forbids formation in a planetary subnebula. Other bulk and chemical characteristics (density, presence of volatile ices) indicate instead a formation in the outer solar nebula, beyond at least 10 AU, although the constraints on the exact location are loose. The existence of the Pluto–Charon pair, with a satellite mass ratio of about 1/9, and the obliquity of the system suggests that one or more substantial physical collisions occurred in the past. It must be stressed, however, that the astronomically low probability of such collisions seems to imply that Pluto and its impactor (the Charon progenitor) were members of a large population of small planets. Charon's orbit attributes suggest that it has undergone quick tidal evolution. Finally, the discovery in recent years of numerous objects with diameters of possibly tens to several hundreds of kilometers in the Kuiper- Edgeworth disk between 32 and 48 AU has placed Pluto in a clear dynamical and population context.

With these various constrains in hand, a baseline scenario can now be elaborated. In this picture, Pluto (and independently the Charon progenitor) formed in a near-circular, low-inclination heliocentric orbit, probably beyond Neptune. At that time, a much higher density of population probably existed in this region, although it is not known whether this population included numerous objects similar in size to Pluto or Charon. Once formed, due to the perturbations by Neptune, these bodies underwent orbital migration and were captured in a stable suite of resonances and ultimately in the 3:2 mean motion resonance, amplifying their eccentricity and inclination. At some point, probably when the two bodies already had significant eccentricities, Pluto and the Charon progenitor underwent a mutual collision which formed the binary system. Charon's orbit then quickly (in $< 10^8$ yr) evolved to its present synchronous state. Neptune perturbations on the 35-50 AU zone cleared the Kuiper-Edgeworth disk of most of its mass and prevented further growth of Pluto into a larger body.

Poincaré, Jules Henri (1854–1912)

Born in Nancy, Lorraine, France, became professor of mathematics at the Sorbonne in Paris, contributed to all areas of mathematics, including the three-body problem of celestial mechanics and studies of the stability of the solar system. He was first to consider the possibility of chaos in planetary orbits, foreshadowing the modern study that restarted in 1963. His work began as the answer to a question in a contest to show rigorously that the solar system, as a multi-body modelled by Newton's equations, is dynamically stable. Poincaré realized that the outcome prediction was sensitive to the initial conditions: 'If we knew exactly the laws of nature and the situation of the universe at the initial moment, we could predict exactly the situation of that same universe at a succeeding moment. but even if it were the case that the natural laws had no longer any secret for us, we could still only know the initial situation approximately. . . it may happen that small differences in the initial conditions produce very great ones in the final phenomena. A small error in the former will produce an enormous error in the latter. Prediction becomes impossible. . .' Poincaré also determined the shape of a rotating fluid subject only to gravity. He wrote *Les Méthods Nouvelle de la Méchanique Celeste* (1892–99) and *Leçons de Mecanique Celeste* (1905). He wrote on the philosophy of science, worked on equations of mathematical physics, and, with ALBERT EINSTEIN and HENDRICK LORENTZ, developed the special theory of relativity.

Polar

Part of NASA's Global Geospace Science programme and the International Solar Terrestrial Physics (ISTP) programme. Launched in February 1996 to study the interaction between Earth's magnetosphere and the solar wind at high latitudes. Imaging instruments measure visible, ultraviolet and x-ray spectra of the polar regions.

Polar Caps

Bright, icy surface deposits in the polar regions of a planetary body. In the solar system, the Earth, Mars and Neptune's major satellite Triton are known to possess polar caps. The Earth's polar caps are permanent and consist of water ice, with a maximum thickness of about 4 km. The northern cap lies over Greenland and the Arctic Ocean; the southern covers the continent of Antarctica. Both show a little seasonal variation, with different limits of sea ice in winter and summer. Mars's polar caps show a marked seasonal variation. At their minimum extent (about 600 km across for the northern cap, 400 km for the southern) they have a distinctive swirled pattern, the ice filling valleys that curve outward from the poles. In the winter the southern cap extends to around 60 °S (50 °S in the Argyre Basin), the northern to about 65 °N, as carbon dioxide sublimes out of the atmosphere to form extensive deposits of frost. While the permanent southern polar cap consists of carbon dioxide ice, the northern one is of water ice. Triton has a pink southern polar cap, probably of nitrogen ice and frost. This is expected to migrate to the north polar region and back as the angle of solar illumination changes over the course of Neptune's 165-year orbit round the Sun.

Polar Motion and Length of Day

Polar motion

Polar motion refers to the movement of the axis about which the Earth rotates. The length of day is the difference between the day measured using astronomical observations and the day as measured by an atomic clock. Both quantities are needed to specify the orientation of the Earth in space and both vary with time.

The angles which characterize the direction of the rotational pole with respect to the Earth's surface are called the polar coordinates, x and y. Variation of these coordinates is called polar motion. The polar coordinates specify the direction of the Earth's pole of rotation in a reference frame which is defined by the adopted locations of terrestrial observatories. The coordinate x is measured along the 0º (Greenwich) MERIDIAN while the coordinate y is measured along the 90ºW meridian. These two coordinates determine the directions on a plane onto which the polar motion is projected (figure 1).

Polar motion consists largely of two motions. The largest is a mostly circular path which repeats after approximately 435 days and is called the 'Chandler' motion after Seth Chandler, who discovered it in 1890. It is caused by the misalignment of the EARTH'S ROTATION axis with respect to its axis of symmetry. The second motion is one which follows an elliptical path and repeats annually. This motion is caused by the redistribution of atmospheric mass during the year. These two motions account for the spiral motion of the pole as seen from the Earth's surface (figure 2).

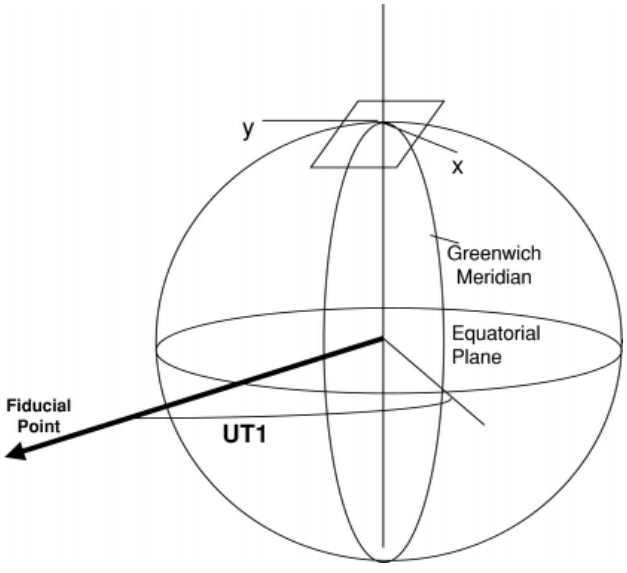

Figure 1. UT1 and polar coordinates x and y.

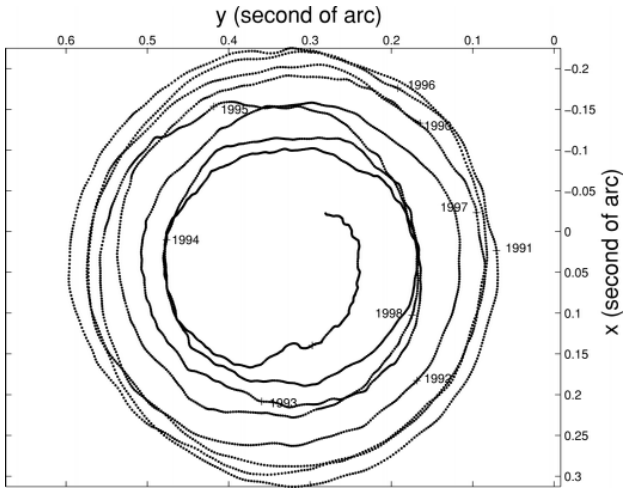

Figure 2. The path of the rotational pole of the Earth. 0.1 arcsecond corresponds to 3 m.

Earth rotation

The Earth rotation coordinate is the angle through which the Earth has turned in a given period of time. This angle expressed as the difference between a time scale measured by the rotation of the Earth, UT1, and a uniform time scale, UTC, refers to the angular separation between the direction of the 0º meridian on the Earth and the direction to a point defined in space astronomically (figure 1).

Historically some form of time based on the rotation of the Earth has always been the basis for civil time, the definition and the measurement procedures depending on available technology and precision requirements (see TIME SCALES: TERRESTRIAL). In modern practice, UT1 is determined using a fiducial direction defined mathematically in the celestial reference system. This direction is referred to as the Mean Sun.

UTC, standing for Coordinated Universal Time, designates the atomic time scale which approximates the rotational time of the Earth (see UNIVERSAL TIME, TIME SCALES: ATOMIC). From the time of its inception, its rate and/or epoch have been adjusted to keep it near UT1. The current practice is to adjust UTC in epoch by integral seconds (leap seconds) to keep the difference between UT1and UTC less than 0.9 s. UTC as defined by the International Radio Consultative Committee (CCIR) Recommendation 460-4, differs from TAI (Temps Atomique International INTERNATIONAL ATOMIC TIME) by an integral number of seconds. TAI is an atomic time scale determined by the Bureau International des Poids et Mesures (BIPM). Its unit is exactly one Systeme Internationale (SI) second at mean sea level.

The difference between the length of the day measured astronomically and 86 400 s (24 h × 60 min × 60 s) is defined as the excess length of day. It is often referred to as the 'length of day' and abbreviated 'LOD'.

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

This quantity is related to the rotational speed of the Earth, such that a slower rotational speed will be seen as an increase in the LOD and vice versa.

Until recent times the rotation of the Earth has served as the basis for timekeeping. The assumption was made that the rotational speed of the Earth was essentially constant and repeatable, and that the length of the day which resulted from this constant rotational speed was naturally useful as a measure of the passage of time. Comparisons of astronomical observations of different kinds and of terrestrial clocks have shown, however, that the speed with which the Earth is rotating is not constant with time. Variations in rotational speed may be classified into three types: secular, irregular and periodic. The secular variation of the rotational speed refers to the approximately linear increase in the length of the day due chiefly to tidal friction. This effect causes a slowing of the Earth's rotational speed resulting in a lengthening of the day by about 0.0005 to 0.0035 s per century.

The irregular changes in speed appear to be the result of random accelerations, but may be correlated with physical processes occurring on or within the Earth. These have caused the length of the day to vary by as much as 0.01 s over the past 200 years. Irregular changes consist of so-called decade fluctuations with characteristic periods of 5–10 years as well as variations that occur at shorter time scales. The decade fluctuations are apparently related to processes occurring within the Earth. The higher-frequency variations are now known to be related to the changes in the total angular momentum of the atmosphere.

Periodic variations are associated with periodically repeatable physical processes affecting the Earth. Tides raised in the solid Earth by the Moon and the Sun produce periodic variations in the length of the day as large as 0.0005 s with periods of 1 year, 1/2 year, 27.55 days and 13.66 days, among others. Seasonal changes in global weather patterns occurring with approximately annual and semi-annual periods also cause variations in the length of the day of this order.

Knowledge of the rotational speed of the Earth is required for observers on the Earth who find it necessary to know the orientation of the Earth in an inertial reference frame. This includes navigators, astronomers and geodesists. The rotational speed of the Earth remains essentially unpredictable in nature due to the incompletely understood irregular variations. Because of this, astronomical observations continue to be made regularly with increasing accuracy, and the resulting data are the subject of continuing research in the field (see EARTH'S ROTATION: THEORY).

Analyses of astronomical observations reveal different types of variations in the speed of rotation. The ancient observational data form the basis for estimates of the secular deceleration in the speed of rotation. The more recent information, having been obtained with higher accuracy and more regularity, has shown the changes in the acceleration causing irregular variations in the length of the day. These data have also been used to detect the periodic variations in the length of the day. Figure 3 shows the excess length of day in milliseconds or the difference between the rotationally determined length of day and 24 h of UTC time.

Causes of variations in the Earth's orientation

The conservation of ANGULAR MOMENTUM of the Earth requires that changes in the Earth's moments of inertia produce changes in the Earth's orientation. The moments of inertia are dependent on the distribution of mass on and within the Earth. This includes the mass contained in the atmosphere and in the oceans. As mass is redistributed, the moments of inertia change, producing the subsequent changes in the Earth's orientation. An example of such an effect is that of the spinning skater who is able to change rotational speed by redistributing mass through the changing of the positions of the arms.

The crust and the interior of the Earth are not strictly rigid. Tides generated by the Sun and the Moon change the shape of the Earth. The Earth is thought to have a fluid core with material possibly in motion. Coupling between such a core and the mantle would change the speed of rotation of the mantle from which the observations are made. The Earth may undergo changes in the moments of inertia as landmasses move or rise and fall. All of these motions cause changes in the Earth's moments of inertia and may cause changes in the rotational speed. Seasonal variations are caused by an exchange of momentum between winds and the crust of the Earth.

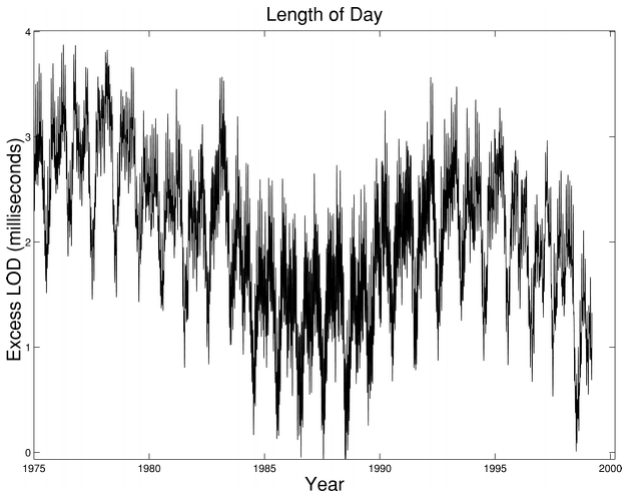

Figure 3. Excess length of day.

Changes in the total angular momentum of the atmosphere have also been shown to be correlated with changes in the length of the day. Precise calculations of the total angular momentum using global observations of the wind speed and direction have been used to demonstrate this effect. The variations in the rotational speed are apparently caused by the interaction of the winds with the Earth's topography, and may be the leading cause for all of the irregular variations in the rotation of the Earth.

Another known cause of variations in the rotational speed is tidal friction. The Moon raises tides in the ocean. Friction carries the maximum tide ahead of the line joining the center of the Earth and Moon. The resulting couple diminishes the speed of rotation of the Earth, and this reacts on the moon to increase its orbital momentum. The sum of the angular momentum of the Earth and the orbital momentum of the Moon remains constant. This produces an increase in the size of the orbit of the Moon and a reduction of its angular speed about the Earth. Tidal friction should be distinguished from actual changes in the moments of inertia of the Earth brought about by the tides.

Observations of variations in the Earth's rotation

In order to detect variations in the Earth's orientation, observations must be made from the Earth of objects located in space. These include stars, artificial satellites, the Moon and distant radio sources called quasars. These bodies provide useful reference directions with which to measure the Earth's orientation.

Stars were observed photographically for decades to determine the motion of the pole and the rotation of the Earth. Recently, more accurate methods have been devised including the use of lasers, the Global Positioning System (GPS) and radio telescopes. Laser bursts can be bounced off of artificial satellites or the Moon. The length of time to receive the reflected pulse provides information on exactly where the object is at a particular time which, in turn, can be used to determine the Earth's orientation in space.

Observations of the GPS satellites at stations participating in the International GPS Service provide estimates of the Earth's orientation with respect to the constellation of the satellites. Measurements of the length of time taken for a radio signal to travel to the observer on the Earth from the different satellites are used to locate the observer's site on the surface of the Earth as well as determine the orientation of the entire globe in the celestial reference system.

Radio telescopes can also be utilized in a technique called Very Long Baseline Interferometry (VLBI). By having several radio telescopes looking at the same quasar at the same time and recording the information that is seen at each telescope, the Earth's orientation can be determined. The recorded information then needs to be processed further before the final results can be determined. The reduction procedure involves the use of a highly specialized computer called a correlator. Once the data from a VLBI experiment have been correlated, they can be processed further to produce Earth orientation information.

Astronomical observations are made routinely by a number of observatories located around the world for this purpose. The International Earth Rotation Service (http://www.iers.org/) is the international organization responsible for the coordination of observations of polar motion and nutation as well as astronomical time. The Central Bureau is located at the Bundesamt für Kartographie und Geodäsie (BKG) Frankfurt am Main, Germany. The Sub-bureau devoted to rapid service and predictions is located at the US Naval Observatory. Observations are contributed to the IERS by observatories and laboratories around the world and treated at analysis centers. The information is recomputed twice per week and disseminated by E-mail, anonymous ftp and the world-wide web.

Polar Plumes

Polar plumes (figure 1) are thin, bright, linear structures that are seen to emanate from the poles of the Sun during the 'minimum' phase of the solar cycle, when there are well-developed polar CORONAL HOLES. They may be seen with the naked eye during a solar eclipse or at any time with coronagraph instruments sensitive to visible or ultraviolet light. When seen with visible light, they are often called 'coronal rays'.

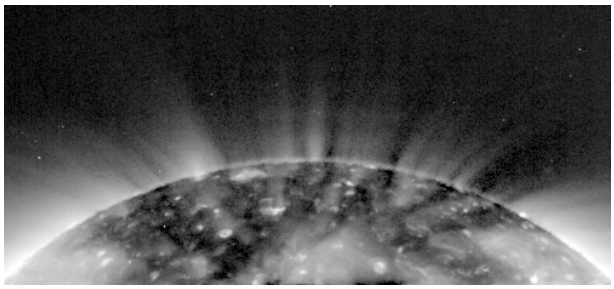

Figure 1. Polar plumes emanating from the pole of the Sun. The photograph was captured with the EUV Imaging Telescope aboard the SOHO spacecraft at Earth's L-1 point, in a cluster of spectral lines given off by Fe IX and X (Fe^{8+} and Fe^{9+}) ions. These ion species are present at approximately 0.9–1.2 million K.

Polar plumes are denser and cooler than the surrounding coronal hole material. They arise from approximately unipolar concentrations of magnetic flux under the polar coronal holes, expanding and spreading with altitude as do the holes themselves. Material is constantly accelerated along the plumes, forming part of the fast SOLAR WIND that streams from the polar coronal holes to fill most of the solar system. The plumes trace out the predominantly open magnetic field lines that connect their magnetized footpoints to the interplanetary medium. Near the limb of the Sun, they subtend about 2° relative to the center of the solar disk, but they expand superradially with altitude, subtending up to 30° at 15 solar radii above the disk in the plane of the sky. Above 25 solar radii, they fade from view, merging with the surrounding fast solar wind from other parts of the coronal hole.

Polar plumes are important to the study of the solar corona because they present the simplest, most quiescent system within the corona and because they may contribute significantly to the high-speed solar wind that fills virtually the entire solar system. Because the flux tubes that make up the plumes are magnetic open structures, no magnetic stresses can build up along their length: displacements of individual field lines are free to propagate out the top of the plume at the Alfvén speed. Without concentration via magnetic stress of the energy available from the turbulent motions of the SOLAR PHOTOSPHERE, the physical mechanisms available to heat plumes are a small, strict subset of those available elsewhere in the corona. Likewise, the unipolar nature of the overall polar fields near solar minimum ensures that

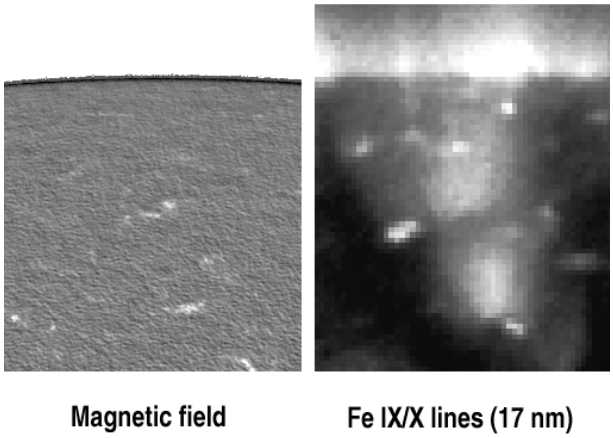

Figure 2. A close-up of a pair of polar plume footpoints from figure 1. The left panel shows the line-of-sight component of the magnetic field at the visible surface of the photosphere. The right panel shows corresponding plume structures in the corona, using spectral line emission at 17 nm. The plumes arise from unipolar magnetic structures in the photosphere; their shape is defined by the lines of magnetic force that are 'pinned' to the surface at the magnetic footpoints.

the plumes are only weakly coupled to other features in the corona, so they are well isolated from the more complex activity elsewhere. These two aspects make polar plumes a simple but important test case for our understanding of the more general problem of the coronal heat.

Overall shape and magnetic structure

Plumes take the form of tall, thin structures that follow a particular bundle of magnetic field lines from the surface out to interplanetary space. They arise from unipolar magnetic flux concentrations (i.e. magnetic dipoles with one pole buried inside the Sun and the other poking out through the photosphere). The flux concentrations are approximately 3000–10 000 km in size with typical total magnetic fluxes of 10^{19}–10^{20} Mx and peak field strengths of up to several hundred gauss. The field lines diverge rapidly at first from their photospheric roots, expanding sideways with altitude until they begin to interact with other field lines of similar polarity from elsewhere in the coronal hole (see figure 2). This initial turning point takes place between 30 000 and 50 000 km above the surface of the Sun, giving them the appearance of blunt pencils near the surface of the Sun.

At higher altitudes, the plumes expand and diverge slightly faster than radial (vertical) lines would. This is due to the fact that the entire coronal hole expands with altitude to fill the void left by closed magnetic structures (such as streamers and loops) at lower latitudes. By 4–5 solar radii (3 million km) over the surface, each polar coronal hole fills almost a complete hemisphere around the Sun, and its expansion turns radial. The plumes stop diverging, but continue expanding with altitude until ∼10 solar radii over the surface (figure 3). They have been detected as far as

25 solar radii from the Sun using long-duration exposures with space-based coronagraphs.

Plume-like magnetic flux concentrations account for approximately half of the field lines that escape from the coronal hole, although not all flux concentrations support visible plumes. Of the several hundred flux concentrations that are present at any given moment in the solar minimum coronal hole, 10–20 support bright, readily distinguishable plumes. The flux concentrations that harbor plumes are typically associated with weaker opposing flux regions nearby, suggesting that reconnection of the opposing field may be important to plume formation.

At low altitudes, the relatively strong magnetic field dominates the plasma pressure (the plasma β parameter is low), so there is little difference in shape between field lines that harbor plumes and those that do not. Because the coronal hole expands superradially with altitude to occupy approximately an entire hemisphere, and because β remains low to altitudes of several solar radii, these plume-like magnetic structures are connected to a large fraction of the volume of the solar system.

Plume density and temperature

One may determine the temperature of solar coronal features in three principal ways: through spectrography, or by measuring the Doppler broadening of spectral lines by Brownian motion of atoms in the feature ('dynamic temperature'); or by measuring the relative brightness of several spectral lines, indicating the relative abundance of different ionization species ('ionization temperature'); by measuring the rate of falloff of density with altitude, which indicates the equilibrium between gravity and the gas pressure of the plasma ('scale height temperature'). All three methods show that polar plumes are cooler than their surrounding environment at altitudes of 1.05–1.3 solar radii from the center of the Sun (50 000–400 000 km from the surface of the Sun). Spectral line width maps of the visible coronal hole, which measure dynamic temperature versus position, show that polar plumes have somewhat narrower spectral lines than do interplume regions. Ionization temperature measurements indicate that plumes have temperatures close to or under 1×10^6 K, while the interplume coronal hole may be as hot as 1.5×10^6 K. At low altitudes (<1.5 solar radii), where the plasma motion is negligible compared with the local speed of sound, plumes' scale heights are shorter than those of the surrounding interplume regions, resulting in a decreasing contrast with altitude. Above about 1.5 solar radii, the plumes are not in hydrostatic equilibrium, because the outward and upward gas flow is not negligible compared with the local speed of sound, and scale height is not a meaningful measure.

Plumes appear bright in visible light instruments such as SOHO/LASCO and the HAO Mk III White Light Coronameter located on Mauna Loa. Those instruments image visible white (continuum) sunlight that is scattered by free electrons in the corona; the amount of scatter depends only on the number of electrons and not on their temperature. The plumes must be denser than the surrounding media to be seen. Several measurements of plume density have been made using both integrated emission measure in visible and EUV images and ratios of particular density-sensitive emission lines. Near their bases, plumes are seen to be anywhere from 2 to 10 times denser than the surrounding media, with the brightest plumes perhaps 10 times denser than the surrounding coronal hole. A typical low-altitude coronal hole density is a few 10^{13} m^{-3}; the very brightest plumes may be as dense as 10^{15} m^{-3} near their bases.

The fact that plumes are cooler and denser than their surroundings indicates that they are heated principally at their bases. Heat deposited more than a few 10^5 km above the surface of the Sun would mainly increase the local temperature, yielding hot, rarefied plumes. However, heat deposited near the surface is readily conducted downward into the dense, cool CHROMOSPHERE below, causing cool material to evaporate into the corona and yielding cooler, dense plumes. In the latter case, the additional density causes the plumes to be cooler than the surrounding coronal hole, because the denser plasma radiates energy more efficiently than a more rarefied one would. Coronal plasma is cooled mainly by radiation of collisionally excited spectral lines. These lines' brightness varies as the square of the plasma density, so that the denser plumes have a proportionally higher rate of energy loss and hence a lower equilibrium temperature than does the less dense interplume plasma.

Temporal evolution

On human timescales of a few minutes to a few hours, plumes are quiescent structures: their brightness and overall shape remain almost constant over several hours. However, each plume comprises many smaller filamentary structures less than 5 arcsec (3000 km) across at the base of the plume. These smaller structures fluctuate in brightness very rapidly, lighting up and dimming in just a few minutes. A typical plume may support three to five bright filamentary structures at a time. The bright substructures are thought to be the result of numerous small magnetic reconnection events inside the base of each plume. Each entire plume stays bright for about 20–30 h at a time, which roughly corresponds to the time it takes for its plasma to cool by radiation alone. However, after a plume has vanished new plumes are seen to recur in roughly the same location on the solar surface, brightening repeatedly in the same location over periods of up to several weeks. This recurrence suggests that the field lines over a particular flux concentration on the surface are re-filled with plasma from time to time, perhaps because of reconnection with new opposing flux regions that are carried to them by the motion of supergranules in the photosphere (see SOLAR PHOTOSPHERE: SUPERGRANULATION).

Plumes support low-frequency magneto-acoustic waves that propagate upward from the photosphere into the corona. These wave fronts are quasi-periodic, coming in trains of only a few wavefronts at a time, with periods

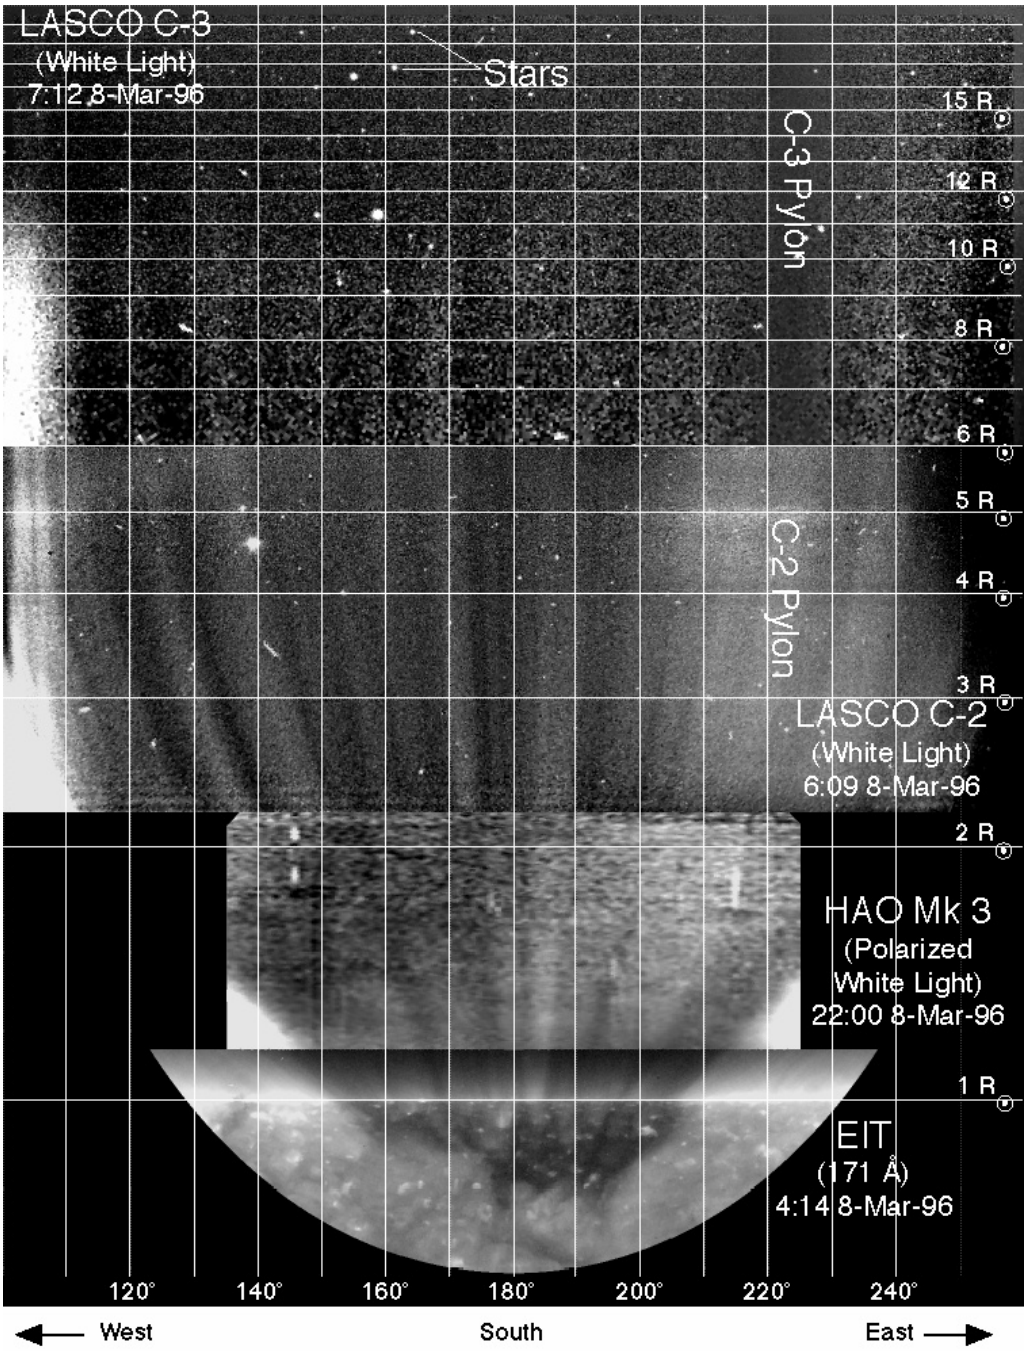

Figure 3. The plumes in figure 1 in the context of the whole corona. Data from four instruments have been combined to make this montage image, in which the horizontal direction measures azimuth around the Sun and the vertical direction measures distance from the center of the solar disk. The vertical scale is logarithmic, to show both the small roots of the plumes and their vast extensions into interplanetary space.

of 10–20 min (1–2 mHz). They have density amplitudes of up to 10%, resulting in traveling fluctuations in brightness in the extreme ultraviolet seen by spaceborne telescopes such as TRACE and EIT. The waves carry energy fluxes of about 50 W m^{-2}, or a few per cent of the energy flux (about 1 kW m^{-2}) required throughout the coronal hole to heat the corona and drive the high-speed solar wind. The origin of the waves is not known.

Connection to the high-speed solar wind

At any given time, there are only a few bright plumes in existence; these brightest plumes cannot account for more than a small proportion of material streaming out in the solar wind. However, the vast majority of plume-like magnetic structures are only slightly brighter–denser than the interplume regions between them; these fainter plumes do subtend a significant part of the solid angle in the coronal hole, and in turn must make up a large fraction of the solar wind. Hence, understanding solar wind flow in polar plumes is important to the broader problem of understanding the high-speed solar wind.

With the advent of both stable coronagraphs and accurate coronal UV spectrometers aboard the SOHO spacecraft, it has been possible to place limits on the flow speeds inside polar plumes. Direct Doppler measurements by the SUMER instrument of spectral lines emitted by the magnesium IX and oxygen V ion species in the lower corona show that plumes' outward flow is very subsonic in the lower reaches of the coronal hole: 150 Mm above the surface, SUMER measurements constrain the radial outflow speed to less than 30 km s^{-1}. Higher up, about 1 solar radius over the limb of the Sun, Doppler dimming measurements with UVCS show outflow speeds of 100–200 km s^{-1}, indicating that the sonic point occurs between 1 and 2 solar radii over the limb (2 and 3 solar radii from disk center). This rapid acceleration cannot be explained by hydrostatic forces alone; some other form of momentum transfer, such as waves launched from the photosphere or chromosphere, must be at work.

Because plumes appear to extend well into the outer corona, one might expect traces of them to remain in the high-speed solar wind at interplanetary distances. The Ulysses spacecraft has flown over the poles of the Sun, sampling the solar wind throughout the coronal hole at latitudes from 0° to over 80° at distances greater than 1 AU. Fluctuations in the density of the solar wind are seen on timescales of about a day, suggesting that the traces of plumes may survive as coherent structures to distances of more than 1 AU from the Sun itself. There is no direct evidence that the density fluctuations are actually polar plumes, in part because there was no spaceborne coronagraph in operation to compare with the *in situ* data during Ulysses' first overflight of the poles. The frequency spectrum of the fluctuations shows no major features at particular timescales and does not vary strongly with latitude within the coronal hole. This pattern could result either from randomly sized plume-like structures in the heliosphere or from time-dependent fluctuations in the solar wind itself. Whether or not the plumes survive to high heliographic altitudes, and how much they affect the solar wind, are important unanswered questions.

Polar Ring Galaxies

Polar ring galaxies are peculiar objects in the sky, composed of a primary galaxy disk and a ring of stars orbiting in a plane almost perpendicular to the primary disk (i.e. almost polar). The prototype of these peculiar galaxies is NGC 4650A, in figure 1.

Polar rings are most often found around early-type galaxies, essentially classified lenticular (or S0) in the Hubble sequence (see HUBBLE CLASSIFICATION). In very rare cases, these rings have been found around flattened ELLIPTICAL GALAXIES and, even less frequently, around late-type SPIRAL GALAXIES, which are gas rich themselves. In those cases, they are not well relaxed and are still composed of many tilted rings, in the process of settling to some symmetry plane in the potential of the primary galaxies (e.g. the Spindle galaxy NGC 2685, or NGC 660).

Spectroscopy has shown that the two disks are rotating and that their axes of rotation are almost perpendicular. In the most frequent cases, the polar rings have radii larger than the main galaxy (they are then more detectable); when there is gas in the two systems, they are never at the same radii, since gas cloud collisions will scatter them apart.

Note that a certain class of rare ringed galaxy could also be related to polar ring galaxies, those possessing only one broad ring around a central unbarred disk. The prototype is Hoag's object (figure 2), also called the 'bull eye'. We would then observe the central early-type galaxy end on, and the polar ring face on. The much more abundant barred galaxies possessing one or more resonant rings can be explained easily by the action of the bar. Also, head-on collisions between two galaxies can develop in the disk of each of them a density wave propagating radially as a ring. The prototype is the well-known CARTWHEEL GALAXY. These are recognizable from polar rings, since the galaxy nucleus is off-centered with respect to the ring.

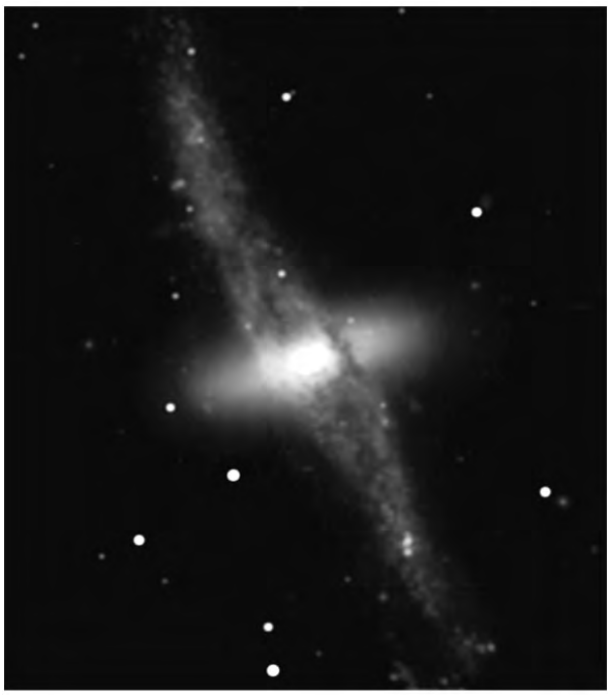

Figure 1. Prototype of the polar ring galaxies, NGC 4650A, a southern sky object in the constellation of Centaurus. Two components can be seen: a primary disk galaxy, oriented almost horizontal in this picture, which is of lenticular type, and an extended ring-like distribution of stars, almost perpendicular to it, which is called the polar ring itself. The latter looks younger, with an irregular and clumpy shape, containing gas and dust, while the primary disk is old, smooth, and mostly stellar. (Photograph from VLT ESO-Press Release 19/98.)

Origin of these galaxies

The existence of two systems with almost perpendicular directions of rotation is not possible without a secondary event in the formation of the system, such as a galaxy interaction or merger. When a galaxy forms, it is composed essentially of gas, and, through dissipative processes, this gas settles in a disk, perpendicular to the average angular momentum of the system (see GALAXY FORMATION, GAS IN GALAXIES). Clouds of gas with other directions of rotation lose their misaligned angular momentum in collisions that mutually re-orient their orbits. The equilibrium state is a disk of gas in rotation, in which stars form progressively, consuming the gas. All the matter is rotating in the same sense.

However, galaxies form in a hierarchical way: they are formed in groups, that belong themselves to clusters, then superclusters, etc.... Galaxies are not distributed homogeneously in the sky, and they have frequent gravitational interactions that lead to mass exchange and mergers. A merger between two galaxy disks, with different angular momenta, is the way to build polar ring systems. When a small galaxy companion is tidally destroyed and swallowed by the primary galaxy, the stellar component is heated and spread all around, since stars cannot collide and dissipate energy. The gas on the contrary can dissipate its energy and fall inside the potential well of the primary galaxy. It settles into a disk, perpendicular to the average angular momentum, as in the case of first formation, and, in general, it becomes aligned in the equatorial plane of the primary galaxy. In rare cases, however, there exists a stable polar orbit, where the gas can be trapped. If the gas disk then formed is massive enough, it changes the gravitational potential in its vicinity, which stabilizes the new disk. Stars can then form in this perpendicular disk, and a polar ring system is born. In most of the polar rings known, stars in the polar disk are a few Gyr old, demonstrating the age and stability of the system.

The formation of a polar ring is rare, since most of the time mass is accreted in the symmetry plane of the primary galaxy, sometimes in a sense opposite to the primary sense, forming a galaxy with two counter-rotating streams of stars. Also, polar rings are difficult to detect,

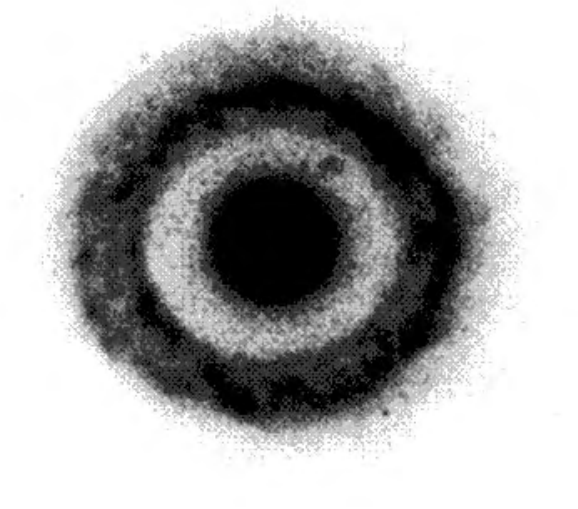

Figure 2. Photograph of Hoag's object, the 'bull eye', showing the central core and surrounding broad ring. The size of the ring is about 15 kpc. Objects of this type have been suggested to be polar rings seen face on. (From Schweizer *et al* 1987 *Astrophys. J.* **320** 454.)

since they are conspicuous only for special viewing angles (see figure 3), when the polar ring appears nearly edge on. The percentage of polar ring systems observed at the present time is about 0.5%, and taking into account the viewing selection bias, together with other factors (such as dimming or short lifetime of the rings), it is estimated at 5% in reality. This percentage should have been even higher in the past, since the rate of galaxy merging is predicted to peak at about one-third of the universe's age, in modern cosmological formation scenarios (see GALAXIES: INTERACTIONS AND MERGERS).

Stability

If the ring is not too massive, and the orbiting matter can be considered as test particles in the potential of the main galaxy, it must evolve quite rapidly, through differential precession. The rings are not exactly polar (tilted by about 20° from the pole), and therefore do not lie in a symmetry plane of the inner galaxy. The gravity field is not spherical, since the primary galaxy is flattened, but has a quadrupole moment, which produces a torque on particles in the ring, causing their orbit to precess. The precession rate depends on the orbital inclination and radius of each particle and is differential, since all particles do not precess at the same rate (the ring is broad and spans a significant range in radius). Then, it can be computed that the polar ring should look warped and twisted in much less than a Hubble time, since the particles in the ring acquire orbits with different orientations according to their radius.

This is a dynamical puzzle, since most present-day polar rings are flat, but also because the gas clouds will collide and dissipate when the disk is twisted and warped,

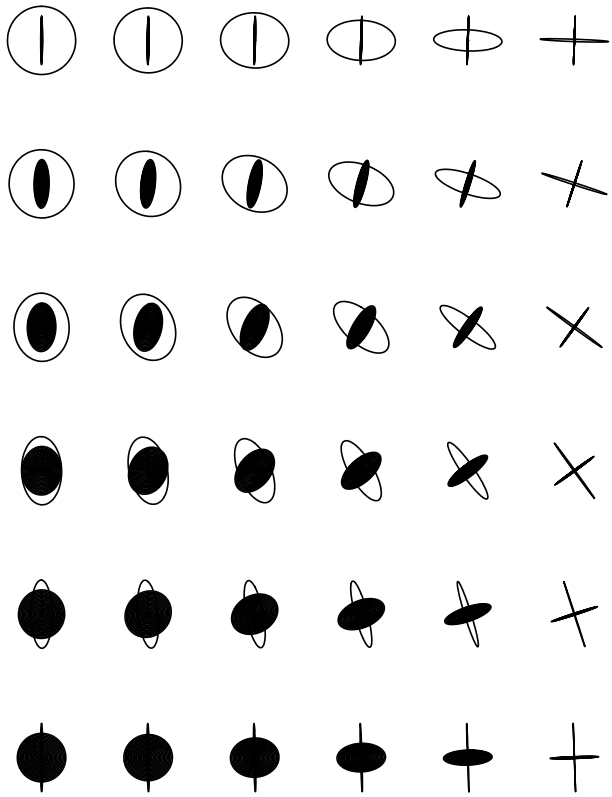

Figure 3. Schematic representations of a polar ring galaxy, as seen from different viewing orientations. The full disk represents the primary (lenticular) galaxy, and the thin ellipse, the polar ring itself. Note that, in the majority of cases, it is difficult to identify the projected system as a polar ring galaxy, the most favorable cases being the two systems nearly edge on.

and rapid inflow and settling to the equatorial plane will follow. The gas will not have time to form a disk of stars, as is observed.

A solution to this problem is that the polar disk is warped in such a manner that the tilt with respect to the pole compensates the decrease of the torque with radius: the polar disk is slightly tilted towards the pole at large radius. Also, the self-gravity of the polar disk produces compensating torques that stabilize the polar ring. In any case, if the ring is too broad, it can break up in a number of subrings that will precess independently. The inner rings will precess more rapidly and settle to the equator, allowing the remaining outer ring to become more polar and more stable.

The 3D shape of dark matter halos

Polar ring systems are very useful, since they give us the possibility not only to test galaxy formation scenarios but also to probe the dark matter distribution around galaxies (see DARK MATTER IN GALAXIES). Indeed, we know from the rotation curves of spiral galaxies, that they are embedded in dark matter halos. In particular, the interstellar gas that can extend in radius much farther than the stars in a

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

galaxy disk is observed to rotate around the center at a high velocity. For this gas to be in rotation equilibrium requires a lot more mass in the disk than is visible by radiation. In other words, there must exist some dark mass that is detected only through its gravitational action.

Since the gravitational action of the dark matter is usually known only in the galaxy disk, through measurements of velocities here, we cannot know the 3D shape of the dark matter distribution: is it a spherical halo or a dark matter disk or has it some flattening in between? The answer to this question will considerably help to determine the nature of dark matter. If it is a non-baryonic exotic particle, interacting only gravitationally with ordinary matter, than it is not dissipative, and cannot be flattened as a disk. On the contrary, a distribution of dark baryons could be more flattened.

In polar ring systems, matter is rotating in two perpendicular disks, allowing us to probe the rotational velocity outside the main disk, in the dark matter halo. This is the occasion to deduce the 3D shape of dark halos. The problem is, however, more tricky to solve than expected. First, there is a selection bias to detect polar ring systems where the polar disk is bright enough: in that case, it is also massive enough to perturb the gravity field and mask the true dark halo potential. In the case of NGC 4650A, for instance, when all the mass is added (gas and stars), the polar accreted disk is almost as massive as the primary visible disk. The mass ratio is so extreme that one has proposed the opposite scenario, where the primary disk is the 'polar ring' and the accreted object is the lenticular old galaxy in the middle.

Second, in general, the polar system is outside and not overlapping with the inner disk, and the velocities in perpendicular planes are not known at the same radii. Extrapolations are therefore required, which are model dependent. This is true in particular when there is gas in both systems, although gas velocities are more precise.

Third, because of the flattened nature of the potential (at least due to the visible mass), there is no matter in circular orbit anywhere in the system (neither in the primary disk, which is no longer axisymmetric, owing to the mass of the polar ring, nor in the polar ring itself). Orbits are all elongated and explore a large range of radii. They must be modelled through shooting techniques and depend on the mass distribution in a complicated way.

Finally, it is also possible that the dark matter, if not spherical, is flattened around the polar disk and not around the primary disk. This has been shown to be a viable model for NGC 4650A in particular. In summary, polar ring galaxies carry a real hope that they will allow the 3D shape of the dark matter halos (and clues to their nature) to be determined, but precise spectroscopy and photometry data are needed to constrain the models, together with further exploration of the many possible models.

Polarimetry: Imaging Polarimetry

Knowledge of the POLARIZATION state of radiation provides far more astrophysical information than intensity alone. Although the degree of polarization can be small, its measurement is relatively straightforward and it can reveal the underlying nature of sources such as young stars and the nuclei of active galaxies that are often hidden from our direct view.

Outline of the article

Our knowledge of the universe comes almost entirely through observing the ELECTROMAGNETIC RADIATION emitted from the great variety of objects contained within it. Yet measuring just the intensity of that radiation, whether it be its spatial variation or spectral composition, gives only a fraction of the information that is potentially available. This article gives a more complete description of light, by including its polarization properties, and then outlines the main physical processes responsible for producing polarized radiation in astronomy and the way it can be used to understand astrophysical processes. The basic components of an astronomical polarimeter are introduced followed by some recent results from astronomical research based on imaging polarimetry.

Basic physics

All electromagnetic radiation, from radio through to γ-rays, consists of an oscillating electric and magnetic field, with both oscillations transverse to each other and to the direction of propagation of the radiation. The polarization state of the radiation is, by convention, defined by the behaviour of the electric field. In the case of unpolarized radiation, the electric field orientation behaves in a random manner. For polarized radiation, the tip of the vector that represents the instantaneous electric field traces out an ellipse, a circle or a straight line, and the radiation is said to be elliptically, circularly or linearly polarized, respectively, with circular and linear polarization being particular cases of the more general elliptical form.

Degrees of polarization p can take any value from 0 to 1, and thus a mathematical description is required that can accommodate zero, complete and partial polarization. The most convenient and most widely used parametrization is due to Sir GEORGE STOKES, who used a 4-vector representation of radiation with components I, Q, U and V.

The link between the Stokes parameters and the geometry of a polarization ellipse is given by

$$I = a^2 \qquad Q = a^2 \cos 2\beta \cos 2\theta$$

$$U = a^2 \cos 2\beta \sin 2\theta \qquad V = a^2 \sin 2\beta$$

where a represents the ellipse size, $\tan\beta$ the ratio of the minor to major axes ($\beta = 0$ for linear and $\pi/2$ for circular polarization) and θ is the orientation of the ellipse. For linear polarization the ellipse collapses to a straight line and θ is known as the position angle of polarization, essentially giving the preferred angle of the radiation's electric field, as projected onto the plane of the sky. By convention this is measured from north, with increasing values rotating eastwards.

The degree of polarization p, linear polarization $p_{\rm lin}$, circular polarization $p_{\rm circ}$, polarized intensity $I_{\rm p}$ and θ are given by

$$p = \frac{(Q^2 + U^2 + V^2)^{1/2}}{I} \qquad p_{\rm lin} = \frac{(Q^2 + U^2)^{1/2}}{I}$$

$$p_{\rm circ} = \frac{V}{I} \qquad I_{\rm p} = Ip \qquad \theta = 0.5 \tan^{-1}\left(\frac{U}{Q}\right)$$

and the sign of V gives the handedness of the circular polarization.

Producing polarized radiation

Some physical processes directly produce polarized radiation. The main examples of these intrinsic processes are cyclotron radiation, which is circularly polarised and produced by the motion of non-relativistic electrons in a magnetic field, and SYNCHROTRON RADIATION, which is linearly polarized and produced by relativistic electrons in the presence of a magnetic field, with the polarization perpendicular to the magnetic field.

More commonly, polarized radiation is produced in secondary processes through the interaction of radiation with matter. For example, scattering off electrons (Thomson scattering) or dust grains whose size is small compared with the wavelength of the radiation (Rayleigh scattering) produces linear polarization, with the degree of polarization $p = (1 - \cos^2\theta)/(1 + \cos^2\theta)$, where θ is the angle through which the radiation is scattered. In both cases the direction of the electric vector is perpendicular to the scattering plane, the plane containing the incident and scattered light, and the degrees of polarization are independent of wavelength. For larger grain sizes (the so-called Mie regime for spherical particles), the scattering becomes more complicated and the degrees of polarization are generally smaller.

Polarized radiation as a diagnostic tool

The detection of scattered (polarized) light is a very important diagnostic tool in astrophysics. It allows regions to be observed that are normally obscured from direct view. Examples are young stars and ACTIVE GALACTIC NUCLEI (AGN), with both surrounded by optically and geometrically thick DUSTY CIRCUMSTELLAR DISKS (see figure 1). These disks obscure the central source unless our view is within typically $\sim 30^\circ$ of the normal to the disk plane (the disk polar axis). Optical and near-infrared radiation is unable to penetrate the dust but can escape along the poles of the disk and is then scattered to us by particles located along the polar axis of the disk. These particles are mostly dust grains in the case of young stars and electrons in the case of AGN. The scattering of light, above and below the plane of the disk, produces a REFLECTION NEBULA

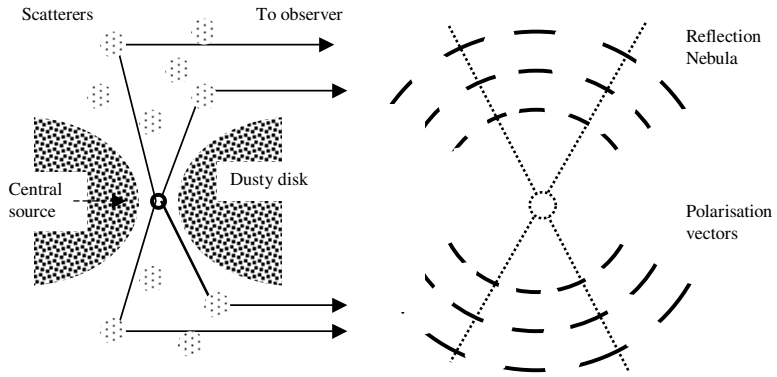

Figure 1. Light scattered from a central source is scattered to the observer by particles located along the poles of the obscuring disk. The reflection nebula is observed as a centrosymmetric polarization pattern with the length of each vector representing the degree of polarization and the direction of the line the position angle of polarization. The intersection of the normals to the polarization vectors (shown by dotted lines) gives the location of the illuminating source.

with observed polarizations ranging typically from a few per cent to 50%.

The scattered (polarized) flux in the reflection nebula gives the spectrum of the obscured source, although this will be modified if the scattering is off dust grains (in the Rayleigh domain, the scattered flux $\propto 1/\lambda^4$), but is unchanged by electron scattering. The degree and position angle of polarization give the geometrical relation between the source and scatterers relative to the observer, e.g. the inclination and position angle of the polar axis respectively, as well as providing the location of the illuminating source, given by the intersection of the normals to the polarization vectors. Importantly, polarimetry is able to provide geometrical information on scales that could never be spatially resolved directly at optical or infrared wavelengths, even with the largest telescopes.

In many astrophysical situations light is scattered more than once, and the scattering of linearly polarized radiation off non-Rayleigh particles produces circular in addition to linear polarization. Whereas linear polarization is dominated by the last scatter, circular polarization depends on the initial polarization state of the last-scattered photon and hence provides information on the previous history of that photon. Typical degrees of circular polarization produced by dust scattering are $\sim$2%, or less, presenting a significant technical challenge.

Circular polarization is also produced by the scattering of radiation (of any state) off aligned non-spherical grains. Dust grains can be aligned in many situations, and provided that the grains are paramagnetic they will always align themselves with their short axis parallel to the local magnetic field.

Grains in the interstellar medium (ISM) are aligned, and radiation from any astronomical source, in passing through the ISM, is polarized by dichroic absorption, i.e. the differential extinction of the light, with polarized components parallel to the long axis of the grain being preferentially absorbed. This produces a polarization with the electric field vector parallel to the magnetic field and can be used to measure the direction of the fields. Dichroic absorption is the same process that filters polarized light in sheet Polaroid. Warm dust grains will also emit radiation (at wavelengths longer than a few microns), and if they are aligned the radiation will be polarized perpendicular to the magnetic field.

Measuring polarization

Most imagers and spectrometers can be converted to polarimeters by the addition of two standard optical components. The first is some form of modulator, which is usually a waveplate (also known as a retarder), and the second an analyzer.

Both components are made from a birefringent crystal such as quartz or magnesium fluoride. Birefringent crystals have the property that the speed of light in the crystal depends on the direction of propagation and the polarization of the light. However, they do have one axis, known as the optical axis, along which all light—irrespective of the polarization state—travels with the same speed.

A birefringent crystal has two refractive indices (n_1 and n_2, with $n_1 - n_2$ known as the crystal birefringence), and light incident on a crystal surface, that is neither parallel to nor perpendicular to the optic axis, is doubly refracted. This is best understood by noting that, for polarized radiation, the electric field consists of two orthogonally polarized components which are refracted through different angles, producing two separate beams of light with orthogonal polarizations. This is the basis of the polarization analyzer.

If light is incident normally on a crystal, with its optical axis parallel to the crystal surface, the two light components coincide but there is a phase difference or retardance between them. If the difference in crystal optical thickness $d(n_1-n_2)$, where d is the crystal thickness, is exactly one-half or one-quarter of a wavelength then the

Dirac House, Temple Back, Bristol, BS1 6BE, UK

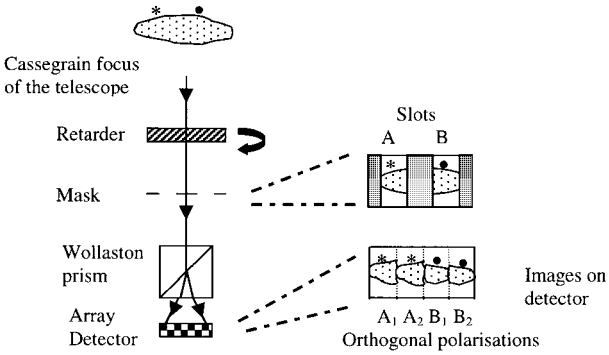

Figure 2. Typical polarimeter system used in optical and near-infrared imagers.

crystal is known as a half-wave and quarter-wave retarder respectively.

For measuring linear polarization a half-wave retarder is used. When rotated in the telescope beam it rotates the radiation's plane of polarization through an angle twice the mechanical rotation. Following the modulator is the analyzer (here a Wollaston prism, see figure 2). The intensity of the emergent, orthogonally polarized, beams depends on the direction of the electric field of the light incident on the analyzer.

As the half-wave retarder is rotated, the electric field of the emergent light rotates. On passing through the analyzer two light beams are produced with their relative intensity depending on the angle of the retarder. The two light beams are then recorded on an array detector. For light that is unpolarized no change in light intensity will occur as the waveplate is rotated, whereas if the light is 100% polarized the two beams will each have zero intensity for positions of the retarder separated by 45°.

The most common polarizers are calcite plates, which produce a lateral separation of the two beams equal to one-tenth of the calcite thickness, and Wollaston prisms that produce an angular divergence given by $2(n_1 - n_2)\tan\Omega$, where $n_1 - n_2$ is the birefringence of the prism material and Ω is the prism angle.

Exposures are normally taken with the retarder at 0°, 22.5°, 45° and 67.5°, where 0° is along the equatorial north–south direction. The Stokes parameter Q is calculated from the relative difference between the intensities of the two beams with the retarder at 0° and 45°, and U is calculated from the relative difference with the retarder at 22.5° and 67.5°. In principle, only the 0° and 22.5° positions are required but the 45° and 67.5° exposures provide some element of redundancy and also allow corrections for any difference in sensitivity between the two beams.

Essentially the same procedures are used for measuring circular polarization except that a quarter-wave, rather than a half-wave, retarder is used. The action of this retarder is to convert the circular polarization to linear, which is then analyzed.

In an imaging polarimeter, the two beams form two images on the detector, with both images representing the same area of the sky. A focal plane mask has to be employed to prevent overlap of these images and thus loss of all the required information (see figure 2).

Results from imaging polarimetry

(a) Studying reflection nebulae around young stars, embedded in dusty molecular clouds, has been one of the major uses of imaging polarimetry at optical and particularly near-infrared wavelengths. Up to the mid-1990s all measurements were of linear polarization. The degrees of polarization give the inclination of the system to our line of sight, the symmetry axis of the polarization pattern gives the position angle of the normal to the circumstellar disk and the wavelength dependence of polarization gives the size of dust grains responsible for scattering the light to us.

More recently, circular imaging polarimetry has been introduced. The degrees of circular polarization, produced by multiple scattering, are usually small (<2%), but nonetheless give important information on scatters close to the source, including in the circumstellar disk. Combined with the linear polarization, this technique provides far more information on grain composition and sizes.

For some high-mass star-forming regions very high degrees of circular polarization have been reported (∼20%). This is most likely produced by scattering off dust grains that have been aligned by magnetic fields in the region. Such high values, in a star-forming region, add weight to the suggestion that homochirality, the (left)-handedness of the amino acids of all living organisms on Earth, has an extraterrestrial origin, with the selective destruction of the other (right)-handed molecules by circularly polarized light.

(b) Imaging polarimetry of ACTIVE GALAXIES, in the optical and near-infrared, has been used to study those cases where the nucleus, presumed to be a massive black hole fuelled via an accretion disk, is obscured by direct view by an optically and geometrically thick torus (type II AGN). The spectrum of scattered light reveals the nature of the obscured source and its spatial distribution gives the geometrical distribution of the scatterers.

Light scattered from material along the torus polar axis (pointing away from us) is obscured by the torus. Hence the torus itself can be viewed in silhouette, back-illuminated by the scattered flux, and its size and inclination determined.

(c) Imaging polarimetry of galactic disks is used to map the galactic magnetic field structure, with the polarization presumed to arise from dichroic absorption at optical and near-infrared wavelengths, although contributions from scattered radiation can cause confusion. A more powerful technique is imaging polarimetry at radio wavelengths where the polarization is produced by synchrotron emission from charged particles, moving in the galactic magnetic field, with the electric field perpendicular to the direction of the magnetic field. At radio wavelengths scattering is unimportant.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

(d) Polarization images in the mid- and far-infrared of the central regions of the Galaxy, and some star-forming regions, have been obtained. Here the polarization is due to thermal emission from dust grains aligned by the ambient magnetic field and the position angle of polarization is at right-angles to the projected field direction. The mechanisms involved in STAR FORMATION are a major unsolved problem in astrophysics and this technique is at present the only one capable of studying the magnetic fields in the dense, neutral, molecular clouds where stars form.

Polarimetry: Spectropolarimetry

Spectropolarimetry is an observational procedure in which the POLARIZATION characteristics of the light from an object are measured as a function of WAVELENGTH. Modern spectropolarimeters are capable of measuring not only the wavelength dependence of linear and/or circular polarization but also the total intensity of light at the same spectral resolution. In fact many spectropolarimeters are constructed by retrofitting a module containing the polarization optics to an existing spectrograph. The technique is most useful in objects that show relatively rapid changes in polarization with wavelength; otherwise imaging polarimetry (see POLARIMETRY: IMAGING POLARIMETRY) may suffice.

Polarization is caused by anisotropy. This can be the simple geometry of scattering from electrons, dust or molecules or it can be the direction of a magnetic field. Spatial resolution in astronomy is always at a premium, and complex geometries often go unrecognized because they cannot be seen directly. Polarimetry in general, and especially spectropolarimetry, can give information on spatially unresolved geometries in objects which would be nearly impossible to study with conventional techniques.

Spectropolarimetry has been used to discover hidden regions in the nuclei of active galaxies, study the asymmetric winds of stars, find parent stars of Herbig–Haro objects, separate reflected emission from emission produced *in situ* in the lobes of nebulae and characterize the magnetic fields of white dwarfs, among other things.

Polarization analyzers

Different wavelengths require different solutions to the measurement of polarization. For example in the x-rays Bragg scattering may be used. This article concentrates on UV–optical–IR applications. The simplest form of polarization analyzer is a material that preferentially absorbs one sense of polarization and which can be rotated in front of the detector. This is analogous to rotating a camera's polarizing filter in front of the lens to change the contrast of the sky in a daylight scene or reduce the reflection on a lake's surface.

Almost all spectropolarimeters, however, use some sort of optic (the *analyzer*) that can split light into two beams of opposite linear polarizations[1], plus some mechanism (the *modulator*) for changing the relationship between the analyzer and the incoming light. In *dual-beam* instruments the analyzer outputs, and the detector records, two orthogonally polarized beams. The calibrated intensities of the two beams are compared, and the difference implies the polarization level. In *single-beam* instruments one of the polarization senses is discarded, either by absorption within the analyzer or by instrument design, and two separate measurements must be made to determine one sense of polarization. In this case the modulator is necessary to present the polarization sense differently to the analyzer. In practice some number of inherently redundant measurements may be made, in either technique, in order to remove other effects within the system, such as drifting gains, changing backgrounds, etc.

Many analyzers use the intrinsic birefringence of some crystals, most notably calcite, magnesium fluoride and quartz. Sapphire and lithium niobate are common choices in the infrared. In birefringent crystals the different linear polarizations have different refractive indices. Light will naturally separate into two side-by-side beams in such crystals, although the separation of the beams is sometimes inadequate for use in real instruments. In analyzers such as the Glan–Taylor (or Glan–air) and Glan–Thompson prisms, one polarization undergoes total internal reflection at an interface, effectively separating it from the other polarization, which passes through the interface. In single-beam instruments the separated beam is discarded; in dual-beam instruments both beams are used. These analyzers can have relatively large beam separations and are achromatic over wide wavelength ranges.

In instruments that use smaller beam deviations, a 'comb dekker' is often used. This consists of alternating clear and opaque strips, each roughly one beam separation wide. This allows the second, offset beam from one clear strip to fall on a part of the detector that normally would be illuminated by the first beam of the adjacent opaque strip. A comb dekker allows relatively thin analyzers to cover large fields of view, but effects from the edges of the strips often further reduce the field available in a single image.

Polarization modulators

The modulator is also required to measure the other sense of polarization using the same analyzer. Sometimes the entire instrument may be rotated, but more common is the use of a *wave plate*. These are typically two or more birefringent materials combined to provide either a half wave or quarter wave of phase difference between the two polarization senses. A half-wave plate will rotate the plane of polarization of linearly polarized light; hence a rotating half-wave plate is a common component of a linear spectropolarimeter. A quarter-wave plate can be used to convert linearly polarized light to circularly polarized light and vice versa.

Wave plates are often designed to work over a large range in wavelength. Materials with different birefringent properties can be combined to produce achromatic or even 'superachromatic' wave plates, similar to the way in which different lens materials are combined to produce achromats or apochromats in lens design. The 'Pancharatnam' design, which uses six pieces of two different materials, is the most popular form of 'superachromatic' wave plate design. It is used in instruments which span a factor of 4 in wavelength coverage, such as optical spectrographs working from 3000 Å to 1.2 μm.

[1] Outside of the realm of radio astronomy, there are few analyzers that can efficiently split *circularly* polarized light.

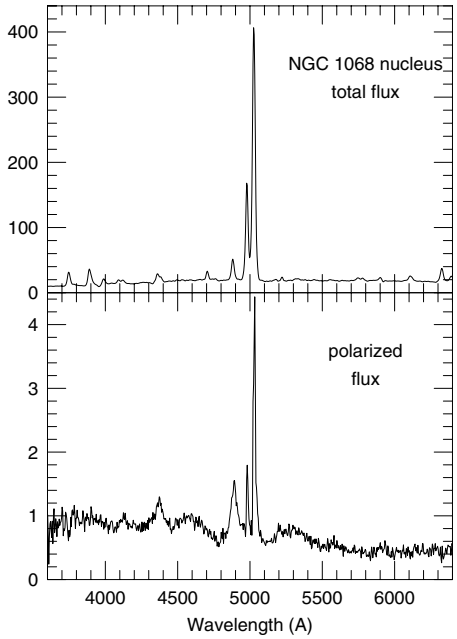

Figure 1. Spectropolarimetry of NGC 1068. In total flux (top panel) the spectrum shows relatively narrow emission lines. In polarized flux (bottom panel), however, the spectrum looks quite different, with broad permitted lines and strong blends of Fe II emission, both characteristic of high-density regions. In total flux NGC 1068 was classified as a Seyfert 2 galaxy, while in polarized flux it would be a Seyfert 1.

Applications of spectropolarimetry

$P(\lambda)$ is particularly powerful when emission or absorption features are expected to show some polarization signature. It allows understanding of the geometry and kinematics of regions separated by angular distances far smaller than the diffraction limit of the telescopes.

A dramatic example comes from the field of research into ACTIVE GALACTIC NUCLEI (AGN). In many AGN our view into the center of the nucleus is blocked. Yet the nucleus is bright enough that its light reflects off surrounding material—dust and electrons—that we can see. Since reflection generally polarizes light, the light from the blocked nucleus is polarized. Light generated in the outer, unblocked regions seen directly is unpolarized; hence spectropolarimetry provides a way of separating the two. Normal spectroscopy may be overwhelmed by light from the regions in direct view and show little evidence of the obscured region.

Such 'mirrors' into hidden regions will also impart their own signature on the polarized spectrum. Electrons, for example, have a scattering cross-section independent of wavelength and will not change the overall shape of the scattered spectrum. Hot electrons will also broaden spectral features. Dust grains tend to 'bluen' the spectrum, having a scattering cross-section that rises towards the blue. The velocity of the mirror can be revealed as a wavelength shift between polarized and unpolarized spectral lines.

These effects can be seen in figure 1, spectropolarimetry of the Seyfert 2 galaxy NGC 1068. A normal spectrum, shown in the top panel, displays relatively narrow emission lines of hydrogen, oxygen, nitrogen, sulfur, etc. The polarized flux spectrum at bottom shows a large broad component to the Balmer lines and strong emission of Fe II, something not obvious in the top spectrum.

If the scatterers are flowing toward or away from the light source, we have a 'moving mirror', in which the emission features in the source are Doppler shifted by two effects: the mirror moving relative to the source itself and the mirror moving relative to the observer. For an outflow velocity, $V(\text{out})$, of the scatterers, the observed Doppler shift is given by

$$V(\text{obs}) = V(\text{out}) - V(\text{out})\cos\theta(\text{obs})$$

where $\theta(\text{obs})$ is the observation angle, 0° if the mirror is moving directly towards us, 180° if it moves away from us. The first term is simply the mirror-source Doppler shift, while the second is the mirror–observer shift. Note that when the mirror is moving towards us the Doppler shift is small, and when the mirror moves away from us the shift is largest. Realistic situations, in which the outflow covers a range of angles, require integration of the polarized flux as a function of velocity, favoring velocities closer to $V(\text{out})$ because forward and back scattering generally show low polarization compared with scattering at 90°.

Some types of stars show features similar to active galaxies, albeit on a smaller scale. An interesting case is GL 1403, a cool, highly polarized carbon star. Figure 2 shows its unusual polarization spectrum. The polarization is high towards both the blue and the red, but drops to

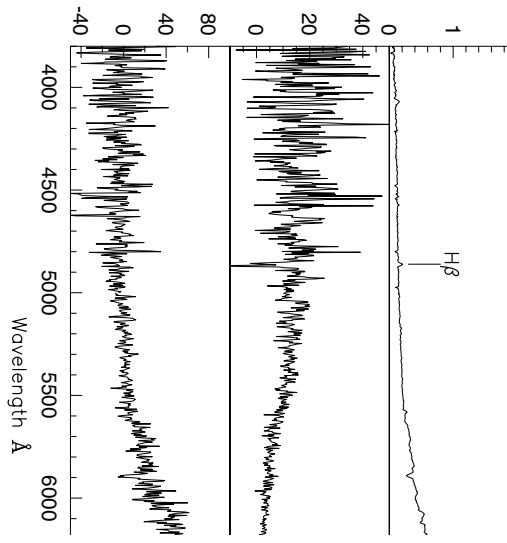

Figure 2. The very red carbon star GL 1403 shows strong polarization at both the b
between. Coincident with this drop is a dramatic swing in the angle of polarizatio
borne out by HST imaging. In the red one sees light reflected by the equatorial tor
dust in the torus becomes opaque, and instead one sees light dominated by scatter

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

nearly zero in between. At this minimum, the polarization position angle swings through a nearly 90° change.

The interpretation of this spectrum is that in the blue we see scattering of light from the star, hidden by an equatorial torus, much the same as in some active galaxies. Towards the red, however, the dust in the torus becomes progressively less opaque, until we finally can see in to the stronger scattering occurring within the torus itself. The polar scattering seen in the blue occurs at a 90° angle to the scattering in the torus seen in the red, hence the position angle swing. High spatial resolution images using HST have confirmed that the blue image of the nebula is extended more or less orthogonally to the red image.

Spectropolarimetry has also been used to determine the parent stars of HERBIG–HARO OBJECTS AND EXCITING STARS (HH objects), small gas blobs ejected from the vicinity of young stars. Quite often the young stars are obscured by their parent molecular cloud. They also tend to lie in regions with many other stars, so that infrared surveys that might penetrate the surrounding dust in fact show a number of stars, any one of which might be the HH object's parent. When the spectrum of the HH object contains enough light reflected from its parent, the angle of polarization indicates the direction in which the parent lies (with a 180° ambiguity). Further, the polarized flux will give a spectrum of the hidden parent, providing some information on its spectral type, activity, etc. Note that measurements of the PROPER MOTION of the HH object supply similar directional clues, without the 180° ambiguity inherent in the polarization measurements. Of course, the proper motion data do not give any indication of the type of star.

Another common scenario is light passing through nonspherical dust grains, which are magnetically aligned by the local magnetic field (see INTERSTELLAR GRAINS). The asymmetry leads to scattering of the light that prefers one polarization sense over another. The transmitted light is hence polarized, at a level dependent on the shape, size and composition of the dust grains and the efficiency of the alignment mechanism. This 'dust transmission' polarization is accompanied by reddening, and in most cases is small. In our Galaxy an empirical upper limit to the polarization is given by $P(\max) \times 9\%\ E(B-V)$. As a function of wavelength the polarization shows a convex curvature, with the peak polarization typically occurring at visual wavelengths near 5500 Å. The peak can be shifted towards the red for dust grains larger than typical and to the blue for smaller grains. Except for interstellar absorption lines, the shape of $P(\lambda)$ is smooth and can be studied using multicolor imaging polarimetry as well as spectropolarimetry. However, there have been notable cases in which broadband polarimetry has misled researchers into thinking they were seeing polarization by interstellar dust, when in fact a far more complicated situation was revealed by spectropolarimetry.

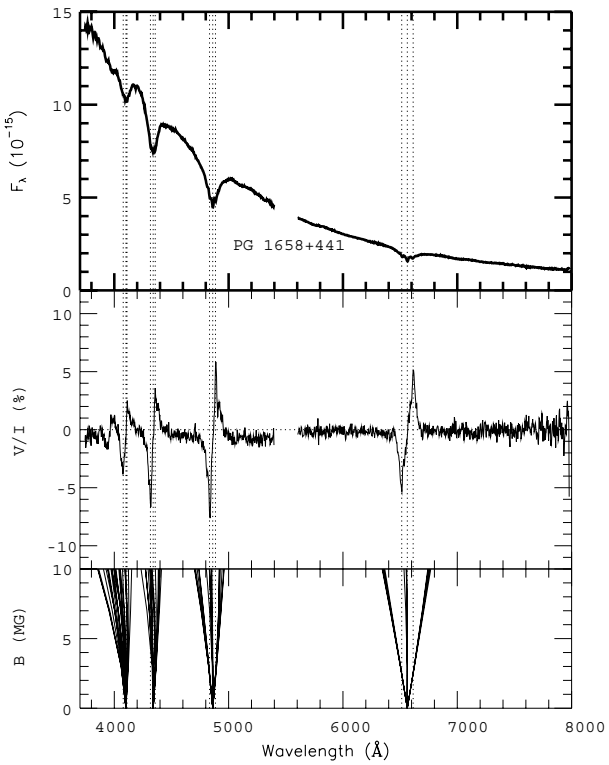

Figure 3. The white dwarf PG 1658 + 441 shows only broad Balmer absorption lines in total flux (top panel). Circular spectropolarimetry, however, shows that some of the broadening is actually due to the splitting of the lines in a strong magnetic field (middle panel). The amount of splitting can be estimated from theoretical models and can be used to measure the mean field strength (bottom panel).

A third source of polarization involves magnetic fields. As electrons spiral around magnetic field lines, their emission is polarized. If the electrons are relatively slow moving, cyclotron emission, both circularly and linearly polarized, is produced, while if the electrons are relativistic linearly polarized synchrotron emission results. Cyclotron emission is seen in white dwarfs with magnetic fields and synchrotron emission is often seen in the powerful nuclei of radio galaxies.

The magnetic fields in the atmospheres of some stars will also cause the splitting of absorption features in the stellar spectra (see STELLAR ATMOSPHERES). The presence of the magnetic field splits previously degenerate energy levels in the atoms, causing a single transition to break up into multiple transitions. Consequently the spectrum will show multiple components of normally single absorption lines. Depending on the geometry and details of the energy levels, some of these components will be circularly polarized in one sense, some in the other, and some will be linearly polarized. In the weak-field cases the absorption features simply look broadened, and spectropolarimetry can be used to cleanly separate the components of different polarization and determine the field strength (see figure 3). In high-field white dwarfs the lines can be shifted so far from their original wavelengths that polarization information is necessary even to identify them.

Polarization measurements are usually photon starved, meaning that the accuracy obtained is limited by the number of photons one can collect. The new generation of 10 m class telescopes is opening new realms of research using the powerful techniques of imaging polarimetry and spectropolarimetry, spurring renewed interest in a number of fields spanning much of astronomy and astrophysics.

Polaris

The star α Ursae Minoris, the (north) Pole Star, currently situated 44.16′ from the north celestial pole. Owing to the effect of precession, Polaris is currently approaching the pole; its closest approach will be 27.52 in AD 2102. A pale yellow supergiant of spectral type F7:Ib–IIv, apparent magnitude 1.97, Polaris is at a distance of 430 light-years (parallax 0.008″, absolute magnitude 3.6). It is a Cepheid variable with a period of 3.97 days, magnitude range 1.9–2.1. Polaris is also a binary system, having a ninth-magnitude companion at a separation of 18.4″, a useful test object for small telescopes. Two fainter companions have also been detected.

Polarization

The extent to which the vibrations of an electromagnetic wave display a non-random orientation. Light, and other forms of electromagnetic radiation, consists of a periodically varying electric and magnetic disturbance that travels through space as a transverse wave motion (a wave that vibrates perpendicular to the direction in which it is propagating, like a wave on water). A beam of light is said to be unpolarized if it contains waves vibrating with equal amplitudes (heights) in all directions perpendicular to the direction in which the beam is propagating. By contrast, a plane-polarized (or linearly polarized) beam contains waves vibrating in one plane only. If, as a wave advances, the direction of vibration rotates (clockwise or anticlockwise, with the same frequency as the wave itself) but the amplitude remains the same, it is circularly polarized. The most general case is elliptical polarization, in which both the amplitude and the orientation vary as the frequency of the radiation.

Where a beam contains a mixture of polarized and unpolarized radiation, it is said to be partially polarized, the degree of polarization being given by the ratio of the strength of the polarized component to the total strength of the beam. The state of polarization of a beam of radiation provides information on the mechanism responsible for producing the radiation at its source and/or on what has happened to that radiation between leaving the source and arriving at the observer. For example, thermal radiation and blackbody radiation are unpolarized, whereas synchrotron radiation (radiation emitted by charged particles moving at high speeds in magnetic fields) is highly polarized (elliptically or linearly). Light emitted from an ordinary star is usually unpolarized, but becomes partially polarized when it passes through clouds of interstellar dust grains. Radiation from pulsars and supernova remnants, which is produced largely by the synchrotron process, is strongly polarized.

Polarization in Active Galaxies

In the absence of a strong magnetic field, the emission of photons is a random process and light is unpolarized. The mere presence of POLARIZATION therefore signifies asymmetry in the emission mechanism or light path through a source—structural details which in principle may be inferred from observations of sufficient quality. Since radiation sources in the nucleus of an ACTIVE GALAXY generally overwhelm all other components, these techniques can be extended to very high REDSHIFT where the entire object is unresolved. POLARIMETRY of active galactic nuclei (AGN) therefore offers the potential of not only discerning structural characteristics of individual objects, but also identifying relationships between various classes of objects and testing for evolution in the dimensions and activity level of the central engines.

Taxonomy of active galaxies

The classification of AGN reflects an historical background in which categories were defined more by observational than physical characteristics. The myriad of classes can be broken down according to two primary criteria: optical 'spectral type' and radio 'loudness' (see ACTIVE GALAXIES: OVERVIEW). Objects dominated by a featureless power-law continuum and broad emission lines ($\gtrsim$3000 km s^{-1} full width at half-maximum) are termed spectral Type 1, while those exhibiting a prominent starlight component and narrow lines are Type 2. The division by radio power commonly considers the ratio $R = F(5\,\mathrm{GHz})/F(4400\,\text{Å})$, with $\log R \gtrsim 2$ indicating a radio-loud object and $\log R \lesssim 0.5$ radio-quiet. As indicated in table 1, QSOs, Seyfert 1 and broad-line radio galaxies (BLRGs) are Type 1, while Seyfert 2 and narrow-line radio galaxies (NLRGs) are Type 2 examples.

Table 1. AGN classification*.

	Radio-quiet	Radio-loud
Type 1		
Strong featureless cont.	Seyfert 1	BLRG
Broad permitted lines	**QSO**	**Quasar**
Narrow forbidden lines		
Type 2		
Weak featureless cont.	Seyfert 2	NLRG
Galaxy starlight	**IRAS QSO**	**Hi-z RG**
Narrow forbidden lines		
Blazar		
Variable polarized cont.	Don't exist?	**Blazar**
BALQSO		
Type 1 +	**BALQSO**	Don't
Broad absorption lines		exist?

* Boldface indicates objects with $L \gtrsim 5 \times 10^{12} L_{\odot}$.

The unified scheme

Beginning in the late 1970s, evidence began to point to relationships between certain classes of AGN. For example, it was found that SUPERLUMINAL MOTION is confined to objects which exhibit strong, highly variable, polarization—the BLAZARS. SEYFERT 1 GALAXIES and QSOs (QUASISTELLAR OBJECTS) seemed to form something of a luminosity continuum, as did RADIO GALAXIES and QUASARS. However, the breakthrough in understanding came with Miller and Antonucci's detection in 1985 of polarized broad emission lines in the prototype Seyfert 2 galaxy NGC 1068. This remarkable discovery established two crucial points: (a) at least some objects displaying Type 2 spectra contain broad emission-line regions, and (b) the fact that these regions can be detected in light polarized by scattering implies that other vantage points (i.e. those in the direction of the scatterers) would observe an object with prominent broad lines (Type 1). The observations quickly led to models which 'unified' broad- and narrow-line AGN into a single type of object whose observed properties depend on viewing aspect (see ACTIVE GALAXIES: UNIFIED MODEL).

The key element of the unified scheme (figure 1) is a dense dusty/molecular torus which obscures the central engine and compact broad emission-line region for low-inclination sightlines. Small portions of the intense featureless continuum and broad emission-line spectrum of the internal QSO that escape through the polar hole of the torus is scattered by small particles (electrons and/or dust grains); this reflected component is linearly polarized. Evidence for a torus as opposed to other geometries comes from 'ionization cones' revealed by emission-line imaging and which are thought to arise from gas within the toroidal opening illuminated by the nuclear UV radiation field. Imaging polarimetry of favorable examples also depicts highly polarized centrosymmetric scattering regions (figure 2) very similar to the bipolar reflection nebulae observed in our own Galaxy. Finally, direct images of some nearby AGN have uncovered toroidal structures several hundred LY (light-years) across—these may be large-scale extensions of the structures which absorb much of the nuclear radiation and define the opening angle of the escaping radiation.

The unified scheme represents an enormous improvement over previous pictures; indeed the polarization properties of essentially all AGN are explicable in this context. However, it is important that the picture should not be over-interpreted. The scheme is perhaps better regarded as a valuable tool rather than a physical model—a starting point from which many mysteries of the nature of AGN must still be explained.

Polarization of AGN

The critical parameter of the unified scheme—in radio-quiet and radio-loud objects alike—is the inclination of the line of sight to the toroidal axis.

High-inclination objects (Type 2)

Type 2 spectra are measured for near edge-on examples. In this case the optical spectrum is dominated by starlight from the host galaxy and by the extended narrow-line emission region. The direct view of the nucleus is highly

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

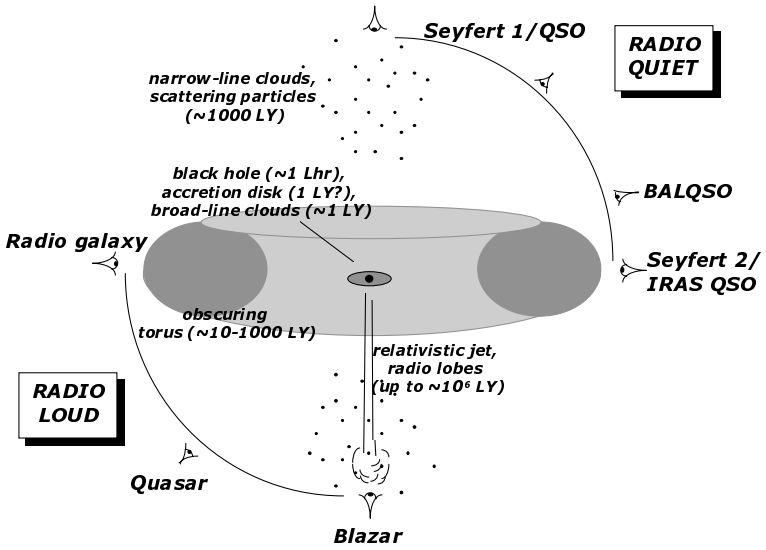

Figure 1. The unified scheme for AGN, indicating object class as a function of viewpoint. For objects with Type 2 spectra (e.g. Seyfert 2s and IRAS QSOs) where the central continuum and broad emission-line source are hidden from direct view, nuclear light is visible only as a component polarized by scattering off polar clouds of small particles. The degree of polarization declines with decreasing inclination and as the nucleus becomes progressively more exposed for the BALQSOs and objects displaying Type 1 spectra. In nearly pole-on radio-loud examples (Blazars), an additional highly polarized, variable component appears due to beamed synchrotron emission from a relativistic jet directed nearly along the line of sight. Drawing is not to scale.

extinguished at wavelengths shorter than 1 μm, and re-radiation by the dusty torus in the mid-infrared ($10 - 30$ μm) is prominent relative to the optical light. Narrow-line radio and Seyfert 2 galaxies are viewed at these angles, as are the luminous IRAS QSOs selected by the Infrared Astronomical Satellite (IRAS).

Light escaping through the polar hole of the torus is scattered at large angles, resulting in high linear polarization. With the dusty torus blocking the nucleus that would otherwise dilute the scattered light, the net polarization of the object can exceed 15%. Because the scattering particles are mixed with the extended narrow-line emitting gas, the broad emission lines and continuum share the same polarization, but the narrow lines are unpolarized. Finally, lack of dilution from the central source results in narrow emission lines which are overemphasized in total flux spectra (figure 3).

Low-inclination objects (Type 1)

At a lower-inclination sightline, our view is unhindered by the torus, and a Type 1 spectrum is measured. Thus, optical surveys which discriminate according to near-UV excess or strong, broad emission lines catalog primarily classical broad-line QSOs and Seyfert 1 galaxies. The overall polarization is found to be weak, $P \lesssim 2\%$, and spectropolarimetry of the emission lines reveals a range of properties: polarization which is weaker, but at the same position angle θ as the surrounding continuum; a position angle which differs from the continuum value; even a rotation in θ through the lines. The strongly polarized but faint scattered component is presumably

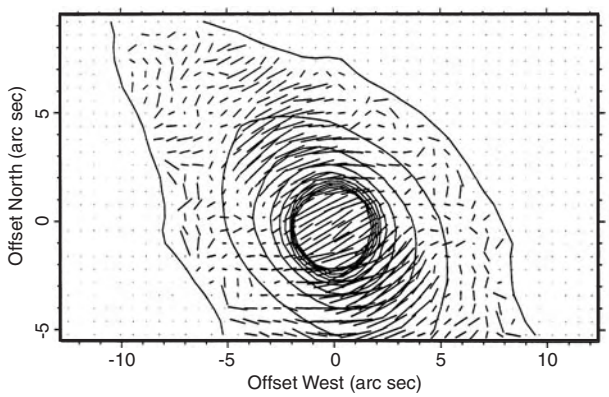

Figure 2. Imaging polarimetry of the nucleus of NGC 1068 at 2.2 μm. A scattering bicone is evident in the centrosymmetric polarization pattern represented by the (pseudo)-vectors. Contours represent the total intensity. (After figure 3 of Packam C *et al* 1997 Near-infrared imaging polarimetry of NGC 1068 *Mon. Not. R. Astron. Soc.* **288** 375.)

still present, but it is diluted to obscurity by the brilliant featureless continuum and broad emission-line spectrum. Instead, the observed polarization of Type 1 objects is thought to originate in the heart of the nucleus: through scattering off electrons in the broad-line clouds, scattering off the inner torus or the accretion disk which feeds the supermassive black hole, and in the radio-loud objects, possibly residual synchrotron emission from an inclined jet (see below). Much like the observations that led to

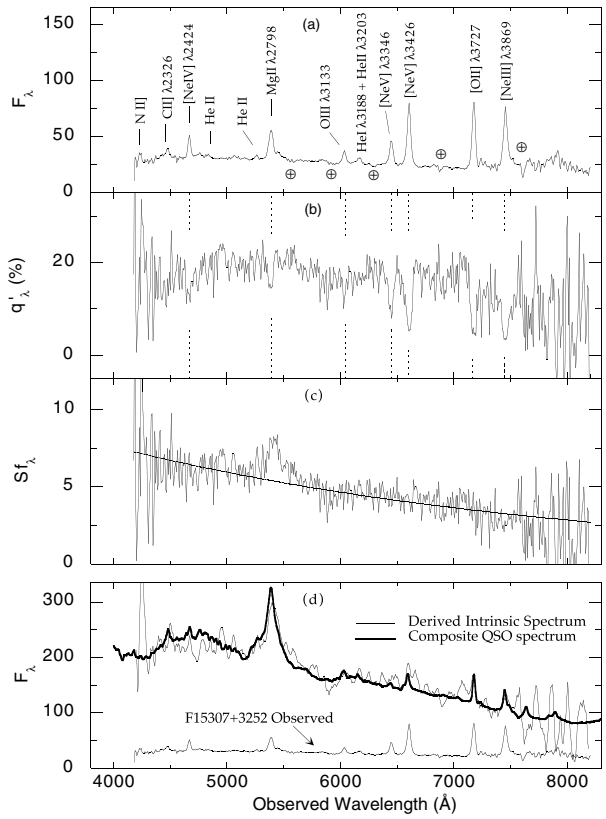

Figure 3. Spectropolarimetry of the IRAS QSO F15307+3252. (*a*) The observed (Type 2) total flux spectrum. (*b*) The degree of polarization. (*c*) The polarized flux with same units as for (*a*). (*d*) Comparison of the 'intrinsic' nuclear spectrum of F15307+3252 with that of a composite quasar (heavy line). The intrinsic spectrum was constructed by summing the polarized flux and observed narrow emission-line spectra, assuming isotropic narrow-line emission with equivalent widths typical of a luminous QSO. The smooth curve in (*c*) is a power-law of slope typical of unobscured Type 1 spectra.

the unified scheme itself, detailed polarimetric studies of these objects may dramatically revise our thinking about the innermost regions of the central engine.

Transition objects

Evidence has accumulated over several years suggesting that QSOs which show broad absorption lines displaced to the blue of the resonance emission lines represent objects seen from a vantage point that just skims the surface of the obscuring torus. Emission-line spectra of these so-called broad absorption-line QSOs (BALQSOs) closely resemble unobscured QSOs, but extinction by intervening dust is indicated by the significant reddening exhibited by certain examples (see also QUASISTELLAR OBJECTS: INTERVENING ABSORPTION LINES). In some models, the absorbing clouds represent material ablated off the dense torus and radiatively accelerated to outflow velocities of at least 20 000 km s^{-1}.

Polarimetric evidence supports the interpretation of BALQSOs as 'transition' objects between Type 1 and Type 2. Not only do they exhibit a degree of polarization which is intermediate between the types, but spectropolarimetry indicates that we are presented with multiple light paths from the nucleus—a direct route which provides a large portion of the continuum but is heavily extinguished in the absorption features, a polarized continuum component which is presumably the same scattered light that is seen in the edge-on examples, and the largely unpolarized broad emission lines whose larger emitting area is not completely occulted by the absorbing clouds.

Pole-on radio-loud sources

The event which originally focused the attention of polarimetrists on AGN was the discovery in the early 1970s of strong linear polarization in BL Lac (BL LACERTAE) and several other compact radio sources. The property was quickly attributed to non-thermal (synchrotron) emission of relativistic electrons in a magnetic field, and a common opinion held that the objects, which collectively became known as Blazars, represented 'naked' QSOs where the central engine is viewed directly. This static picture led to many difficulties in explaining the short variability timescales, high apparent luminosities and superluminal motion—difficulties which Blandford and Rees proposed would be largely alleviated if the emission occurred in a relativistic plasma jet whose velocity v is directed roughly along our line of sight. Doppler boosting enhances the brightness within a cone of opening angle $\theta \sim \sqrt{2/\Gamma}$, where $\Gamma = 1/\sqrt{1 - v^2/c^2}$, leading to more than a hundred-fold increase in brightness on-axis for modest Doppler factors ($\Gamma \sim 5$). The polarization of optically thin synchrotron emission is almost entirely linear, with

$$P = \frac{\alpha + 1}{\alpha + 5/3} = 75\%$$

for a uniform magnetic field and power-law emission spectrum characterized by $\alpha = 1$ ($F_\nu \propto \nu^{-\alpha}$). The position angle is perpendicular to the projection of the magnetic field axis on the plane of the sky. Because of the many physical attributes of the beamed picture and its natural place in the unified scheme (figure 1), it is nearly universally adopted today.

Unfortunately, it is proving difficult to extract physical details of the central engine from the enormous observed polarizations (up to 40%) and dramatic variability of Blazars. The beamed picture means that modest changes in the injection direction into a jet or of the magnetic field arrangement within a plasma blob can translate into wild variations in P and θ at the observer (see figure 4); in this sense the problem is one of 'the tail wagging the dog'. Time dilation further complicates the situation. Certain sources exhibit 'preferred' position angles of polarization which are often thought to indicate the general projection of the jet axis on the sky. BL Lac (figure 4) commonly exhibits a position angle which hovers around $\theta \sim 30°$.

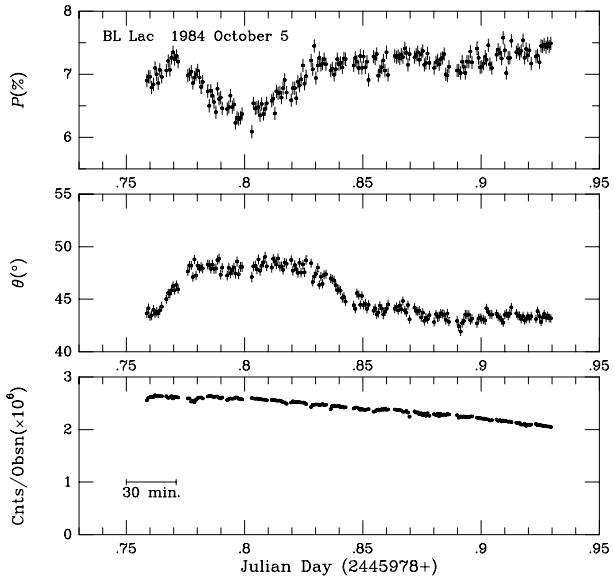

Figure 4. Optical polarization of the synchrotron source BL Lac recorded at 1 minute time resolution. The 'event' centered near fractional JD = 0.8 can be represented by an emission component which rotates by 90°—and back!—in an interval of 2 h. The slow decline in brightness is due to increasing airmass as the object sets in the sky.

Remaining mysteries

The unified scheme has proven qualitatively correct for both radio-quiet and radio-loud AGN over at least eight orders of magnitude in luminosity. It is a tool which can be used to disentangle pure orientation from fundamental properties of the nucleus and eventually lead to 3D models. From the combination of multiwavelength imaging and spectroscopic observations, it is now possible to infer the sizes and structures of obscuring tori, and to measure scattering cone opening angles, accretion rates and black hole masses. Polarimetric observations formed the foundation of the unified scheme, and polarimetry plays a key role in these studies as well, particularly at distances where the nuclei cannot be resolved directly.

We have still not solved the radio-quiet/radio-loud dichotomy. Progress in identifying this essential ingredient of the central engine will likely require much improved theories of the fate of magnetic fields in the innermost regions of the accretion disk and their role in launching relativistic jets. Interferometric and polarimetric observations at the shortest possible wavelengths will probe deep into the base of the jets and lend clues to their formation. For some as yet unknown reason, a correlation between radio loudness and galactic morphology persists. That puzzle touches upon the overriding question of the feeding and evolution of AGN, and of how they form in the first place. The historical record of this field has shown that answers do not come easily. When they do, as in the polarimetric catalysing of the unified scheme, they can appear from the most unlikely corners.

Bibliography

Comprehensive reviews of the unified scheme for AGN are given in:

Pond, John (1767–1836)

As an amateur astronomer, Pond had used the mural quadrant at Greenwich and analysed its inaccuracies. He participated in the committee which supervised its replacement by a 6 foot mural circle by EDWARD TROUGHTON. When Maskelyne died in office, Pond was appointed to succeed him and, as sixth Astronomer Royal, concentrated on upgrading the instrumentation at the Royal Observatory. Its measurements of star positions and time were raised to an accuracy never before achieved. During his administration the observatory was taken over by the Royal Navy, for which the observatory regulated chronometers, and he instituted in 1833 the public dissemination of time through the dropping of a time ball at 1 p.m. each day (this still happens). What gave under the pressure of all this new work was the *Nautical Almanac*, and it fell into disrepute, being transferred for recovery to the responsibility of a separate office, called the Nautical Almanac Office.

Pons, Jean-Louis (1761–1831)

Born in Peyre, France, joined the Observatory at Marseilles as concierge, becoming an astronomer there. Like Australian supernova-finder Robert Evans, he remembered the star fields that he observed and recognized changes; this enabled him to discover comets at the rate of about one per year from 1801 until 1827. He suggested to J F ENCKE that a comet found by him was one already discovered by Encke in 1805. Calculating a period of 3.3 years, Encke successfully predicted its return for 1822. This comet is known as 'Encke's Comet', but Encke himself referred to it as 'Pons' Comet'. Pons became director of the observatory at Marlia (Italy), and director of the Florence Observatory. 26 comets bear his name, but he discovered or co-discovered up to 37.

Population I Stars

The relatively young, metal-rich stars that are found in the disks and spiral arms of spiral galaxies. Originally differentiated from Population II stars by the German-born American astronomer Walter Baade (1893–1960) in 1944, on the basis of their metallicity and spatial distribution, they are now seen as representing stars that have formed in the latest stages of galaxies' morphological and chemical evolution. Their orbits about the galactic center have a low eccentricity and a low inclination to the galactic plane.

The oldest Population I stars are fairly strongly concentrated towards the galactic plane, where their spatial distribution overlaps with the youngest of Population II. Intermediate Population I stars have approximately circular orbits, are strongly concentrated along the galactic plane, and have an irregular distribution. The Sun belongs to this population, together with the stars in older open clusters, many A stars, giants, and emission-line (Me) dwarfs. Extreme Population I stars have an extremely uneven distribution within galaxies' spiral arms and have the greatest abundance of heavy elements. They include young stars in the process of formation, T-Tauri stars, OB associations, stars of spectral classes O and B, supergiants, classical Cepheids, and young open clusters.

See also: Population II stars.

Population II Stars

Old red stars that occur throughout elliptical and lenticular galaxies, and in the haloes, globular clusters and central bulges of spiral galaxies. They differ from Population I stars in having a very low metal content, and those heavier elements that they do contain are thought to have been produced by massive, short-lived earlier stars which form a hypothetical Population III. Population II stars are now seen as forming a continuum with the younger Population I stars, although, for convenience, various subclasses are recognized. Their respective distribution may be related to the gradual concentration of material towards the galactic plane that occurs in galactic evolution, together with the chemical evolution of stars themselves, and hence of the interstellar medium.

The oldest stars with the lowest metal content have an essentially spherical distribution, and are known as Halo Population II stars. This group includes the stars in globular clusters, long-period RR Lyrae stars (period >0.4 days), the W Virginis stars (also known as Type II Cepheids), and certain metal-poor subdwarfs. The stars of Intermediate Population II, which include most high-velocity stars and many Mira-type variables, are also metal-poor, but are more strongly concentrated towards the galactic plane. Both subclasses show an increasing spatial density towards the galactic center.

The youngest Population II stars are those of the galactic bulge, where they intermingle with the very oldest Population-I stars, and form part of the Disk Population. They include short-period RR Lyrae stars (period <0.4 days). The orbital eccentricity and inclination to the galactic plane show a decrease from Halo Population II stars to the Disk Population.

Population III Stars

A hypothetical population of stars that may have existed in the very early universe. As originally proposed, these extremely massive stars would have formed before the earliest galaxies, and have been responsible for the 'primordial' helium content of the universe and also for a large part of the cosmic microwave background radiation. This hypothesis does not agree with the currently generally accepted theory of the Big Bang, nor with 'top-down' theories of galaxy and star formation. Subsequently, the term has been used for an early population of massive stars, long extinct, that would have exploded as supernovae, and thus account for the metal content of the Population II stars in globular clusters. The remnants of this early population would be neutron stars or black holes, and could thus account for some of the dark matter postulated to explain the missing mass in galactic haloes.

Position Angle

A measure of the direction of one object relative to another on the celestial sphere, for example the direction of one component (usually the fainter) of a double star from its companion. Together with the separation, this defines the observed form of the system, and such measurements repeated over many years enable any binary motion to be determined.

Position angle, usually abbreviated 'PA', has been defined in the literature in various ways, often confusing and sometimes mutually contradictory. The best definition of the system, now accepted as standard, is 'position angle is measured anticlockwise as seen on the sky, from the $+\delta$ direction' (the '$+\delta$ direction' being the direction of increasing declination, i.e. northwards).

Position angle may also be used in recording the location of an observed feature on the disk of a planet or the Sun, or to define the direction of an axis of rotation. In such cases, PA is measured eastwards from a line joining the center of the disk to the direction of the north point.

Positron

The antiparticle of the electron. It has the same mass as the electron but carries unit positive charge (1.602×10^{-19} coulomb). Like the electron, it has a spin of 1/2 (in units of the Planck constant, h, divided by 2π) but when an electron–positron pair is created, the positron will have the opposite spin to the electron. Electron–positron pairs can be produced from high-energy gamma-ray photons. Conversely, when electrons and positrons collide, they liberate energy on the form of gamma-ray photons. Where the electrons and positrons have been accelerated to very high speeds and kinetic energies, for example in particle accelerators, the energy released when they collide and mutually annihilate may be high enough to create hadrons and quarks.

Poynting–Robertson Effect

A net force acting on small particles which causes their orbits to decay, also known as *Poynting–Robertson drag*. When photons of light strike a dust particle in orbit around the Sun, they impinge not directly 'side-on' but slightly on its leading side (the 'forward' side in terms of its orbital motion). Their energy is absorbed, and subsequently re-radiated, but it is re-radiated isotropically—in all directions. The transfer of energy from photon to particle can be thought of as the application of a force to the particle. There is a component of this force that acts in the opposite direction to the tangential component of the particle's orbital motion which is not compensated for when the absorbed energy is re-radiated. As a result the particle loses kinetic energy, which reduces its velocity, so it spirals inward, toward the Sun. This simple picture is complicated by, among other things, the fact that particles have different shapes and spins; a ring of dust particles of the same mean radius but with a distribution of shapes would gradually broaden out. The decay time is shorter for smaller and low-density particles. The effect can be counteracted by radiation pressure, more so with decreasing particle size below about 1 μm. The Poynting–Robertson effect also acts on particles in planetary ring systems. John Poynting was the first to describe the effect, in 1903; Howard Robertson derived it from relativity theory in 1937.

Poznań Astronomical Observatory

This Poznań Astronomical Observatory is a unit of the Adam Mickiewicz University, located in Poznań, Poland. From its foundation in 1919, it has specialized in astrometry and celestial mechanics (reference frames, dynamics of satellites and small solar system bodies). Recently, research activities have also included planetary and stellar astrophysics (asteroid photometry, catalysmic binaries). The scientific staff consists of twelve researchers and six PhD students. In 1949, a new minor planet was discovered at the Observatory, receiving the name 1572 Posnania. Nowadays, due to light pollution, observations are carried out abroad as well as at the 0.4 m photometric telescope located outside the city.

Precession

The slow periodic change in the orientation of the Earth's axis of rotation due to gravitational attractions of the Sun and Moon on the non-spherical globe (geoid) of the Earth. The effect is often referred to as luni-solar precession. The term is also applied to the periodic change in the rotation axis of any spinning body, for example, an artificial satellite. The axis of the Earth is inclined to the perpendicular to the ecliptic by an angle of 23.44° and precession causes the celestial pole to trace out a circle of this radius around the pole of the ecliptic in a period of some 25 800 years. Thus the north celestial pole is at present located close to the fairly conspicuous star Polaris, known as the Pole Star. It lay close to the star Thuban in the constellation Draco 4500 years ago. In 12 000 years time, it will be near the bright star Vega.

As the celestial pole moves, so the celestial equator moves relative to the ecliptic. Thus the points of intersection of these two circles, in other words the equinoxes, move along the ecliptic in a clockwise direction at a mean rate of about 50 seconds of arc per annum (i.e. 360× in 25 800 years). Since the celestial longitude of a star is measured from the vernal equinox, it follows that this must increase at a rate of about 50 arcseconds per annum due to precession.

The gravitational attractions of the planets cause a very slow charge in the orientation of the ecliptic (the plane of the Earth's orbit) which causes the right ascensions of stars to decrease by about 0.13 arcsec per annum and which is known as planetary precession. The combined effects of luni-solar and planetary precession are called general precession.

Because of precession, star catalogs and charts must be drawn up for a particular equinox (e.g. 00 h on 1 January for the years 1900, 1950, 2000 etc). If a precise position for a star is required at some other time, the effects of precession must be calculated to determine by how much the stars coordinates will have changed from its tabulated position.

Hipparchus first noted the effects of precession in the second century BC.

Prehistoric Astronomy

For many decades arguments have raged about the nature and level of sophistication of astronomical achievements among pre-literate cultures in the Old World and among pre-Columbian peoples in the New. The often-heated debates have tended to revolve around some claim that astronomical knowledge reached a remarkable degree of sophistication among a particular group of prehistoric people—for example, the people who built and used conspicuous stone monuments during the Neolithic and earlier part of the Bronze Age in Britain and Ireland—and sceptical reactions by archaeologists and anthropologists.

A fundamental problem that is still not always recognized is that to talk about levels of sophistication is already to measure prehistoric 'achievements' against our own and by implication to see scientific astronomy in the modern Western world as a pinnacle of achievement with all other developments in understanding either as steps along the road towards it or as dead ends along the way. Many archaeologists and anthropologists still feel that to speak of prehistoric 'astronomy' at all is to fall into this very trap. It is crucial to appreciate at the outset that many other 'astronomies' are simply different, and if we are to attempt to understand and evaluate them in their own terms—that is, if we are to study what celestial bodies and events meant to different groups of prehistoric people and how astronomical 'knowledge' was used—then we must attempt to discover something of the wider frameworks of understanding within which the sky was observed and perceived by those people.

Such world-views or 'cosmologies' are likely to have been very different from the Western perspective, as is evident from the many examples still existing in the world today among a variety of indigenous peoples. Things that from a Western point of view seem widely separated and to bear no relationship to one another may in other world-views be understood as inextricably linked. Indigenous cosmologies generally draw no clear distinction between terrestrial and celestial realms, between sacred and mundane activities, between animate and inanimate objects or between (what to us is) empirically real and what is imagined: thus, to the Barasana of the Colombian Amazon, 'Old Star', chief protector of the inhabitants of the sacred *He* world, is at once a human warrior, the fierce thunder jaguar, a constellation corresponding to Orion and a short trumpet.

Space and time in the Western view are abstractions: backdrops upon which objects and events can be placed and plotted. To indigenous communities, on the other hand, particular places may acquire specific meanings and significance for any number of reasons, and spatial perceptions of the world are developed, in very particular ways, in relation to such places. Similarly, the timing of various human actions tends to be defined in terms of natural events and cycles, celestial ones included. In some measure this is for very practical reasons to do with subsistence, but it is also the case that where and when certain activities take place tend to be defined by the perceived need to keep human action in harmony with the COSMOS as it was perceived and understood. It is this propensity that enables archaeologists to extrapolate from spatial patterning in the material record to make deductions about prehistoric cosmologies.

It is in this context that astronomy is of particular importance to the modern archaeologist, because we can reliably reconstruct recurrent elements of prehistoric skies. Thus celestial correlations in the archaeological record (such as the alignment of buildings on solstitial sunrise or sunset) are easily recognizable as such, whereas many other referents that might have been crucial in determining the location or orientation of a house, temple or tomb are no longer detectable. On the other hand, an astronomical alignment could easily have arisen fortuitously, as a result of factors quite unrelated to astronomy, and where there is no independent evidence to support the astronomical interpretation it often takes the recurrence of a similar phenomenon among a group of related structures (e.g. a consistent pattern of astronomical alignment among a group of similar monuments constructed in a local area at a particular stage in prehistory) to provide convincing evidence that astronomical considerations were indeed important.

It is impossible to make sweeping generalities about 'prehistoric astronomy'. For a start, the pre- (and 'proto'-) historic societies about which one might speak differ hugely from one another, spanning a time period from the Upper Palaeolithic ca 30 000 BC to times immediately prior to European contact in the Americas and elsewhere. They also vary from small groups of hunter-gatherers to complex city-states such as those of the Maya, Aztec and Inca which, unlike the urban states of the Near and Middle East, were in no way precursors of the Western tradition. Furthermore, there can be huge disparities between the nature of world-views even of communities of a similar nature in similar locations, as is evident from certain indigenous groups living in relative proximity today.

The earliest claim for astronomical observations relates to the Upper Palaeolithic, the period when fine depictions of animals first appeared in western European caves. A large number of engraved portable artefacts such as pieces of bone and antler are also known from this period. One, part of an eagle's wing from a cave at Abri Blanchard in the Dordogne valley, France, contains a series of notched marks in a serpentine pattern. In the early 1970s Alexander Marshack concluded from microscopic studies of these marks that they had been accumulated over a period of time. Furthermore, the numbers of marks in different parts of the pattern suggested that they were tallies of days in the lunar phase cycle. Others have questioned these conclusions, and they remain controversial.

Marshack's claims aside, there is little direct evidence of any interest in the skies among hunter-gatherer communities during the Upper Palaeolithic and

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Mesolithic. However, the evidence from modern hunter-gatherer groups such as Australian aboriginals suggests this should not be taken to indicate a lack of interest in the sky or that world-views of considerable complexity were not developed by such communities; it is merely a reflection of the paucity of the material evidence relating to such groups.

It is in the subsequent Neolithic period, when early farmers around the Atlantic fringes of Europe started to construct the large communal tombs that still remain in considerable numbers as conspicuous monuments in the modern landscape, that substantive evidence relating to prehistoric astronomy first appears in many areas. It is clear that orientation was important as early as the fifth and fourth millennia BC: regional trends in tomb orientations are sufficiently strong and distinctive in many places that simple factors such as local topography or prevailing wind may be ruled out as a satisfactory explanation. Regional orientation trends are also evident among groups of communal long-houses built in the earlier part of the Neolithic across northern Europe. Each spread of orientations has a distinctive 'signature', many of which seem to be related in a general way to the motions of the Sun: for example spreads between north-east and south are quite common, and may reflect a need for tomb entrances to face the rising Sun or the Sun climbing in the sky. A similar remark holds for tombs and other forms of stone monument such as the megalithic rings and rows built during the Neolithic and well into the Bronze Age, perhaps as late as 1000 BC in remote parts of Scotland and Ireland. The orientation signatures of a few of the later groups such as the Scottish 'recumbent stone circles' and short stone rows in south-west Ireland are strongly suggestive that it was the Moon rather than the Sun that was of primary importance for their builders and perhaps regulated the timing of rituals or ceremonials held there.

This picture is very different from that put forward in the 1960s and 1970s by ALEXANDER THOM, who propounded the idea that many standing stone monuments incorporated intentional high-precision alignments on the Sun and Moon, reflecting their use as high-precision 'observatories'. These ideas did not stand up to close scrutiny, the main problem being the fair selection of data. Nonetheless, certain Neolithic chambered tombs do seem to have incorporated more specific solar alignments, a famous example being Newgrange in Ireland, where a specially constructed roof-box above the entrance permitted sunlight to enter the tomb for a few minutes after dawn on days around the winter solstice, shining down the entire length of the 19 m long passage to light up the bones of the dead in the central chambers. The monument was not an observatory in any modern sense of the word; the alignment is probably best seen as a symbolic expression of a relationship between ancestors and the Sun that was of great significance to the builders because of the way they understood their own place, and that of their ancestors, in the cosmos. Similarly, Stonehenge—which for some 500 years had existed as a unexceptional ditch-and-bank enclosure in which various timber structures had been constructed—was reoriented on the solstitial Sun at around the time, ca 2500 BC, when it was transformed into the stone edifice whose remains are so famous today. It could well be this realignment helped to strengthen its symbolic power by legitimizing its place at the center of the perceived cosmos.

In the European Iron Age, the evidence shifts to domestic structures such as British roundhouses, which not only manifest distinctive orientation trends but where there is evidence to suggest that certain activities may only have been appropriate in particular quarters of the house, paralleling what is known from various indigenous groups in north America. It seems too that certain places were preferred when disposing of the dead, of animals or of other objects, also reflecting symbolic or cosmological principles. Celtic cult sites also show distinctive orientation trends.

In other parts of the world astronomies developed in distinctive ways. Polynesian navigators, for example, developed a practical astronomy based on 36 linear star-to-star 'constellations' that formed a three-dimensional 'star-compass' enabling navigators to locate distant islands. Central to Inca cosmology was the system of *ceques*, conceptually straight lines radiating outwards from the Coricancha temple in the Incaic capital Cuzco, which at once reflected Inca knowledge of the sky, dictated the layout of the city and organized social groups within it, and functioned as a calendar. Life in the Mayan world revolved around a multitude of ritual acts which were dictated by the calendar, and in particular by a repeating cycle of 260 days used widely in pre-Columbian Mesoamerica, each day of which had particular symbolic associations and omens. However, the Mayans, who had developed a base 20 system of numeration together with a form of hieroglyphic writing, also developed a quantitative, predictive astronomy capable of forecasting eclipses, the appearances of Venus and Mars, and the passage of the Moon through the zodiac. They were prepossessed with the passage of time, always trying to equate integer multiples of different cycles: thus 73 cycles of the 260 day count equals 52 years of 365 days, and 405 lunations (11 960 days) equals 46 cycles of the 260 day count equals (actually to within 3 h). This prepossession developed not in a spirit of abstract enquiry but in the context of a world-view in which the ruling class communicated with, and were legitimized by, the gods; there was a cosmic 'right to rule' that needed to be constantly reinforced by keeping their activities in tune with various celestial cycles (see MAYAN ASTRONOMY).

Many investigations of prehistoric astronomies now take place within the framework of archaeoastronomy, an interdiscipline which arose in the 1970s as a result of the need to resolve the cross-disciplinary disputes raised by the work of Alexander Thom on the British megaliths. In north-west Europe, archaeoastronomy was mainly concerned with statistical appraisals of putative astronomical alignments amongst prehistoric

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

stone monuments, but in the Americas it quickly began to assess such alignments in the context of a wider variety of cultural evidence bearing on the nature and meaning of astronomies in pre-conquest times, such as historic accounts, ethnographic accounts of modern descendants of pre-Columbian peoples and the written record in the form of codices, inscriptions and iconography.

Archaeoastronomers have moved on from the days when they simply looked for astronomical alignments in prehistoric architecture—a sort of celestial 'butterfly collecting' which fails to consider the social context in which prehistoric astronomies might have operated and to address the cognitive issues that are vital for their interpretation. This has been replaced by a much broader approach which tends to highlight particular themes such as concepts of space and time, calendar development and the place of celestial referents in different schemes of 'sacred geography' which are the concrete reflection in the physical landscape of the cosmologies which structured human action within the world as prehistoric communities perceived it.

The sky is a symbolic resource of immense significance, not only because many of its cycles are convenient and reliable for regulating human activity, but also because its immutability confers power on those individuals who can convince others that they wield control over celestial cycles and events. Most archaeologists expect that the meanings attached to what was seen in the sky were highly specific, varying greatly between different cultural contexts. This specificity works against the need to seek repeated instances of patterning in the material record in order to be better assured that they were meaningful to the people who created them. As we have said, a solstitial alignment could easily have arisen fortuitously, as a result of factors quite unrelated to astronomy. On the other hand there is evidence to suggest that traditions of public ritual tend to change slowly, even in the face of social upheaval, and it is this—reinforced by clear trends in the archaeological record such as the strong patterning in sets of orientations of prehistoric tombs in many parts of Europe from Neolithic times onwards—that most clearly suggests the existence of a great deal of evidence yet to be explored that will give us new insights into prehistoric astronomies, and into the broader frameworks of cosmology in which they operated.

Pre-main-sequence Binary Stars

The typical product of the STAR FORMATION process is a multiple star system, most commonly a BINARY STAR. A pre-main-sequence (PMS) binary star is a pair in which, typically, both stars have not yet fully contracted to the main sequence and are not yet fusing hydrogen at their cores. Such binary stars are recently formed, with usual ages of less than 10 million years. Since stellar contraction times decrease with increasing stellar mass, most known PMS binary stars include stars with masses from a few solar masses to masses of less than one-tenth of a solar mass, at the threshold of brown dwarfs. Although formally the definition of a PMS binary star includes only two stars, they are sometimes found in higher-order systems (e.g. triples and quadruples) with a hierarchical ordering of their separations.

Given their youth, PMS binary stars are often found still associated with the parent molecular clouds out of which they formed. They are also often surrounded by protostellar (and likely, PROTOPLANETARY) disks. Observations show that a PMS binary star can dynamically clear regions in such disks on size scales comparable to the binary separation, as predicted by theory. The impact of such cleared regions on the evolution of binary systems and the formation of planets is at the forefront of the field of star and planet formation.

Pre-main-sequence binary star populations

It has long been recognized that most stars in the galactic field are binary, and thus it was expected that most PMS STARS would also be binary. Even so, it came as a surprise to find that in some star-forming regions PMS binary star frequencies are higher than the binary star frequencies found among main-sequence stars. For example, near the Taurus dark clouds the binary star frequency is a factor of two higher than the main-sequence binary star frequency, a remarkable result given that the main-sequence binary star frequency is more than 50% for solar-type stars. (This apparent mathematical contradiction is the result of triple systems being counted as two binary stars and so on when deriving binary star frequencies.) Such high binary star frequencies among PMS stars leads to the profound result that most stars form in the immediate vicinity of another star.

Presumably the main-sequence stars in the solar neighborhood derive from earlier generations of stars which formed in molecular clouds elsewhere in the galaxy. Hence the higher binary star frequencies among PMS stars also leads to the conundrum of how the main-sequence binary star population derives from the apparently more abundant PMS binary star population. While the answer to this question is not secure, present studies suggest that this is not primarily an evolutionary process—that is, PMS binary stars do not break up to become single field stars. More likely, the PMS binary star frequency may vary with the environment of star formation. For example, PMS binary star frequencies may be higher among stars formed in cold dark clouds, and lower in young clusters and OB associations formed in dense, hot environments. If, as has been suggested, young clusters and OB associations are the primary contributors to the galactic STELLAR POPULATION, then the conundrum is resolved.

Orbital properties

PMS binary stars have been found with orbital periods ranging from 2 days to longer than 100 000 years (the latter inferred from projected separations). The logarithmic distribution of periods is roughly Gaussian, peaking at periods of about 50 years and decreasing to shorter and longer periods. For binary stars made up of two solar-mass stars this peak in the period distribution corresponds to an orbital semi-major axis of 17 AU, similar to the orbital radius of Uranus. So for more than half of the binary stars both stars would reside within the dimensions of our planetary system.

At present our knowledge of the distribution of orbital eccentricity of PMS binary stars rests entirely upon spectroscopically determined orbital elements. Orbital eccentricities from $e = 0$ to $e = 0.8$ have been found. Most of the shortest-period binary stars ($P < 6$ days) have circular orbits; on the other hand, no circular orbits are found at longer periods. Together, these results suggest that circular orbits are not favored by the binary star formation process, and that the circular orbits at short periods are the result of rapid tidal circularization between these large convective stars.

The PMS binary star period and orbital eccentricity distributions are similar to those found for main-sequence solar-type binary stars. Evidently the orbital properties are largely established by the PMS phase of stellar evolution. The secondary mass distribution of PMS binary stars is not yet well determined.

Disks around young binary stars

Circumstellar ACCRETION DISKS are an inevitable consequence of conservation of angular momentum in a contracting cloud, and recent studies have found them to be an essential component of single star formation. The same is almost certainly true for binary star formation. Nonetheless, the conceptual framework of circumstellar disks must be transferred to binary stars with care. Perhaps most importantly, a binary star introduces its semi-major axis as a scale length in the process. We cannot expect disks in binary stars with separations of thousands of astronomical units (AU) to mimic disks in binary stars with separations of a few AU. Furthermore, the concept of a single disk must be discarded. A binary star embedded within a coplanar disk is expected to dynamically clear a region on the scale-length of its semi-major axis. Consequently three distinct disks may be identified (figure 1). Each star can have an associated disk within its ROCHE LOBE, referred to generally as circumstellar disks and specifically as circumprimary and circumsecondary disks (where the primary star is taken to be the most massive star). In addition, a circumbinary disk may be present external to the binary star orbit. One

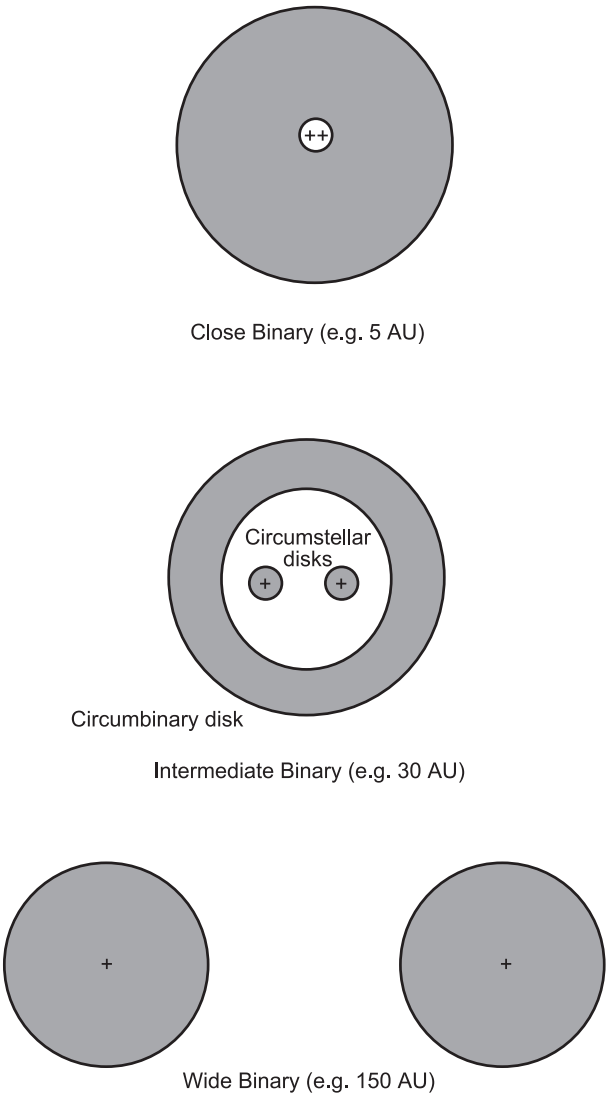

Figure 1. Schematic illustration of circumstellar and circumbinary disks among pre-main-sequence binaries of different separations. The outer radii of the upper two circumbinary disks are not to scale; actual disks have larger outer radii by factors of a few.

or all of these disks may be absent in any given PMS binary star system. Finally, the coplanarity of these disks has not been established by observation, and eventually may be a critical property for distinguishing among binary star formation hypotheses.

Disk–star interactions

Observations of disks around binary stars are best understood in the context of the dynamical theory for the gravitational interaction of stellar companions with an associated disk. In the presence of the periodically varying gravitational potential of a binary star, gravitational resonances are established in disks (similarly to resonances established in planetary rings by orbiting moons, or Lindblad resonances). Torques at these resonances act to transfer energy and angular momentum to or from the binary star orbit, resulting in evolution of both the orbit and the disk structure.

A more detailed discussion is not appropriate here, but the essential elements of the evolution of the binary-disk system can be presented. In this spirit we develop a simple scheme for the evolution of an isolated, coplanar, binary-disk system. We consider initially the case of a binary star with a circular orbit and a small secondary/primary mass ratio. We ignore the details of binary star formation and *ad hoc* begin with the binary star embedded in a continuous coplanar disk having an outer radius much greater than the binary star separation and a mass less than that of the secondary star. Given the posited binary star mass ratio the primary star lies near the center of this disk. On a dynamical (orbital) time-scale the gravity of the companion will initially clear an annular gap in the disk which includes its orbital path. Two circumstellar disks are created, with the circumprimary disk being the larger of the two. A circumbinary disk also remains, with its inner radius set by a balance between the angular momentum transport in the disk (e.g. from viscosity) and the torque provided by the binary star. Calculations find the inner radius of the circumbinary disk to be approximately twice the semi-major axis of the circular orbit.

Once this annular gap is established, disk evolution continues on slower (e.g. viscous) time-scales. Accretion of material from the circumstellar disks onto the stellar surfaces may proceed. However, because of the torques provided by the binary star at the inner edge of the circumbinary disk, material is not expected to flow from the circumbinary disk to the circumstellar disks (but see below). Unless replenished from otherwise infalling material, the circumstellar disks will exhaust themselves. Depending on the time-scale of this exhaustion with respect to the lifetime of the circumbinary disk, the binary star may then reside in a hole within the circumbinary disk. Outside the binary star orbit the circumbinary disk will adjust its surface density distribution so as to match the angular momentum drawn from the binary star with the outward angular momentum flow of the disk. Once the appropriate surface density distribution has been established, a prolonged phase ensues during which the circumbinary disk is expelled.

Such disk evolution requires a response from the binary star. From energy arguments the semi-major axis of the binary star must decrease. The direction in which the orbital eccentricity will evolve depends on the relative rates of extraction of energy and angular momentum from the binary star orbit by the disk. Binary star orbital elements can be expected to change significantly in thousands of orbital periods. For binary stars with semi-major axes less than 100 AU this time-scale is shorter than PMS disk lifetimes.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

This binary-disk system is the simplest case. Among other things, the detailed distribution of disk material will depend on both the mass ratio of the binary star and the orbital eccentricity. For example, stars in a circular binary star with unit mass ratio are equidistant from the center of mass of the system. Consequently the morphology of the dynamically cleared region changes qualitatively, but the essential nature of the evolutionary history of the disk will not change. The interaction of a disk with an eccentric binary star is a more difficult problem. In terms of resonant clearing, the primary modification is that for given semi-major axis the inner radius of the circumbinary disk increases with eccentricity and the outer radii of the circumstellar disks decrease.

Observations of disks around pre-main-sequence binary stars

The observational case for disks in young binary stars is well established. Observations of PMS binary stars reveal many of the classic signatures of disk material and accretion, including excess emission at near-infrared through millimeter wavelengths, spectral veiling, Balmer and forbidden emission lines and polarization. Every indication is that the frequency of disk material in the environments of PMS binary stars is similar to that around PMS single stars.

Given the scenario above, most attention has focused upon the structure of these disks. Flux measurements at submillimeter wavelengths provide insight into total disk masses. Interestingly, while submillimeter flux is easily detected from many PMS binary stars with large (>100 AU) and small (<1 AU) separations, most binary stars with intermediate separations have gone undetected, indicating reduced disk masses. These observations suggest the rather intuitive picture that binary stars much wider or much closer than typical disk radii do not significantly alter disk structure, while those binary stars whose separations are comparable to disk radii substantially modify the associated disks as in the theoretical scenario above (figure 1). The threshold of roughly 100 AU is similar to the sizes of circumstellar disks around PMS single stars.

The submillimeter observations strongly suggest that companions do alter disk structure, but images are required to understand in detail the actual structure of the resulting disks. The PMS binary star GG Tau has proven particularly fruitful as a case study (figure 2). Millimeter wavelength interferometric observations reveal a circumbinary disk around the binary star. The total circumbinary mass is $0.12 M_0$, about 10% of the stellar mass. The images clearly show the circumbinary disk to be separated from circumstellar disks by regions of very low surface density, indicative of disk clearing. In addition, the circumbinary disk has an inner radius consistent with theory under reasonable assumptions about the orientation of the binary star. These observations are supported by beautiful near-infrared ADAPTIVE OPTICS images which also reveal a ring with the same dimensions. These images are seeing stellar light scattered off the inner edge of the circumbinary disk, confirming the presence of a physical structure.

While observational evidence seems to support the theoretical picture for the structure of disks in binary environments, the frequent observation of ongoing mass accretion at stellar surfaces in PMS binary stars of all separations and ages has been a surprise. Although theory suggests that circumstellar disks in binary stars cannot be replenished with material from circumbinary disks, there is no evidence that circumstellar disks in binaries are in fact being depleted at a faster rate than circumstellar disks around single stars. This is all the more remarkable when evidence for mass accretion is found in the very closest binaries, with separations as small as tenths of an AU (see CLOSE BINARY STARS). These observations have led theorists to re-examine the torque barrier at the inner edge of circumbinary disks, and recent calculations have found that given appropriate conditions accretion streams with substantial flow rates may be able to flow inward from a circumbinary disk. The implication of such streams for the evolution of both the disks and the binary orbit are an important theoretical problem.

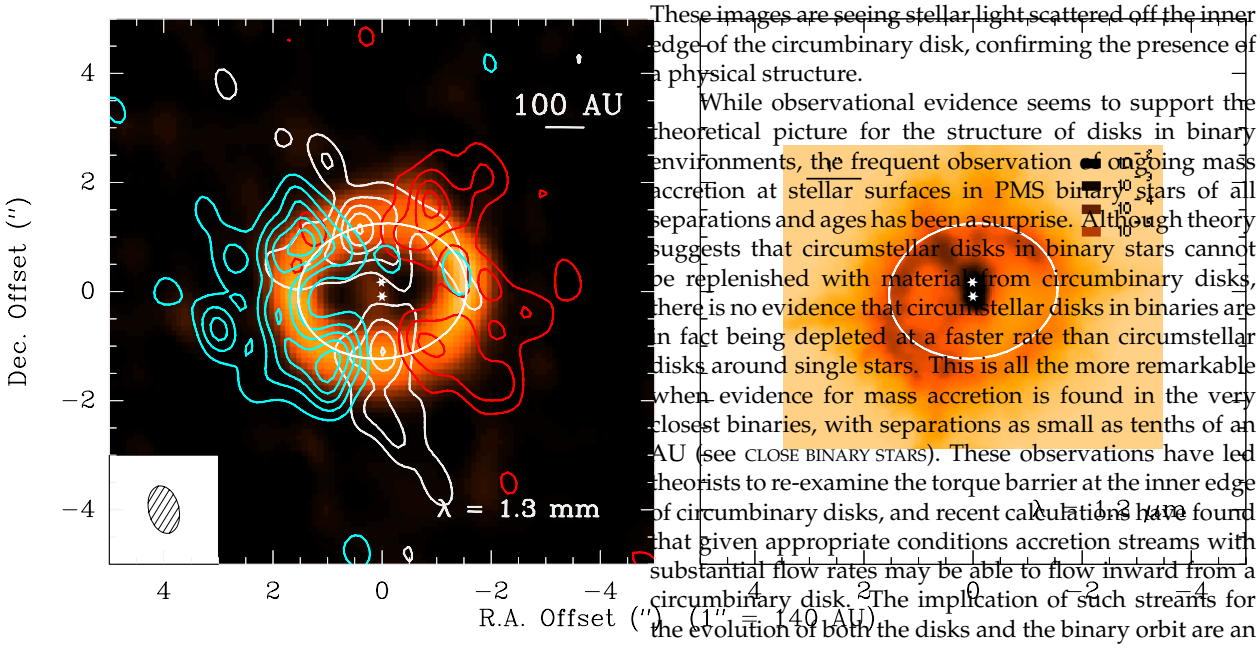

Figure 2. Left: the stellar components of the GG Tau binary are shown as stars. The circumbinary disk is evident as the orange shaded region which shows millimeter wave (1.3 mm) continuum emission. The contours display three velocity channels of ^{13}CO (2-1) line emission, 5.55 km s^{-1}, 6.30 km s^{-1} and 7.05 km s^{-1}, from left to right in the figure. The change in velocity from blueshifted on one side of the binary to redshifted on the other is consistent with Keplerian orbital motion around the binary. Right: the near-infrared (J-band) adaptive optics image. The white ellipse is the same physical size in both images. Evidently the light in the near-infrared image is associated with the circumbinary ring seen in millimeter light, and is interpreted as scattered light off the inner edge of the ring. **This figure is reproduced as Color Plate 38.**

Protobinary stars

Evidently binary star formation occurs prior to the PMS phase. Evolutionary models of the more massive PMS binary stars suggest that the properties of main-sequence binary stars are already at least approximately present in the PMS phase, and likely

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

were established earlier. With the PMS binary stars now opened to observational study, the forefront of discovery is moving to yet younger, embedded protobinary stars. Several very wide pairs have been found embedded within dark clouds. The case of L1551 IRS5 best shows the prospects for the study of protobinary stars.

L1551 IRS5 is the canonical protostar still undergoing infall from an envelope. Recent millimeter wavelength observations demonstrate that the system is a protobinary star with a projected separation of 45 AU (in projection on the sky). Observations reveal a system with three components: a large surrounding envelope of dust and gas, a circumbinary disk or extended structure with a size scale of order 150 AU, and the inner binary star system with two circumstellar disks. Very Large Array millimeter wavelength observations indicate circumstellar disk radii of 10 AU, with disk masses of $0.06M_0$ and $0.03M_0$. These disk masses are comparable with the minimum mass required to form a planetary system like our own. It is also notable that such large circumstellar masses are found in a system with a projected separation of 45 AU, since, as noted above, PMS binary stars typically do not have detectable millimeter flux at this separation. Perhaps these substantial circumstellar disks are maintained by rapid accretion from the envelope, or by an accretion stream from a circumbinary disk.

The presence of such massive circumstellar disks in L1551 IRS5 and near-infrared and submillimeter observations of PMS binary stars suggest that while the radii of disks in binary systems may be constrained by the presence of a companion, the circumstellar disk material may be similar in temperature and surface density to that in disks around single stars. The implication is that in a significant fraction of young binary systems planet formation may be able to proceed relatively undisturbed. Clearly this is true for the widest systems, in which extrasolar planets have already been discovered (see EXTRASOLAR PLANETARY COMPANIONS AND BROWN DWARFS). The possibilities for planet formation among closer systems remains to be explored. Given that most stars are in binary star systems, the answer will have an important impact on the frequency of planetary systems.

Pre-main-sequence Stars

Prior to their ignition of hydrogen, stars undergo a phase of bulk contraction. This process drives both the central density and the temperature upward, until nuclear fusion can begin. Somewhat paradoxically, the star's luminosity, which stems from the released gravitational binding, is relatively high at this early stage. The luminosity generally decreases as a result of contraction, reaches a minimum just at the point of hydrogen ignition, and then rises again during post-main-sequence evolution. Thus, observed pre-main-sequence stars are relatively bright, a fact which aids in their detection. Several thousand low-mass examples have now been cataloged, despite the fact that the relevant lifetime is only about 0.1% that of the main-sequence phase.

A snapshot of the star taken during the contraction epoch would show it to be very nearly in hydrostatic equilibrium. That is, the compressive force of self-gravity closely balances the internal pressure gradient. Evolution is driven by radiative emission from the photosphere, which gradually drains thermal energy. Note that the star's interior temperature rises even as its heat content falls. Thus, the entire object is characterized by negative heat capacity. Note also that the inward velocity of any mass element is always well below the local sound speed. The contraction is therefore termed quasi-static, to distinguish it from more rapid, dynamical motion.

This basic physical picture was already well established by the 1950s, when L Henyey constructed the first detailed, numerical models of young stars. At the time, the role of thermal convection in STELLAR INTERIORS was still not fully appreciated, even in mature objects such as the Sun. Henyey assumed that pre-main-sequence stars would be radiatively stable and found that they contracted at nearly constant luminosity. However, the opacity in the sub-photospheric layers is enhanced by the presence of H^- ions. It was C Hayashi who first realized, in the early 1960s, that the H^- opacity forces the star to radiate at nearly constant surface temperature. The luminosity L_* is therefore high when the radius and surface area are both large. In particular, L_* is more than can be transported by radiation alone, and the interior is convectively unstable.

Within a few years after Hayashi's discovery, the extensive numerical models of Iben, Cameron and others added more quantitative details. The theory now assumed the form it was to retain for many years. Each stellar mass has its own pre-main-sequence track in the HERTZSPRUNG–RUSSELL (HR) DIAGRAM, which it follows down to the zero-age main sequence (ZAMS). Early on, the star indeed contracts almost vertically, as found by Hayashi. The track then veers sharply to the left, and proceeds to the ZAMS along the more horizontal path obtained by Henyey. This change reflects a transition to radiative stability with falling luminosity.

Figure 1 shows the traditional set of tracks, as obtained by Ezer and Cameron. Each track is labeled by the corresponding mass is solar units. Also indicated at a number of points are the times required to evolve along the track to the position in question. It is immediately apparent that more massive stars evolve faster than their low-mass counterparts. The great utility of pre-main-sequence theory is its ability to supply both a mass and an age for any observed object with known bolometric luminosity and effective temperature. These data help us not only to analyze individual stars, but to discern the star formation history of entire clusters.

Despite the systematic drop in contraction time with mass, all the tracks in figure 1 are qualitatively the same. Each begins by descending vertically from a very high luminosity, before turning onto its more horizontal, radiatively stable portion. In contrast, figure 2 displays results from a more recent calculation. Although the individual tracks are still recognizable, the landscape has markedly changed. The upper portion of the diagram, corresponding to the highest luminosities, is now inaccessible to pre-main-sequence stars. So too is the area to the left containing objects of the highest effective temperature. In the new picture, the most massive stars have no pre-main-sequence contraction phase at all, but appear directly on the ZAMS.

What has brought about this change? How, in turn, have these revisions impacted our understanding of STAR FORMATION? My purpose in this review is to answer these two questions. It should be recognized at the outset that the theoretical developments, initiated over 20 yr ago, still continue, although the key ideas are probably secure. During the same period, our empirical knowledge of pre-main-sequence stars has increased tremendously. Here, I can only sketch the major advances and indicate the ongoing effort to accommodate these observations with a more refined theoretical treatment.

Protostars and the birthline

Most of the alterations to pre-main-sequence theory reflect the impact of new initial conditions. Compared with Hayashi and his contemporaries, we now have a better, although still imperfect, understanding of how each star begins its contraction phase. This knowledge in turn translates into the stellar birthline, a rather well-defined upper boundary for the set of evolutionary tracks in the HR diagram. Referring again to figure 2, it is the presence of the birthline that now restricts the luminosities to relatively modest values. In addition, the joining of this curve to the ZAMS sets the upper mass limit for all pre-main-sequence objects.

Earlier calculations of quasi-static contraction needed to adopt specific initial conditions, whatever their physical plausibility. In the absence of relevant observational data, researchers set the stellar radii at very large values. The distended young stars had correspondingly high luminosities, as is evident in figure 1. Hayashi and others attempted to justify this choice on theoretical grounds, arguing that the youngest stars gain their mass too quickly to radiate away appreciable energy. In reality, the hope

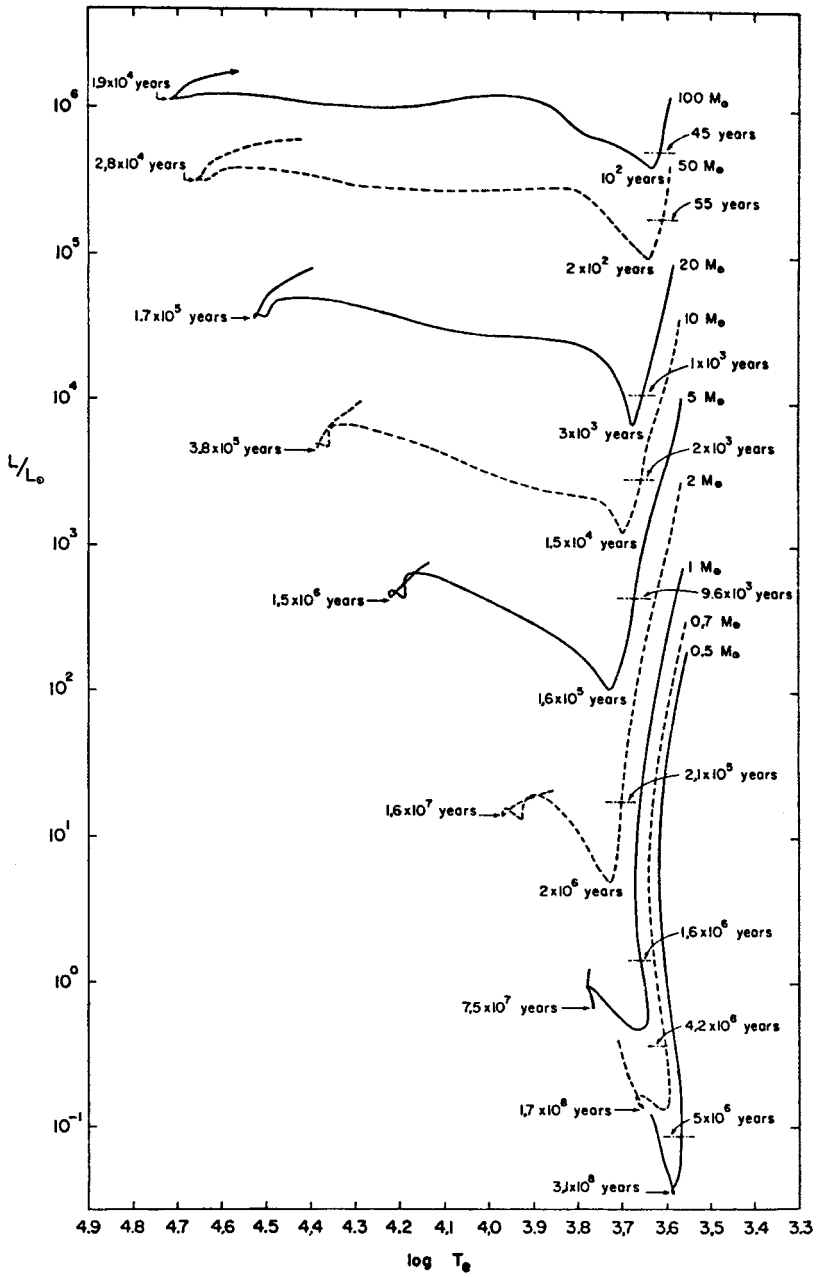

Figure 1. Pre-main-sequence tracks in the traditional theory. Each track is labeled by the appropriate mass. Dashed lines and corresponding times denote the point at which the stars cease to be fully convective. The times to reach the ZAMS are also indicated.

was that all memory of the earliest epoch would quickly be lost during subsequent evolution.

This idea does receive support from the temporal behavior of contracting stars. As we have just noted, any self-gravitating object must lose a large portion of its total energy content in order to reduce its size substantially. Now the virial theorem tells us that this energy is comparable with that from gravitational binding alone. Thus a star of mass M_*, radius R_* and luminosity L_* contracts over the Kelvin–Helmholtz time scale, given by

$$t_{\rm KH} = \frac{GM_*^2}{R_* L_*} = 3 \times 10^7 \text{ yr} \times \left(\frac{M_*}{1M_\odot}\right)^2 \left(\frac{R_*}{1R_\odot}\right)^{-1} \left(\frac{L_*}{1L_\odot}\right)^{-1}. \quad (1)$$

The luminosity, in turn, is that due to a radiating blackbody:

$$L_* = 4\pi R_*^2 \sigma_{\rm B} T_{\rm eff}^4 \quad (2)$$

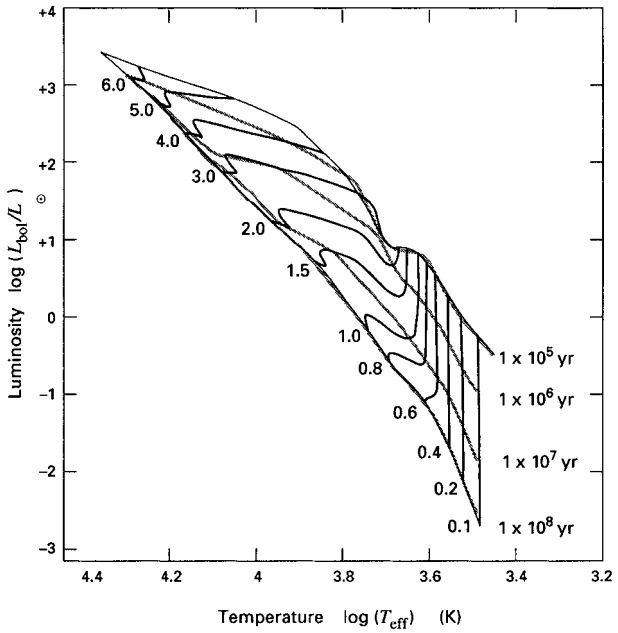

Figure 2. Recent calculation of pre-main-sequence tracks. The upper curve is the stellar birthline, and the lower one the ZAMS. Each track is labeled by the mass in solar units. Also shown are isochrones for selected times.

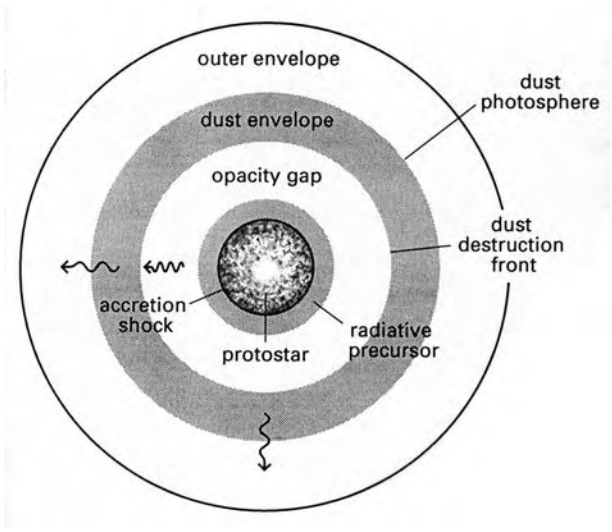

Figure 3. Structure of a protostar and its environment. The range of distances is greatly compressed in this schematic rendering.

where $T_{\rm eff}$ is the star's effective temperature. As the star contracts with nearly constant $T_{\rm eff}$, we see that $t_{\rm KH}$ increases as R_*^{-3}. Thus, the contraction slows down markedly, and any early, distended state indeed occupies a small fraction of the total time to reach the ZAMS.

From an observational perspective, their relatively brief evolutionary lifetimes would make the brightest pre-main-sequence objects relatively uncommon. The difficulty is that stars with the highest L_* values depicted in figure 1 are never seen. Given the large sample sizes, one must conclude that the adopted initial conditions were mistaken. A star actually begins contracting at a much smaller radius and luminosity than was originally envisioned. Although the contraction indeed slows down, the time spent in the earliest state is not negligible. In other words, initial conditions do matter.

The three decades since the original pre-main-sequence calculations have witnessed a substantial growth in our knowledge of stellar formation. Astronomers of the 1960s had no knowledge of molecular clouds, now established as the breeding grounds for stars of all mass. Nor did they understand well the mechanism of gravitational collapse, i.e. the transformation from diffuse cloud fragments to compact stars. Needless to say, these central developments have impacted the theory of pre-main-sequence evolution.

Radio astronomers have by now supplied detailed maps of molecular clouds over a vast range of size scales. Largest are the giant complexes, elongated structures some 50 pc in size, and containing perhaps $10^5 M_\odot$ of gas, mostly in the form of molecular hydrogen. Complexes are self-gravitating swarms of clumps, each one containing about $10^3 M_\odot$. These clumps, in turn, are dotted with numerous dense cores. Each core measures some 0.1 pc in diameter, has a mass of $3M_\odot$ or so and shares the same low temperature (from 10 to 20 K) of its parent cloud. Although the origin of these smallest units remains mysterious, we do know that they are responsible for individual stars.

The first phase of STELLAR EVOLUTION, then, is not the pre-main-sequence, but that earlier epoch when a dense core is undergoing gravitational collapse. The hydrostatic object forming at the center of this converging flow is known as a protostar. Theoretical work on protostars began almost 30 yr ago, with the first direct simulation of a collapsing, spherical cloud by R Larson. It is the subsequent development of this theory that has led to our present, altered conception of pre-main-sequence stars.

Figure 3 depicts schematically a protostar and its surrounding cloud environment. Material in the collapsing dense core rains down onto the surface of the star, forming a strongly radiating accretion shock front. The ultraviolet and x-ray photons produced here work their way back upstream through the infalling gas. As they do so, they elevate the temperature of the envelope to the point where all dust grains thermally sublimate. Since dust is the cloud's chief source of opacity, the protostar is surrounded by a relatively transparent region known as the opacity gap. Beyond this region, photons diffusing through the dusty envelope become degraded to infrared wavelengths. The full accretion luminosity then leaves the cloud at the dust photosphere, typically located about 10 AU from the central star.

A more complete theoretical description endows the parent dense core with a finite degree of rotation. Some portion of the infalling matter then misses the star itself,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

and instead forms a circumstellar disk. This material then spirals onto the stellar surface. The structure and growth of the protostar are largely determined by the total mass accretion rate, conventionally designated $\dot{M}$. The geometrical pattern of infall, i.e. the proportion coming through a disk or by direct infall, is less significant than the overall magnitude and temporal behavior of this rate. The former is set by the basic physics of gravitational collapse. If the parent cloud was largely supported by thermal pressure, its subsequent collapse yields a characteristic accretion rate toward the center:

$$\dot{M} \approx \frac{a_T^3}{G}. \tag{3}$$

Here, a_T is the isothermal sound speed in the dense core, a quantity depending only on the ambient temperature T and molecular weight μ. In a molecular cloud with T between 10 and 20 K, equation (3) yields $\dot{M}$ values ranging from $10^{-6} M_\odot$ to $10^{-5} M_\odot$ yr^{-1}.

The most detailed protostar calculations focus on the star itself and represent the infalling cloud envelope solely through the mass accretion rate. Collapse simulations designed to cover the large-scale dynamics of the cloud find that $\dot{M}$ has a rather slow variation with time, at least beyond an initial, transient phase. Thus, it is worthwhile examining the idealized case of a protostar accumulating mass at a strictly constant rate.

Figure 4 shows the results of such a theoretical calculation. Here we see the protostellar radius R_*, displayed as a function of the mass M_* for $\dot{M} = 1 \times 10^{-5} M_\odot$ yr^{-1}. The first thing to notice is that the radii are not much larger than the corresponding main-sequence values. This result contradicts the original assumption of Hayashi and his contemporaries. Protostars have modest sizes because they lose significant amounts of energy while accumulating their mass. Radiation is generated at the accretion shock front bounding the stellar and disk surfaces. As we have seen, this energy readily escapes the cloud by virtue of the opacity gap.

The relatively small sizes of protostars create elevated internal temperatures. Specifically, the stars become hot enough for deuterium to ignite, in the reaction

$$^2\mathrm{H} + \mathrm{p} \rightarrow {}^3\mathrm{He} + \gamma. \tag{4}$$

Although the number fraction of this isotope is only of order 10^{-5}, heat from the fusion swells the star's radius. This swelling begins at subsolar mass and is evident as the first knee in the curve of figure 4. The second, even more dramatic, rise occurs when deuterium subsequently ignites in a subsurface shell. At still higher mass, $M_* \gtrsim 4M_\odot$, the protostar largely exhausts its deuterium supply and starts to contract under the influence of self-gravity. Its temperature rise concurrently accelerates, and ordinary hydrogen ignites by the time M_* reaches about $8M_\odot$. Even more massive protostars are essentially main-sequence objects still gathering material from their surrounding clouds.

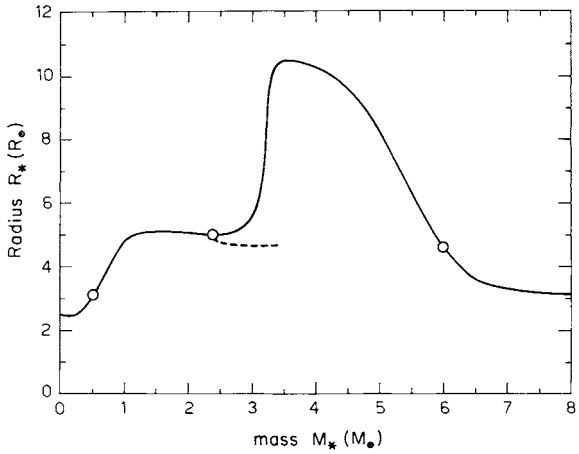

Figure 4. Protostar radius as a function of mass. Open circles mark the onset of deuterium-induced central convection, appearance of a radiatively stable interior region, and the onset of central convection due to hydrogen burning.

Deuterium-generated energy not only swells the protostar but acts as an effective thermostat, locking the central temperature to a value not far from 10^6 K. One important consequence is that the mass–radius relationship is rather insensitive to the adopted $\dot{M}$ value, at least for changes of about a factor of 10. On the other hand, the protostar's history would be very different indeed if no deuterium at all were present. The short dashed curve in figure 4 was obtained by artificially ignoring the fusion reaction in the subsurface shell. In this hypothetical situation, the pronounced swelling would not occur at all.

Protostar calculations like the one illustrated assume a continuous flow of mass onto the central object. Naturally, something must eventually truncate this flow to produce stars of finite mass. One possible factor is rotation of the parent cloud. We have remarked, however, that rotation merely shifts the infall trajectories from the stellar surface to a circumstellar disk. It is likely that internal torques within the disk then promote transfer of this material onto the star. Another possibility is that the star itself blows back its infalling envelope through the action of a strong wind. Finally, infall may cease because the remaining dense core is mechanically prevented from collapsing.

We shall later revisit these last two possibilities. Even without a definitive answer to the question of infall termination, however, we can still address our original concern of pre-main-sequence initial conditions. As long as infall ends relatively quickly, the curve in figure 4 yields the radius of any star of mass M_* at the beginning of its quasi-static contraction phase. The stipulation here is that $\dot{M}$ must decrease substantially over a time that is brief compared with t_{KH} for the mass in question. Provided that this condition is met, we may construct a sequence of initial pre-main-sequence models with a range of masses and the appropriate radii. These objects, unlike their protostellar antecedents, are optically visible, and so may be placed

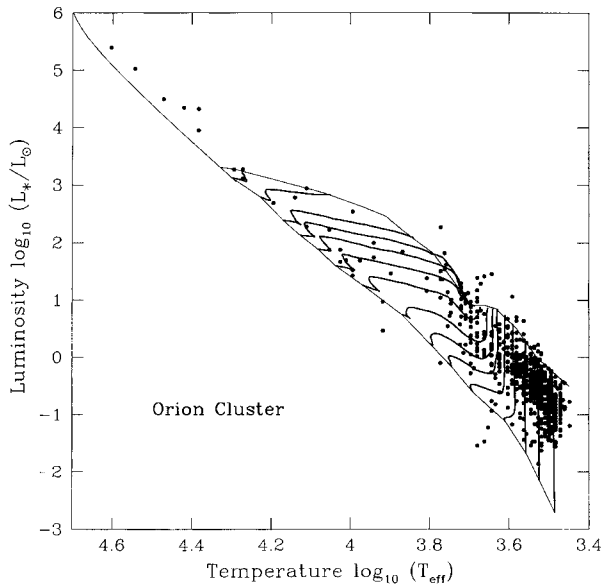

Figure 5. HR diagram of the Orion Nebula Cluster. The theoretical birthline, tracks and ZAMS are identical to those of figure 2, but the ZAMS has been extended to include massive stars.

in the HR diagram. The resulting curve is the birthline depicted in figure 2.

The existence of the birthline is thus motivated by basic theoretical considerations. From an observational perspective, the curve should represent the upper envelope to the positions of young stars in the HR diagram. That is, no stars should be found above the birthline, whether they are observed in isolation or in heavily populated clusters. So far, the voluminous photometric observations of pre-main-sequence stars largely conform to this expectation. For example, Hillenbrand has recently placed over 900 stars of the Orion Nebula Cluster in the HR diagram, after obtaining their bolometric luminosities from I-band observations. The crowded diagram (see figure 5) shows a reasonably sharp upper boundary, which coincides well with the theoretical birthline.

Quasi-static contraction

Low-mass objects

The presence of a birthline in the HR diagram means that pre-main-sequence tracks now fall into two broad categories. Those of lower mass depart from the birthline vertically downward. Observationally, these correspond to T TAURI STARS. In the second category are tracks that begin more horizontally. Here, the theoretical models have radiatively stable interiors, and represent the observed class of Herbig Ae and Be stars. Figure 2 shows that the dividing point is about $2M_\odot$.

We may understand this difference, i.e. predict the fate of any newly formed pre-main-sequence star, by comparing two luminosities. One is the surface value L_*, as given by the blackbody formula of equation (2). The second is $L_{\rm rad}$, the maximum value that can be transported through the interior by radiation alone. This critical luminosity actually varies spatially within a star and also depends on the specific stellar model. Dimensional arguments show, however, that it must be approximately

$$L_{\rm rad} = L_1 \left(\frac{R_*}{R_\odot}\right)^{-1/2} \left(\frac{M_*}{M_\odot}\right)^{11/2} \tag{5}$$

where $L_1 \approx 1L_\odot$. Note the steep mass dependence, reflecting the temperature sensitivity of the interior opacity.

Consider now a sequence of very young pre-main-sequence stars. For sufficiently low mass, $L_{\rm rad}$ is much less than L_*. These objects are radiating more energy than can be transported by radiation. Their interiors are thus fully convective. On the other hand, stars of greater mass have $L_{\rm rad} > L_*$, and are radiatively stable. Because $L_{\rm rad}$ climbs so rapidly with M_*, the transition between the two cases occurs at a rather well-determined mass value, even considering plausible uncertainties in the initial stellar radii.

Schwarzschild's criterion dictates that stars become convective once their specific entropy s decreases outward, i.e. when $s(M_{\rm r})$ is a declining function of the internal mass coordinate $M_{\rm r}$. In practice, however, convection is so efficient at transporting energy that $s(M_{\rm r})$ is nearly uniform, apart from a thin super-adiabatic layer near the surface. Now the heat equation governing evolution of the entropy reads

$$\frac{\partial L_{\rm int}}{\partial M_{\rm r}} = \epsilon - T\frac{\partial s}{\partial t}. \tag{6}$$

Here, $L_{\rm int}(M_{\rm r})$ is the interior luminosity crossing any mass shell and ϵ the local nuclear energy generation rate. Prior to deuterium ignition, we may ignore the latter term. The star loses heat during contraction, so that $\partial s/\partial t$ is negative. It follows that $L_{\rm int}$ is a monotonically increasing function of $M_{\rm r}$, rising from zero at the center to the surface value L_*.

The kind of quasi-static contraction we have just described may be termed homologous. Here, the stellar interior at any one time is simply a rescaled version of its earlier state. This simplification arises from the spatial uniformity of the specific entropy. In mathematical terms, the star may be accurately represented as an $n = 3/2$ polytrope, i.e. the pressure P and density ρ are related at every location through

$$P = K\rho^{5/3}. \tag{7}$$

The coefficient K is a surrogate for the specific entropy and also decreases with time.

Even if a pre-main-sequence object begins its life as a convective object, figure 2 indicates that it eventually becomes radiatively stable, at least for $M_* \gtrsim 0.5M_\odot$. We may again understand this transition in terms of our two

luminosities. Contraction reduces R_* and therefore, by equation (2), L_* as well. On the other hand, equation (5) shows that $L_{\rm rad}$ weakly increases at fixed M_*. Thus, the original inequality $L_* > L_{\rm rad}$ may eventually be reversed and the star becomes stable against convection. In stars of the lowest mass, L_* is so much greater than $L_{\rm rad}$ initially that the two cannot reach equality before hydrogen ignites and halts further contraction. That is, the star settles onto the ZAMS while still fully convective.

The transition of a star to radiative stability occurs first at the center, where the temperature is highest and the interior opacity a minimum. The luminosity in the spreading radiative region obeys equation (5), at least in order of magnitude. Thus, the average $L_{\rm rad}$ rises slowly as R_* continues to drop. The surface luminosity must keep pace with $L_{\rm rad}$, so L_* also increases. This rise is evident in the tracks of figure 2. From equation (2), $T_{\rm eff}$ can no longer be fixed but is forced to increase. The tracks now veer to the left in the HR diagram.

This picture of low-mass young stars accords well with a variety of observational data. We note, however, that the evidence for convection itself is entirely circumstantial. The phenomena actually observed are consistent with surface activity, an enhanced version of that present in the Sun and nearby dwarf stars. Thus, many T Tauri stars exhibit periodic fluctuations in light that indicate large, rotating starspots. Prominent optical emission lines, such as Ca H and K, are thought to stem from chromospheric heating. So too is the x-ray emission that has been especially useful in locating pre-main-sequence objects in dense cloud environments.

It is conventional to divide T Tauri stars into two types, classical and weak lined. Objects in the first category have been studied for over 50 yr, ever since the pioneering work of A Joy. They display, besides the emission lines and other signs of surface activity, excess broadband flux in both the infrared and the ultraviolet regimes. Some of their emission lines exhibit P Cygni profiles, signaling the presence of an outflowing wind. Weak-lined stars derive their name from the suppression or absence of Hα emission, another diagnostic of heated, possibly outflowing gas that appears in the classical objects. Originally dubbed 'naked' stars by Walter, they have normal broadband energy distributions for their spectral types.

In the HR diagrams of young clusters and associations, the two types are thoroughly intermingled close to the birthline. The weak-lined variety predominates, however, as one approaches the ZAMS. The generally accepted interpretation of this pattern is that classical stars are surrounded by disks of dust and gas. Stellar luminosity heats the dust, causing it to reradiate at infrared and longer wavelengths. Apparently, the disks vanish as stars contract toward the ZAMS. Note finally that many classical stars also display inverse P Cygni profiles. The suggestion is that matter from the disk may be spilling onto the stellar surface, perhaps along magnetic field lines. In any case, the associated mass transfer rate of roughly $10^{-8} M_\odot\ {\rm yr}^{-1}$ is too low to cause substantial deviation from the constant-mass theoretical tracks of figure 2.

The variety of T Tauri broadband spectra implies that some pre-main-sequence stars first appear with substantial disks, while others seem to lack them entirely. As we have noted, disks represent material from the parent dense core that had too much angular momentum to impact the star directly during collapse. The production of objects both with and without disks may therefore point to a range in cloud rotation rates. However, it will be difficult to quantify this idea before we have a better understanding of how the infall process actually terminates.

There is a smooth morphological progression from T Tauri stars with disks to other stars exhibiting far greater levels of infrared emission. The so-called 'flat-spectrum' and even more extreme 'class I' sources have far too much flux at long wavelengths to be attributable to disk reradiation. Indeed, the typical class I spectral energy distribution shows a broad maximum near 100 μm, far beyond the near-infrared peaks of classical T Tauri stars. What is the nature of these more embedded objects?

One critical observation is that class I sources are invariably located near the centers of dense cores of molecular gas. Thus, their infrared and millimeter radiation plausibly stems from heated dust within more massive circumstellar envelopes. A number of researchers have suggested that these envelopes are collapsing onto their central stars, i.e. that the objects are true protostars. One should then observe, in addition to the star's photospheric luminosity, the additional energy release from infall. Indeed, current theory predicts that this infall component should actually dominate the total. Observationally, however, the bolometric luminosities of class I sources are quite similar to those of optically visible T Tauri stars, whether classical or weak lined. It thus appears that, while some pre-main-sequence stars appear promptly as revealed objects on the birthline, others remain embedded for some time in remnant cloud material. How this gas is mechanically suspended is not well understood, but the ambient magnetic field almost certainly plays a role. In this regard, it will be interesting to see whether high-resolution mapping at millimeter wavelengths eventually reveals systematic differences between dense cores with and without internal stars.

Stars of intermediate mass

Consider next the evolution of objects above the transition near $2M_\odot$. Here $L_{\rm rad}$, the maximum luminosity carried by radiation, exceeds the surface value L_*. The interior opacity is now low enough that the star can have a fully radiative interior. As we have noted, $L_{\rm rad}$ is not just an upper limit, but also a good estimate for the actual luminosity under the condition of radiative stability. The inequality $L_{\rm rad} > L_*$ then implies that the surface cannot emit all the energy generated by the deep interior through gravitational contraction. Very young stars of

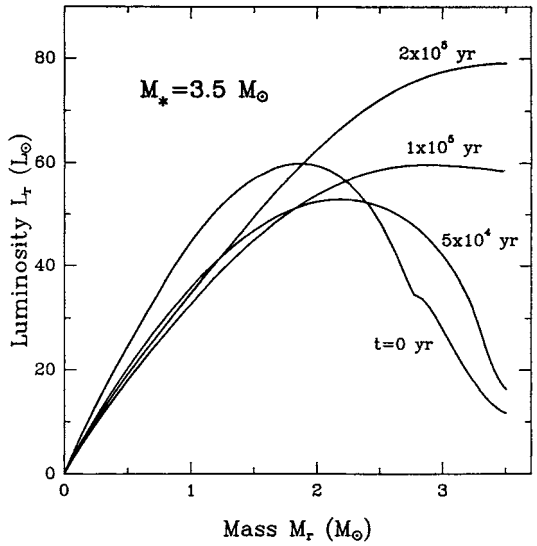

Figure 6. Evolution of the internal luminosity in a $3.5M_\odot$ pre-main-sequence star. The luminosity crossing any shell is plotted against the mass interior to that shell, for the indicated times.

intermediate mass are out of thermal balance and must readjust accordingly.

Figure 6 displays a temporal sequence of luminosity profiles from detailed modeling of a $3.5M_\odot$ star. Plotted is $L_{\rm int}(M_{\rm r})$, starting when the object first appears at the birthline. At this earliest time, we see that $L_{\rm int}$ reaches a maximum value of about $60L_\odot$, while the surface luminosity L_* is only about $10L_\odot$. What becomes of the excess energy? From the heat equation (6), $\partial s/\partial t$ is now positive for all mass shells between the luminosity peak and the surface. The energy being released by contraction thus heats these layers, at least temporarily.

Equation (6) also implies that the entropy is still falling inside of the luminosity maximum. This region therefore contracts as in lower-mass objects. Most of the energy expelled is transferred to the outer layers, which actually expand. The structural evolution of the star is now nonhomologous, and the earlier description in terms of polytropes breaks down. In physical terms, the star has accumulated its mass at a rate which outpaced its ability to thermally relax.

Heating of the outer layers persists until the surface temperature $T_{\rm eff}$ climbs substantially. The luminosity L_* then rises as well, eventually matching the interior peak value. This development may be followed through the alteration of the profiles in figure 6. In effect, the star has released a thermal pulse to the surface. From a more observational perspective, the object may be said to undergo a luminosity jump, a feature evident in the evolutionary tracks of figure 2. The duration of this phenomenon is the thermal relaxation time, or roughly 10^5 yr at the relevant masses. Note that this period is shorter than $t_{\rm KH}$ in equation (1). In the present case, the energy content of the star refers only to its outer layers and is therefore less than the full GM_*^2/R_*.

The observed objects corresponding to these theoretical models are the Herbig Ae and Be stars, first identified nearly 40 yr ago. While these stars are rare compared with their low-mass counterparts, they have come under increasing scrutiny in recent years. There is still no empirical evidence for the thermal transition that should occur at these masses, including the luminosity jump. On the other hand, the very existence of this class is a testament to the essential correctness of the theoretical approach. It should be apparent by now that the location of the birthline in the HR diagram depends solely on the mass–radius relation for accreting protostars. We have seen how those of intermediate mass swell because of deuterium fusion (recall figure 4). Were it not for this effect, the birthline would be shifted downward toward the ZAMS, excluding the region where Herbig Ae and Be stars are actually found. Physically, smaller-radius protostars would have higher central temperatures and would ignite ordinary hydrogen earlier, thus joining the ZAMS at a lower mass.

Pre-main-sequence stars of intermediate mass also display, to varying degrees, excess broadband emission at infrared wavelengths. Subtracting off the likely photospheric contribution to the spectral energy distribution, one often finds that the long-wavelength flux constitutes a large fraction of the total observed luminosity. It was first argued that this emission must stem from accretion through a circumstellar disk, since a more isotropic distribution of dust would have obscured the visible radiation that is actually seen (see DUSTY CIRCUMSTELLAR DISKS). However, the required accretion rates can be so high that the disk would still need continual replenishment from an external envelope of dust and gas. In addition, observers have now spatially resolved the infrared emission in a number of cases, a clear demonstration that the source is much larger than a disk. We are led once more to a picture in which remnant cloud material hovers about the star for a protracted time.

Even more puzzling than the infrared excesses are the signs of surface activity in a large fraction of Herbig Ae and Be stars. Emission in Hα and other lines is present in these cases and frequently displays the P Cygni profiles indicative of winds; other objects have substantial x-ray luminosities. Now the theoretical models do have transient surface convection, powered by the diminishing supply of deuterium. However, convection always vanishes by the time $T_{\rm eff}$ increases to the range appropriate for A and B stars. Could the x-rays and winds instead originate in lower-mass companions that have not been spatially resolved or do they signal residual infall, as is believed for T Tauri stars? Further observations are needed to sort out this issue.

The thermal relaxation characterizing pre-main-sequence stars also occurs in protostars, provided that they accumulate sufficient mass. Thus, the steep increase of R_* seen in figure 4 is caused both by deuterium shell burning and by the shift of internal entropy accompanying the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

thermal pulse. At these masses, the protostar's luminosity stems more from internal energy release than from external infall. The time scale $t_{\rm KH}$ is now significantly shorter than the evolutionary time $M_*/\dot{M}$, and the object rapidly contracts even as it accretes. The mass at which ordinary hydrogen ignites, about $8M_\odot$ for $\dot{M} = 1 \times 10^{-5} M_\odot$ yr^{-1}, also marks the point in the HR diagram where the birthline joins onto the ZAMS. Observations of Herbig Ae and Be stars indeed find an upper mass limit close to this value.

Stars of even higher mass never undergo pre-main-sequence contraction. They exist as obscured protostars, as objects on the ZAMS or as post-main-sequence stars rapidly depleting their nuclear reserves. It is doubtful, moreover, that their protostar phase resembles that at lower masses. Powerful winds from these objects drive back infalling matter, a tendency that is even present to a lesser extent at lower masses. The extraordinary luminosities of massive stars also disrupt the envelope, through radiation pressure acting on the grains. A number of researchers have pointed out that anisotropic infall might lessen the radiative effect. For example, gas in a rotating envelope would not fall directly onto the star, but onto a disk, where it could be shielded by the high optical thickness. However, the disk itself must remain intact for an extended period, despite the star's harsh ionizing flux. Observations of disks in Orion being ablated by the Trapezium stars show that this is no easy matter.

How then do massive stars form? It is significant that the youngest such objects appear close to the density peaks of crowded stellar clusters. The more commonly observed OB ASSOCIATIONS are the expanding descendants of such groups, while systems such as the ORION NEBULA Cluster represent them at an earlier, more compact stage. In the latter example, numerical calculations have demonstrated that the massive stars have not had time to drift to their present, central locations but must have formed *in situ*. One possibility is that these objects originate through the coalescence of previously existing stars. The interaction cross sections of the stars themselves, or even binaries, are probably too small to be relevant, even in the densest observed clusters. However, we have noted that pre-main-sequence stars appear to remain for some time within their parent cloud cores. The merger of these gaseous entities and the subsequent joining of their internal stars is an attractive picture that remains to be developed.

Unanswered questions

Throughout our discussion, the initiation of the pre-main-sequence phase has been a frequently recurring topic. Specifically, we still need to understand what physical event marks the termination of dynamical, protostellar collapse. The derivation of the birthline sidestepped this question by simply assuming that the critical event is suitably brief. We saw, however, that the relevant interval may not be small for many of the stars still surrounded by residual gas and dust. More fundamentally, the issue of infall termination is central in our quest to understand the empirical distribution of STELLAR MASSES.

One possibility we have mentioned is that stars themselves are the responsible agents, through the momentum of their outflowing winds. This idea is motivated by the nearly universal association of optical jets and molecular outflows with embedded stellar objects. Outflows are thought to be cloud gas entrained by the high-velocity wind, where the latter is channeled into a narrow jet. On the other hand, we have no clear example of a cloud being shredded by its internal jet. Such well-observed objects as the Bok globule B335 show both high column densities in molecular gas and vigorous, well-collimated flows. The available evidence is that winds and dense cores coexist for some period. The proposition that the former eventually destroys the latter in all cases remains to be demonstrated.

An alternative viewpoint is that stars accrete all the nearby material available to them. Now the typical masses of cloud cores, as obtained from molecular line observations, are larger by nearly an order of magnitude than the average mass of a newborn star. Assuming that the densest, inner portion of the cloud first collapses, the implication is that the outermost envelope is somehow prevented from joining onto the central star.

The most likely means of preventing, or at least forestalling, collapse is through the embedded magnetic field. Measurements of Zeeman splitting have established a well-ordered field of typical magnitude 10 μG in the lower-density gas surrounding cores. Unfortunately, this observational technique fails within the core itself, but we may assume that the field penetrates this inner region. The narrow linewidths of NH_3 and other tracers show that the core gas is relatively quiescent. Thus, the dominant expansive force aiding thermal pressure is tension from a smooth field, rather than the pressure associated with MAGNETOHYDRODYNAMIC (MHD) WAVES . By the same token, the broad lines observed outside the cores indicate a strong wave influence throughout the larger cloud volume.

Although bending of field lines can effectively resist gravity, it cannot do so indefinitely. Neutral matter slowly drifts across the field through the process known as ambipolar diffusion. Thus we may picture, at least crudely, the collapsing inner core tugging on the ambient field until tension halts rapid infall onto the central star. This event marks the end of the protostar phase. Further mass addition and depletion of the core would occur much more slowly, over the diffusive time scale. The stars receiving this matter would be young, pre-main-sequence objects with strong emission at long wavelengths, perhaps the observed class I sources.

Other vexing problems remain in the study of pre-main-sequence evolution. Chief among them is the issue of ANGULAR MOMENTUM. We remarked before that disks represent cloud material of excessive angular momentum that misses the star during collapse. It would seem to follow that the stars themselves must rotate close to breakup. In fact, the observed rotation speeds of T Tauri stars are very slow, typically under 10% of the breakup value. Furthermore, there is no clear indication of spinup

due to contraction along the evolutionary tracks, except very close to the ZAMS.

It has long been accepted that the torquing action of magnetic winds provides an effective brake on stellar rotation, in all low-mass stars including the Sun. Given a field strength and geometry, theory can predict with confidence the rate of angular momentum loss from the stellar surface. Less well understood is the interior response of the star to this braking action. Nor can theory yet specify what field is generated by a given stellar model. Until these gaps are closed, we will be unable to provide a convincing history of pre-main-sequence rotation.

These problems are fundamental, involving both dynamo theory and the stability of rotating fluids. According to current thinking, regions that are stable against convection may still undergo a kind of anisotropic mixing that serves to transport angular momentum outward. This same process would also affect the internal CHEMICAL COMPOSITIONS OF STARS. Thus, the angular momentum problem relates to yet another outstanding issue, the depletion of lithium and other light elements. In the future, the pre-main-sequence theory outlined here will continue to provide the basic framework for these and other investigations.

Bibliography

Primeval Fireball

A term coined by P J E Peebles, to describe the early phase of the Big Bang universe during which space was filled with an opaque, high-temperature, mixture of radiation (photons) and particles (protons, neutrons, electrons and other elementary particles). Also known as the 'primordial fireball'.

Procyon

The star α Canis Minoris, a cream subgiant of spectral type F5IV–V, apparent magnitude 0.40. Though long known as the 'Little Dog Star' or 'Lesser Dog Star', from the constellation name, the name Procyon is derived from the ancient Greek for 'before the dog', no doubt referring to the fact that it rises before its companion dog star Sirius. The two are the only bright stars in the region to the east of Orion, and hence are especially prominent as they rise in the eastern sky on winter evenings. Procyon is the twelfth star in distance from the Sun at 11.4 light-years, having a parallax of 0.286″. Its absolute magnitude is 2.7.

Procyon is a spectroscopic binary, with a period of 40.4 years. There is also a white dwarf optical companion (magnitude 11.7) at a separation of 122″.

Profession

There was a time, not very many years ago, when professional astronomers were widely regarded as being divorced from the real world. It was thought that they spent their nights in lonely observatories watching the stars, and that many were decidedly advanced in years. This picture was never true, and today it is as wide of the mark as it is possible to be. Your average professional astronomer is young or at most middle-aged, works in a team and very seldom actually looks through a telescope.

In bygone days, of course, there were very few full-time astronomers, and these were supported by the patronage of dukes, princesses, kings and queens, or perhaps through membership of religious orders. Professional astronomers supported by patronage were almost always at least part-time astrologers.

With the rise in Europe, and later in America and the countries of the new world, of the universities, astronomers were employed in larger numbers both to teach astronomy and to research into it, in particular into what we would now call dynamical astronomy or celestial mechanics. With the development of the concept of state responsibility, other astronomers were employed in civic-funded observatories and institutes, financed on a city, regional or national level. Such observatories and institutes were established both for the development of navigation and time-keeping (the Royal Observatories at Paris and Greenwich, and the US Naval Observatory were founded for these reasons), and for making accurate positional observations and calculations about the motions of stars, double stars etc. (astrometry).

After amateurs led the way through observation of the intrinsic properties of the Moon, the planets, the stars and the nebulae (see AMATEUR–PROFESSIONAL COLLABORATION IN ASTRONOMY), by contrast to their positions, more and more astronomers turned to astrophysics, the application of scientific principles to elucidate the nature of celestial bodies—the majority of astronomers at the present time are astrophysicists. The definition of a 'celestial body' is usually taken to mean everything outside the Earth, i.e. in practice everything more than 100 km above the Earth's surface, and the Earth itself in its planetary properties. This includes a very wide variety of natural phenomena! Astronomy is thus an interdisciplinary subject, linked inextricably with all other branches of science: space research (of course), physics, mathematics, chemistry, biology—there are no hard and fast boundaries. The astronomer was never really 'a man apart', but he is even less so now.

The AMERICAN ASTRONOMICAL SOCIETY estimates that there are 6,000 professional astronomers in the USA. In Europe there is about the same number (an estimated 1000 in the UK at post-doctoral level and up). Perhaps the world total is some 15,000–20,000. Established professional astronomers (also, rarely, distinguished amateurs) may become members of the INTERNATIONAL ASTRONOMICAL UNION, through nomination by the Union's national adhering organisations. Global membership is 6,000. The international language of astronomy is English. The number of astronomers is small enough to form a genuinely international community. This tendency is encouraged by the outward-looking nature of the subject, and the scale of investigations of large numbers of stars and galaxies, perhaps from both hemispheres of the Earth, which means that collaborations of astronomers are necessary to tackle the big astronomical questions.

Although astronomy is a universal subject and has a wide appeal, professional astronomers are by no means a representative sample of the human population. They are most numerous (relative to the population) in Europe, North America, Russia and Australia. There are significant numbers of professional astronomers in South America and Asia. There are few in Africa. The proportion of female professional astronomers varies widely from country to country, and is never 50%. Vatican City's Jesuit astronomers are 100% male, for understandable cultural reasons. The northern European nations have the smallest proportion of females. The United States forms an intermediate case between these and the southern European and South American countries. In all countries, the proportion of females decreases with seniority. (In what follows we will have to accept the limitations of the English language and often use male pronouns to denote astronomers of either gender.)

It is difficult to give a simple picture of the prospective development of astronomy as a profession, since the situation varies from country to country. In the USA and the UK, public spending is limited by national economic policy and there is increasing pressure on astronomical budgets in observatories and public institutes. This means that the number of astronomers employed in such places is static, or decreasing. On the other hand, the attraction of astronomy to students has meant that an increasing number of universities offer astronomy components to degree courses, and the number of teachers has been increasing. Telescopes are provided centrally, not necessarily in a big laboratory on campus, so astronomical research is relatively cheap to the universities, and teachers have the opportunity for independent research in bite-sized morsels which have high impact. In general university authorities thus support astronomy research by their teachers.

In continental Europe there has been a history of a larger proportion of astronomers being employed through national, regional or city observatories, and the same economic pressure developing in France and Germany is causing reductions in numbers of astronomers, which may be countered by university growth. Russia and China are special cases, in which astronomers have had high status as respected intellectuals and government employees under the communist governments, a status which has eroded in a negative reaction to everything governmental and disconnected with day to day survival. The difficult economic situation and greater competitivity in both countries has led to a reduction of the numbers

of astronomers, although this seems to have been accomplished mostly at the expense of the less productive ones. In China this process has been called 'Going down to the sea,' meaning making your own way and surviving by a struggle.

At the same time that national facilities are under pressure, established international ones are under pressure too, such as ESA and ESO. However, new international facilities are being set up all the time, such as Gemini and ALMA. The net trend in science is positive as the old gives way to the modern; the net trend in the population of astronomers is hard to discern. In the established astronomical countries, there were periods of great expansion in the population of astronomers after the 1957 launch of Sputnik, and the broadening of tertiary education. These periods of great expansion in traditionally astronomical countries are over, and astronomy in them is now in steady state. The future expansion may be in the astronomically developing countries, like Greece, Spain and South America, with its large mass of astronomical assets especially in Chile.

Astronomy is based on observation of the natural experiments in the Universe. Interpretation of the observations is by theory. Theoretical astronomy suggests further observations. Most astronomers combine theory and observation in their studies to some degree, but most are either principally observational astronomers or principally theorists. In principle, astronomers focus on the natural experiments, and deploy what is required to understand the phenomena, whether theory and calculation, or use of the range of available technology (radio, x-ray or optical telescopes, interferometers, spectroscopy, photometry, space astronomy,...). In practice, a given astronomer will develop skills in a subset of techniques which he or she deploys on the phenomena to which they are most appropriate. An investigation might therefore require the cooperation of a team of astronomers, especially when the investigation is large-scale.

In past times the astronomer had to make his observations at night, often on his own in the cold, up a ladder. The astronomer's presence was required to make and document the observations, initially with the eye and later by photography, and at the same time to operate the telescope, pushing it to new positions and relocating the ladders, while monitoring the performance of the telescope. Travel to an observatory in a remote place may have been arduous, and the sleeping arrangements may have been primitive. This all demanded a certain amount of physical stamina. EDWIN HUBBLE, the great astronomer who first proved that the so-called spiral nebulae are in fact external galaxies, used to relate how he spent night after night in the dome of the Mount Wilson 100 in reflector, checking to make sure that the target object was still perfectly positioned. The degree of domestic comfort may be judged by the name of the hostel on Mt Wilson—'The Monastery'. Today, with computer control of the telescope and data recording, the astronomer need not be in the telescope dome, or even in the same country. Indeed, if the telescope is in space he cannot be in contact with it. This has meant that modern astronomers can specialise in astronomy, rather than technology, and more astronomers than before are 'wavelength independent', happy to use any telescope in pursuit of the astrophysics. Some astronomers lament this, in part from nostalgia, more importantly because there is a generation of astronomers growing up who do not understand the limitations of the observation process and instrumental performance.

It is possible for an individual astronomer to own and have exclusive access to a small telescope, using it whenever he or she wants and conditions are suitable. Moderate sized facilities may be within the scope of a small group of astronomers, say a university department. Large telescopes are however expensive and often provided from national funds and therefore probably with an expectation that access will be 'open'. Competition for access to the facilities may therefore be high—'telescope time' is at a premium because there are simply not sufficient numbers of large telescopes to satisfy everybody in the profession. The same may be true of access to computing power.

All these facts are highly relevant from the viewpoint of the young enthusiast who is considering a career in professional astronomy. As a desirable profession, and a competitive one, modern astronomy is populated by men and women of exceptional ability and drive. Astronomy is an essentially mathematical and physical science; anyone who does not have a natural aptitude for the mathematical sciences may find employment in the role of an assistant to astronomers, for example as engineering or computing support staff, or (as exemplified by one of us) in the astronomical MEDIA, but is unlikely to succeed as a professional astronomer.

In the progression towards being an astronomer it is wise to consider the competitiveness of the profession and to defer specialising wholly in astronomy until the later stages. If you are trained in maths or physics, you can take up astronomy and also a number of other professions; if you are trained exclusively in astronomy you are not so versatile or so desirable to an employer, if your plans to be an astronomer come to nothing. In school it would be wise to take up the maximum quota of science and mathematics subjects, and certainly to aim for a university degree. The first degree (BSc or equivalent) need not be in pure astronomy, indeed, according to the principle of least specialisation perhaps is better not to be, but many general science, physics or mathematics courses in universities offer astronomy and astrophysics options. There is, in fact, evidence in Britain that such options enhance the attractiveness of such courses in universities to students, even those who do not intend to take up astronomy as a career (see EDUCATION). Once a basic science, physics or math degree has been obtained, a further degree in astronomy can be added at Masters level, or in the US must be added as part of the Qualifying Examination for a PhD course. During the astronomy study, the student

will be able to build on the necessary mathematical and physical background acquired in the first three or four years. In France the parallel sequence is the DEUG in mathematical or physical sciences, followed by a "maîtrise" in mathematical or physical sciences with an Astronomy or Astrophysics option.

At Bachelor's or Master's degree level, or its equivalents, career options remain limited to the role of an assistant helping better qualified astronomers, i.e. those with doctorate (PhD or equivalent). The doctorate course (in France Diplôme d'Etudes Approfondies followed by Thèse de doctorat) is a training, not in the acquisition of knowledge discovered by someone else, but in research to acquire new knowledge. The training is supervised by an established astronomer, who will offer guidance on the choice of topic and execution of the research programme. In most cases the supervisor will work with the doctoral student on the research, including any observational work with telescopes, data reduction, and theoretical calculations as appropriate to the topic and the student's inclinations and abilities. Often, a long lasting professional relationship builds up between a supervisor and his students, especially the talented ones. The research is written up by the student into publishable or published scientific papers, and assembled into a thesis.

Success at the PhD stage is the entry qualification into astronomy as a profession. It is likely that the astronomer will be further informally tested for a few years in fixed-term or temporary positions, such as fellowships. It is not uncommon for such positions to be in other countries—indeed in the Netherlands it is regarded as a requirement to become an established Dutch astronomer that at the post-doctoral stage the astronomer should have been overseas, often in North America. During this period he or she has an opportunity to make a name for him- or herself by making important astronomical advances. The result could be to secure that highly desirable, tenured and long-term position as an astronomer in a university, an observatory or an institute.

In past times, the student astronomer worked with a more senior astronomer in a kind of apprenticeship. Just as Johannes Kepler took over the role of his teacher Tycho Brahe, the student would succeed his master. A modern PhD course lasts for three or four years, and a professional astronomer's career lasts perhaps 30 or 40. An active astronomer might supervise a large number of PhD students; even if an astronomer has just one student at a time he might supervise more than ten altogether. It is clear that not all these students can succeed their supervisor, given that that employment opportunities for astronomers are in steady state. As in any population, steady state is not compatible with reproducing oneself several times over. This is the numerical basis for the competition to become a professional astronomer.

In the UK approximately 20% of PhD astronomy students remain in astronomy as a profession. On the other hand there are none who are unemployed. Student astronomers at this level are intelligent, numerically literate, used to interpreting incomplete data (just as you have to in real life), practised in working in teams, often with international colleagues—and they have something to say at their interview. They are very employable, if not all in astronomy. This security has acted as a back stop for astronomy students in the UK who continue in increasing numbers to seek out opportunities to contribute to astronomy and to compete to become professional astronomers. We too were attracted into astronomy at an early age, and we know how powerful is the attraction. If we had to summarise our advice to an aspiring astronomer, it would be 'Recognise the realities and make fall-back plans; but it's not impossible, and it's very rewarding to succeed, so give it your best try.'

Bibliography

Careers advice on joining the community of professional astronomers in the UK is available on the Web from the Cardiff Astronomical Society (http://www.astro.cf.ac.uk/cas/sheet3.pdf). The Royal Astronomical Society publishes a leaflet: Becoming an Astronomer. An Australian perspective is available from the Astronomical Society of Australia (http://www.atnf.csiro.au/educate/become.html). Three comprehensive American discussions on astronomy as a profession are available from NOAO (http://www.noao.edu/education/astfaq.html), from the American Astronomical Society (http://www.aas.org/education/career.html) and from the US Bureau of Labor Statistics (http://stats.bls.gov/oco/ocos052.htm). All these references include realistic statements about employment prospects. The French route to an astronomical career is described by the Société Française d'Astronomie et d'Astrophysique (SF2A) at http://www.iap.fr/sf2a/metier.html.

Prognoz

Series of 10 Soviet spacecraft launched 1971–85 to investigate the solar wind and its interaction with Earth's magnetosphere. Prognoz-9 (launched July 1983) carried experiments to study the Sun, x-ray and gamma ray bursts as well as the Relict-1 radio astronomy experiment. Prognoz 10 (launched April 1985) carried instruments for studying the plasma, the magnetic field, electric and magnetic components of waves, solar flare x-ray bursts and kilometre radiation. Prominence

A plume of luminous gas in the solar atmosphere visible beyond the solar limb (the edge of the visible disk). Although their densities are about a hundred times greater than that of the surrounding coronal material, they are too low to enable them to emit a continuous white-light spectrum. Their visible light consists mainly of emission lines of hydrogen and ionized calcium and, except during total eclipses of the Sun (when they may be seen directly by eye), they are normally studied in monochromatic light (wavelengths corresponding to particular emission lines, such as the hydrogen-α line in the red part of the spectrum).

There are two principal types of prominence—quiescent and active. Quiescent prominences hang like clouds in the corona for weeks or months with relatively little overall change, whereas active prominences undergo rapid changes. Quiescent prominences have lengths ranging from several tens of thousands of kilometers to several hundred thousand kilometers and heights of around 30 000 km. They are suspended above the chromosphere by magnetic fields. Most quiescent prominences look like curtains of gas that connect with the chromosphere at various points and contain many near-vertical strands down which gas flows. From time to time, a quiescent prominence will suddenly erupt outwards and dissipate, often to be replaced, in the same location, by a new one. Active prominences, which are associated with active regions on the Sun, and are often associated with, or triggered by, solar flares, are short-lived phenomena, most of which survive no more than a few hours. They take a variety of forms. Among the most active are loop prominences, structures that connect regions of opposite magnetic polarity and within which coronal material condenses and flows down into the chromosphere. Sprays scatter material over a wide range of angles at speeds ranging from 200 km s^{-1} to as much as 2000 km s^{-1}, whereas surges consist of more closely collimated ejections of material. Giant eruptive prominences (often loop-shaped) surge upwards to heights of 500 000 km or more.

When solar rotation carries prominences across the face of the Sun, they then appear as dark features against the bright solar disk. Quiescent prominences correspond to the extensive, long-lived, dark filaments that feature on monochromatic images of the solar disk.

Proper Motion

Proper motion is the change of position of an object on the celestial sphere, usually measured in seconds of arc (″) per year (figure 1). 'Proper' means intrinsic, as opposed to a motion due to change of coordinates (such as precession). The term is most often applied to stars but is also used for changes in position of clusters of stars, galaxies outside our Milky Way and features within these objects. In 1718 Edmund Halley was the first to recognize proper motions, when he realized the positions relative to nearby stars of Arcturus, Aldebaran and Sirius had changed since antiquity. Proper motion is an angular measurement and depends directly on an object's transverse velocity (the component of velocity across the line of sight) and inversely on its distance. For a given proper motion, the more distant an object is, the higher its transverse velocity must be (figure 2). Barnard's star has the highest proper motion known, 10.″3 yr^{-1}. The term also refers to changes in position of features observed at infrared and radio wavelengths. Proper motions are determined by measuring positions with respect to other objects, typically stars or galaxies. If the comparison objects cannot be assumed to be stationary on the sky, a correction for their motion must be made to determine the absolute proper motion. Together with the RADIAL VELOCITY, the proper motion defines the motion of an object relative to the SUN. If the distance to the object is known, the proper motion and radial velocity define the three-dimensional space velocity of the object, again relative to the Sun.

Proper motions are used to study stellar motions and the correlation, if any, between motions and age, metal abundances and spectral types of stars. Proper motions are also used to calculate the rate of revolution around the center of our Galaxy. Recently proper motions have been applied to the investigation of features associated with young stars, the possible existence of a massive black hole at the center of our Galaxy and the motion of objects in other galaxies. The latter investigations show promise for the direct determination of the distances to other galaxies. Space missions currently under discussion will further extend investigations of objects in our own and other galaxies through the use of proper motions.

There are several components to the motion of stars in our Galaxy. Stars in the galactic disk, like the Sun, partake of a general revolution in a common direction around the center of the Galaxy (see GALACTIC THICK DISK, GALACTIC THIN DISK). Stars in the halo revolve around the galactic center in orbits with random eccentricities and orientations. In addition to the motion around the galactic center, disk stars each have their own peculiar, or random, motions, typically 10–20 km s^{-1}. Peculiar motions are defined with respect to the local standard of rest, a reference frame in which the averaged random velocities of stars near the Sun is zero. The local standard of rest moves around the center of the Galaxy at the velocity corresponding to galactic rotation at the Sun's distance from the galactic center. The apparent motion of stars relative to the Sun is a combination of their motion and the Sun's motion. The position of objects on the sky changes owing to their relative motion perpendicular to the line of sight with respect to the Sun.

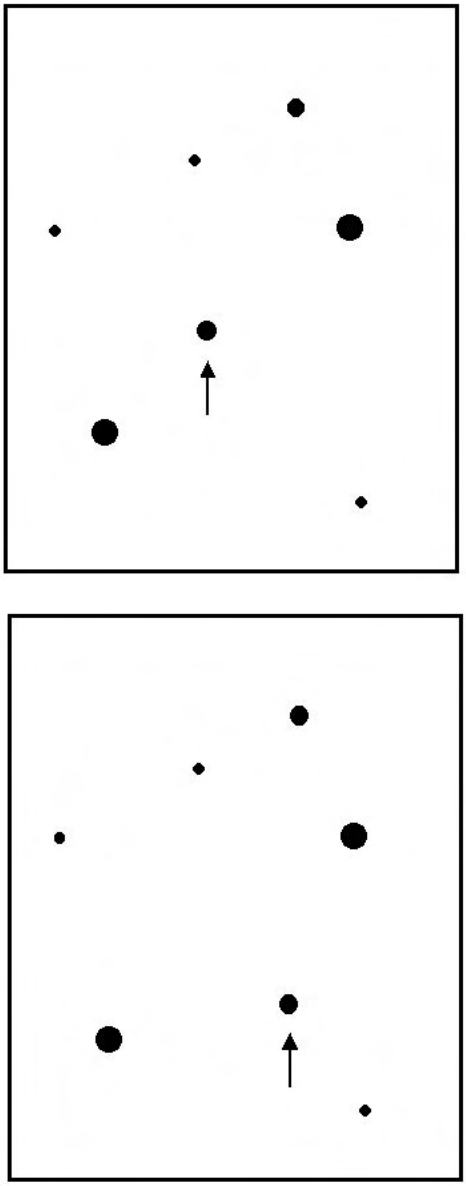

Figure 1. An example of the change of position on the sky of a star, indicated by arrows, relative to other stars.

Because more distant stars tend to have small proper motions, in the past they were used to define a coordinate system in which to measure the motions of nearby stars. As measurement techniques improve, even the proper motions of distant stars can be detected. Modern measurements use the position of faint galaxies to define the reference frame. Motion along the line of sight directly towards or away from the Sun (the radial velocity) does

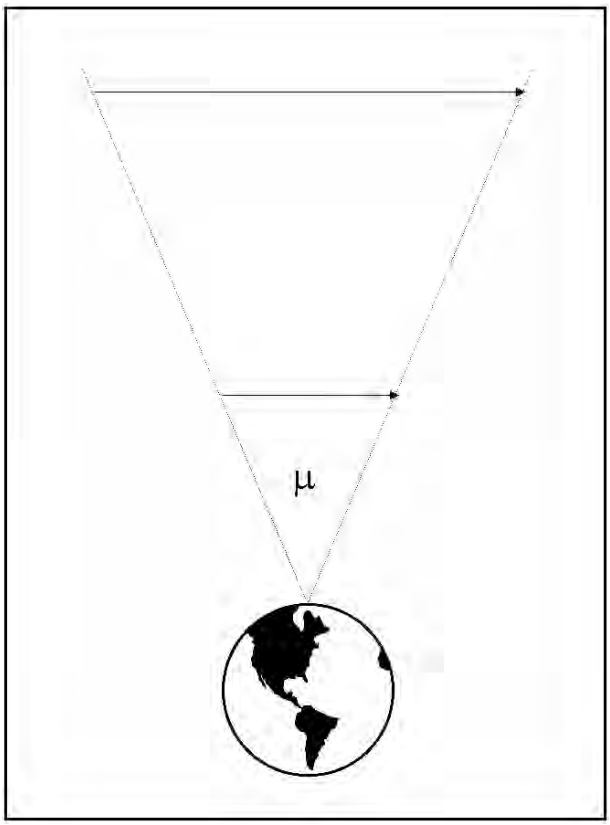

Figure 2. Proper motion, indicated by the Greek letter μ, is the angular change of position of an object on the sky, usually reported in seconds of arc per year. The angle shown is highly exaggerated; the maximum proper motion measured is $10\farcs3\ \mathrm{yr}^{-1}$.

not contribute to the proper motion. Motion relative to the Sun is usually reported, even though measurements made from the Earth contain a component due to the Earth's motion around the Sun, which must be removed.

Measurement

While the concept of proper motion is straightforward, proper motions are difficult and time consuming to measure. In principle, two images of the object of interest separated by 1 yr, to remove the apparent change of position on the sky due to the Earth's revolution around the Sun (see PARALLAXES), are sufficient. The position of the object relative to other objects in the field would then be measured. In practice, because the annual changes in position are small, successive images are often separated by several years or decades. Since one does not know in advance which objects will have detectable proper motions, proper motion surveys often use large photographic plates to observe as many objects as possible simultaneously. Large-area detectors also ensure that there are many stars and galaxies in the field to define the reference frame against which motions are measured. Positions of objects on the images must then be compared. Historically, this was done manually with a blink comparator, a device which allowed the astronomer to look first at one image, then at the other, to see which objects appeared to move relative to the others. Now photographic plates are automatically scanned with densitometers, the output of which is fed into computers which find and catalog stellar positions. Computerized comparison of positions on plates taken at two different times identifies objects whose positions have changed significantly and the proper motion is calculated. Because the changes in position are very small and errors can easily be introduced into the results, it is advisable to take all data on the same telescope and, if possible, use the same instrument. If stars are used to define the reference frame for the measurements, the final results must be corrected for the mean parallax and proper motion of the reference stars.

Results of proper motion surveys are generally produced as catalogs containing positions, proper motions and often photometric information for thousands or tens of thousands of stars. Modern surveys use faint galaxies to define the reference frame, which can then be linked to the International Celestial Reference Frame, based on extragalactic RADIO SOURCES. Accuracies of 3–8 marcsec yr^{-1} are typical for ground-based observations, depending on the brightness of the star.

Techniques to improve this accuracy and thus obtain more precise proper motions are constantly being investigated. One source of uncertainty is the size of the stellar images on the photographic plates. Motion in the EARTH'S ATMOSPHERE blurs astronomical images as the light passes through. This blurring, referred to as seeing, produces stellar images larger and more diffuse than they would be outside the Earth's atmosphere and makes it difficult to determine the center of the image.

Problems associated with seeing can be minimized by obtaining a series of images, each exposed for a fraction of a second, and then combining those data to produce the final image. In these exposures a star image is broken up into a series of blobs, or speckles, produced as the light passes through cells in the atmosphere. The speckle pattern changes rapidly, producing the blurred image normally observed. By aligning the speckle patterns of all the images, the spatial resolution of the telescope is significantly enhanced. Because the exposures must be taken rapidly in succession, an electronically read-out detector must be used, so the area of sky observable is limited by the available detector arrays.

Space astronomy has also contributed to improved measurement of proper motions. Taken above the Earth's atmosphere, these images do not suffer from the atmospheric seeing. Space observatories also avoid the problem of deflection of the telescope, optics and instruments due to the gravitational attraction of the Earth. They can, however, be subject to large temperature fluctuations, which can also cause deflection problems unless controlled or counterbalanced.

In 1989 the EUROPEAN SPACE AGENCY launched the HIPPARCOS (High Precision Parallax Collecting Satellite) astrometric satellite, which measured the positions, parallaxes and proper motions of 118 000 stars to an average accuracy of 1 marcsec. Astrometric data were obtained for a second group of more than one million stars at lower precision. The satellite was designed to spin slowly, scanning the entire sky several times during its mission. While only early results of the Hipparcos mission have been reported, they are already having a large impact on our understanding of stellar motions and other fundamental questions in astronomy.

Scientific results

Nearby and high-velocity stars

One of the first applications of proper motions was to identify nearby and/or high-velocity stars, because stars with large proper motions are either nearby or have high transverse velocities relative to the Sun. Proper motions are an efficient way to identify intrinsically faint, nearby stars, which are otherwise difficult to distinguish from brighter stars that are more distant. Once nearby stars are identified, parallaxes and other data can be obtained. If several measurements of the stellar position are made and the star appears to follow a wavy path across the sky, the star has a fainter companion. In such systems, the center of mass follows a straight line, while the combination of star's motion around the system center of mass and the system's motion through the Galaxy produces the apparent wobble. Such systems can be used to derive stellar mass data. Astronomers are particularly interested in two classes of intrinsically faint stars: RED DWARFS and WHITE DWARFS. Red dwarfs are the faintest, yet most numerous, stars on the main sequence (stars which generate energy by converting hydrogen to helium in their cores). Red dwarfs are studied to determine the physical characteristics and space densities of the least massive stars. Because they are very numerous, red dwarfs are a significant component of the stellar mass in the Milky Way. A white dwarf is a stellar remnant, the remains of a star after it has consumed all of its fuel. Such stars are studied to test theories of the end state of STELLAR EVOLUTION and also to determine their contribution to the stellar density of the Galaxy.

Proper motions are also an efficient way to identify stars moving rapidly with respect to the Sun. Such stars probably originated outside the Galaxy's disk, and their high velocities may be clues to the star's location at its time of formation, its age, chemical composition and even the evolutionary state of the Galaxy when the star was formed. According to some theories of GALAXY FORMATION, the Milky Way formed from a large rotating cloud of gas which collapsed into a disk containing most of the stars. In this scenario, some stars formed during the collapse. On the other hand, recent work suggests that some of the stars far from the Galaxy disk originated in stellar satellites which were destroyed by gravitational interaction with our Galaxy. Whatever their origin, stars far from the disk in the galactic halo have large components of motion perpendicular to the galactic plane and relatively large (100–200 km s^{-1}) velocities compared with stars in the disk. Therefore stars with high proper motions may belong to a population that formed while the gas in the Galaxy collapsed or to a population that formed in star clusters or satellite galaxies accreted by our Galaxy. Investigations of these stars can reveal the physical conditions in their place of origin and thus how the galactic halo formed.

In principle, astronomers can identify high-velocity stars from radial velocities as well as proper motions. However, proper motion surveys have the advantage of screening large numbers of stars simultaneously. Until the advent of SPECTROGRAPHS with two-dimensional detectors, stellar radial velocities were measured individually. Even with modern electronic detectors, spectra of at most a few hundred objects can be obtained simultaneously. Measurements of positions and therefore proper motions can be obtained for thousands of stars simultaneously from imaging surveys.

'Runaway' stars are a second type of high-velocity star that can be identified from proper motions. These are stars that are too young to belong to the halo population whatever its origin. Of particular interest are runaway O and B stars, which have lifetimes of a few million to a few hundred million years. Such stars are found at greater distances from their birthplaces in the galactic disk than they could travel in their lifetimes at the normal peculiar velocities of such stars.

Two hypotheses have been suggested to explain the location of runaway O and B stars: they were ejected from their birthplace by a dynamical interaction among stars in a young, compact STAR CLUSTER or they were originally members of a BINARY SYSTEM containing two massive stars in which one star became a SUPERNOVA. Stellar evolution theory predicts that massive stars become supernovae when they have exhausted all of their nuclear fuel. Models indicate that, in binary systems with two massive stars, the system may be disrupted if the first supernova is asymmetric. Such a system could produce a high-velocity O star and a high-velocity PULSAR, the remnant of the exploded star. Even if the first supernova does not disrupt the system, the second supernova can, producing two high-velocity single pulsars. The two hypotheses make different predictions concerning the kinematic ages of the stars, the times since they left their birthplace. Kinematic ages can be estimated from the space velocity of the stars and the distance back to their point of origin or, if that is not known, to the plane of the galaxy. Recent investigations of O and B stars by Moffat and collaborators tend to favor the cluster ejection scenario, although the binary disruption mechanism cannot be ruled out.

Kinematics of stellar populations

One of the fundamental goals of galactic astronomy is to understand the spatial distribution and kinematic properties of the stars in the Milky Way. These data not only reveal the current state of these objects but also contain information about the gravitational potential of

the Galaxy and the history of STAR FORMATION. The proper motions, distances and radial velocities of a group of stars are needed to completely define their space velocities. The data are typically analyzed by comparing the observations with a model of the Galaxy and deriving the desired parameters. In some cases the model is expressed only in terms of transverse velocities, so that radial velocities may not be required. Quantities that can be estimated for the stellar group include the mean velocity and velocity dispersion perpendicular to the galactic plane, in the direction of galactic rotation in the plane and in the radial direction in the galactic plane. The velocity of rotation of the local standard of rest, the distance of the Sun from the galactic center, the peculiar velocity of the Sun and the density gradient parallel to the galactic plane in the solar neighborhood also can be determined.

Because different types of stars have different kinematic properties, it is important to use a homogeneous stellar sample to derive the velocities. Then one may study the average velocity perpendicular to the galactic plane as a function of spectral type or other parameter. One result of such studies has been an anti-correlation between the age of a stellar population and the degree of concentration of its space distribution to the galactic plane. Investigations like these led to the classification of stars into multiple STELLAR POPULATIONS. Recent work by Wielen investigated the mean velocities and velocity dispersions of RR LYRAE stars as a function of metallicity. (Astronomers refer to all elements other than hydrogen and helium as metals. It is generally agreed that on average older stars have lower abundances of metals than younger stars.) RR Lyrae stars are old pulsating stars often found in GLOBULAR CLUSTERS. Such investigations relate the increase of metals in the Galaxy, which is directly dependent on the rate of massive star formation, to the rate of collapse of the gas in the galactic halo. The deviation of the stellar velocity from the circular rotation velocity also may be investigated. It has been found that, at the Sun's distance from the galactic center, the rotational velocity derived from the youngest stars is closest to the circular velocity.

Statistical analysis of proper motions is used to determine the mean parallax, and thus distance, to a sample of stars. If the stars are selected to have similar spectral type and luminosity class, and thus absolute magnitude, the mean distance can be used to determine a value for the mean absolute magnitude. There are two methods to determine distances, secular and statistical parallaxes. For secular parallaxes, the averaged velocity of a sample of nearby stars is assumed to be zero. The mean proper motion of the sample is therefore just due to the average of the Sun's motion, 20 km s^{-1}, projected onto the plane of the sky at the positions of the stars. The average distance for the sample is directly calculated from the ratio of the distance traveled by the Sun during a year projected on the sky and the mean proper motion. Statistical parallaxes assume that the three-dimensional space velocities of the stars are isotropically distributed. If the radial velocities of the stars are known, by the isotropic assumption, the mean of the radial velocities must be equal to the mean of the transverse velocities. Since the proper motion is the distance traveled by a star in a year at its transverse velocity divided by its distance, the mean distance to the stars can be determined. More complex analyses for stars far from the Sun assume a model for motion of stars as a function of location in the Galaxy. The resulting statistical parallax is of course dependent on the model, just as the results described previously depend on the assumption that the average velocity of the sample stars is zero or the velocities are isotropic.

Statistical parallaxes are useful for stars too distant to measure individual stellar parallaxes. Statistical parallaxes have been used to estimate the absolute magnitude of RR Lyrae stars. Because these stars vary in a recognizable way, they can easily be identified in globular clusters, in the galactic halo or in nearby galaxies and are useful as a distance indicator. If their absolute magnitude is known, the distance to the cluster or galaxy can be determined. Distances to globular clusters are particularly important because the ages of the clusters are determined by the absolute magnitude and spectral type of stars beginning to evolve off the main sequence. Globular cluster ages are a lower limit to the age of the universe. RR Lyrae variables are also observed in nearby galaxies and can be used to determine their distances. Unfortunately they are relatively faint and can only be detected in the closest galaxies.

Star clusters and associations, nearby galaxies

Detailed studies of the proper motions of stars in clusters (groups of physically associated stars thought to have a common origin) and associations (looser groupings of young stars which are probably not gravitationally bound) can reveal a great deal about the membership and dynamics of these groups. Since clusters are first identified as a concentration of stars in a small area of the sky, proper motions enable astronomers to confirm membership of individual stars and even to establish that a cluster really exists and is not just a random superposition of stars along the line of sight. Stars which are not obviously part of the group, for example F stars in an O,B association, can be identified. The proper motion of the cluster can be combined with its radial velocity to calculate the space velocity. For nearby clusters such as the Hyades, these data can be used to improve the precision of the cluster's parallax and thus distance. For globular clusters, which are several billion years old, the space velocity provides information about the kinematics of the gas out of which the clusters formed. Proper motions can be combined with radial velocities to determine the distance to the cluster using the method of statistical parallax. Because even the closest clusters are somewhat distant, a long time baseline is required to measure accurately the proper motions of stars in clusters.

If the relative proper motions are sufficiently accurate, they can be used to investigate the motions within the star cluster. Because most clusters are distant and the relative

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

motions small and of limited accuracy, the dispersion of the proper motions is often used. If the dispersion can be calculated as a function of magnitude, which relates directly to stellar mass, and distance from the center of the cluster, the mass of the cluster can be estimated. The azimuthal and radial proper motion dispersions relative to the cluster center measure the amount of anisotropy in the relative motions, which tests theories of cluster dynamics.

Proper motions can also be used to study the kinematics of the MAGELLANIC CLOUDS, satellite galaxies gravitationally bound to the Milky Way. Proper motions combined with radial velocities determine the space motions of the galaxies and constrain the gravitational potential of the Milky Way.

Black hole at the center of the Galaxy

It has been suggested that the Milky Way, like many other galaxies, harbors a black hole at its center. In the 1990s the development of infrared array detectors and speckle interferometry has enabled astronomers to test this theory by measuring the proper motions of stars at the center of our Galaxy. Stars at the center of our Galaxy cannot be observed in visible light, owing to dust in the plane of the Galaxy along the line of sight. Infrared wavelengths are not absorbed to the same degree as visible light and can be used to detect stars obscured by dust. Eckart and Genzel (1996) and Ghez and collaborators (1998) have applied the speckle technique to near-infrared (2.2 μm) observations of the stars at the center of our Galaxy. The distribution of the proper motions of the stars is centered at the position of Sgr A*, a radio source previously suspected of being at the center of the Milky Way (figure 3). In general the stars closest to Sgr A* are moving fastest. The dispersion of the velocities obtained from the proper motions also peaks at the position of Sgr A*. If the stars are gravitationally bound, the central mass implied is 2.6×10^6 solar masses. While exotic alternatives such as clusters of elementary particles and very-low-mass black holes cannot be completely eliminated, the mass is most likely due to a supermassive black hole.

Radio proper motions

While proper motions were first observed and used at optical wavelengths, they can be measured at any wavelength for which repeated observations indicate motion on the plane of the sky. Since the late 1960s radio astronomers have used interferometry to obtain high-resolution measurements of the positions of radio sources (see RADIO INTERFEROMETER). Spatial resolutions of 1 marcsec are readily attained with modern arrays of radio telescopes. While there are relatively few strong stellar radio sources, radio astronomers have observed proper motions of features in the continuum radio emission from nuclei of QUASISTELLAR OBJECTS and galaxies. In many cases there appears to be transverse motion at several times the speed of light, probably because of orientation effects in a relativistic beam pointed towards the observer (within a few degrees of the line of sight) (figure 4). These

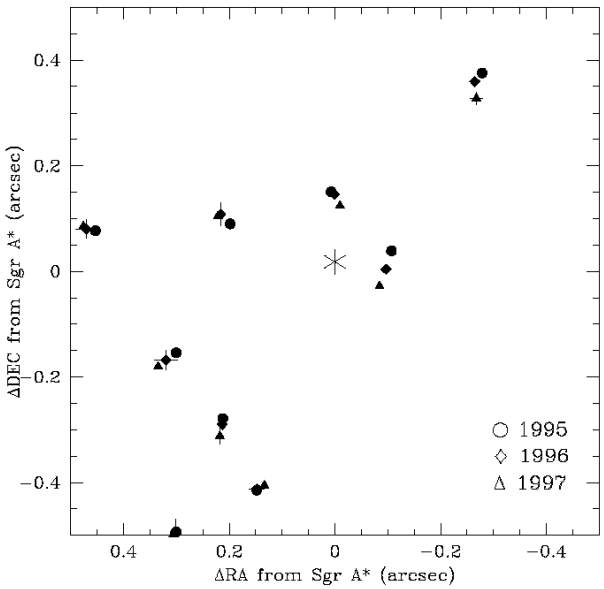

Figure 3. Measured positions of stars in 1 arcsec^2 centered on Sgr A*, indicated by starred point. Significant velocities are readily detected in this region. observations help constrain models for the evolution of radio sources.

Statistical methods have also been applied to the proper motions of radio sources to determine their distances and three-dimensional velocity field. Observations of star-forming regions in our Galaxy reveal that some of them contain numerous microwave radio sources called masers. These are small regions which emit enhanced molecular spectral lines, usually from OH or H_2O. The enhancement is thought to be associated with star formation. Starting in 1977, Genzel and collaborators measured radial velocities and changes in the positions of water masers in star-forming regions. Distances may be determined by two methods. If the motions are random so that all velocity components have the same dispersion, the distance can be directly determined from the ratio of the velocity dispersion in the radial direction to the dispersion of the proper motions. If the kinematics in the source is not random, the proper motions, radial velocities and positions on the sky are used to model the source in three dimensions. The distance is then calculated by scaling the observed proper motions to the transverse velocities predicted by the model. In this method not only is the distance to the source estimated but a model of the source is also determined. If the distance to the star-forming region is known *a priori*, the proper motions and radial velocities can be used to investigate the dynamics within the source. Attempts have also been made to apply these techniques to clouds of molecular masers in nearby galaxies, thus

directly measuring their distances without recourse to assumed luminosity standards.

Proper motions of water masers associated with the centers of galaxies also show promise of enabling astronomers to directly determine distances to galaxies. This technique was used to determine the distance to the center of our Galaxy by Reid and collaborators in 1988. In 1995 Greenhill and collaborators detected water masers which apparently trace a thin, nearly edge-on disk rotating around a central mass in the galaxy NGC 4258. The rotation of the disk was predicted to cause the radial velocities and positions of the masers in the disk to change, with the change in position, i.e. proper motion, dependent on the distance to the galaxy. A series of radio observations indicated that the positions of the masers had indeed changed. Assuming a model for the rotation including the radial velocities, a distance to NGC 4258 was calculated based only on geometry. If such masers, appropriately positioned with respect to the plane of the sky, can be found in other galaxies, this will be a powerful new technique for directly determining distances to galaxies. Not only will the distances to the galaxies be calculated but the results will make possible the calibration of variable stars and other luminosity standards using objects in other galaxies, not just the Milky Way.

Future initiatives

In the future increasingly accurate proper motions can be expected from observations on the ground and in space. Efforts are underway to combine the results of the Hipparcos mission with older ground-based photographic plates to extend the time baseline and accuracy of proper motions.

With the success of the Hipparcos mission, several other space astrometry missions have been suggested. The two that seem most likely to fly at this time are SIM, the SPACE INTERFEROMETRY MISSION, proposed by NASA, and GAIA, Global Astrometric Interferometer for Astrophysics, under consideration by the European Space Agency. GAIA's goal is to assemble a catalog of more than one thousand million stars with three-dimensional positions, space velocities and related information. Astrometric measurements of position, parallax, and proper motions will be obtained for all stars to apparent visual magnitude 20, about one-millionth the brightness of the faintest star visible to the naked eye. Radial velocities for stars down to apparent visual magnitude 17 will also be measured. This mission is expected to measure distances to the center of the galaxy to 10% accuracy and catalog about 1% of the stars in the galaxy. Assuming a 5 yr mission, the predicted precision for proper motions of stars brighter than apparent visual magnitude 15 is better than 10 μarcsec yr^{-1}.

The SIM mission will measure proper motions of individual, bright stars in several nearby intermediate- and late-type spiral galaxies. Assuming the averaged proper motions and ground-based radial velocities are both due to the nearly circular rotation in the disks of the galaxies, rotational parallaxes, distances independent of luminosity-based distance indicators, can be determined. Directly measured luminosities of bright stars, including cepheid and RR Lyrae variables, will then be available for a variety of galaxies, strengthening the calibration of the distance scale. As proposed, the mission is expected

to achieve an astrometric accuracy of 5 μarcsec or better, depending on the target. Other goals for SIM include determining positions and distances for stars throughout the Milky Way and probing nearby stars for Earth-like planets.

Proper Motion: Optical/Infrared

The proper motion of a star, or other object, is its angular change in direction on the sky over a period of time, often expressed in arcseconds per year. Its definition is specific with regard to location of the observer, usually at the Sun, and the background frame of reference against which the motion is compared.

Most of the stars in our Galaxy occupy a flattened, disk-shaped region and central bulge, while the remainder are sparsely distributed in a spherical halo. Some 400 billion stars in our Galaxy, the Sun included, are revolving mostly in the same sense about a distant point, the galactic center, with different speeds and directions. The GALACTIC OPEN CLUSTERS and GLOBULAR CLUSTERS are also in orbit about the galactic center. Within each cluster each member star moves in an orbit about its center of mass. Even the non-stellar galactic nebulae and the dark absorption clouds are also in motion, as well as changing in size and shape. There is more. As we look to our neighboring galaxies, we are aware that they, too, are moving at different speeds and directions. Space motion is a universal characteristic, one component of which is the proper motion. Therefore, we need to measure proper motions in order to see the pattern of galactic motions for stars and clusters, as well as for stellar motions within clusters. The measurement of proper motions for nearby galaxies is becoming a reality that enables tracing their dynamical evolution and tidal interactions, including possible mergers with our Galaxy. These are forefront problems of astronomy.

Consider a star viewed from the Sun in a certain direction on the sky (figure 1). Over a time interval the space motion (S) of the star, pictured here in two dimensions, is described by a vector, like an arrow of certain length and direction. The component of this space velocity projected on the sky is called the *tangential velocity* (T), while the component along the line of sight is the *radial velocity* (V), all expressed in kilometers per second. Proper motion μ is simply the change in direction after some time interval, say one year, for a star moving at the tangential velocity. It may be expressed in units of arcseconds, milliarcseconds (mas), or microarcseconds (μas) per year, where 1 mas = 0.001 arcsec = 1000 μas. Simple formulae relate these motions with distance of the object from the Sun d in parsecs (1 pc = 3.26 light years).

$$S = (V^2 + T^2)^{1/2} \qquad \text{and} \qquad T = 4.74\,\mu\,d.$$

If we measure the distance, proper motion, and radial velocity of a star, we can compute its space velocity with respect to the Sun as origin. The distance and PARALLAX (π in arcsec) are inversely related by $d = \pi^{-1}$.

The observations are made from the surface of a rotating Earth (topocentric), which is revolving about the Sun, so that certain corrections are needed to specify a space motion with respect to the Sun (heliocentric), or to the center of mass of the solar system (barycentric). Observed positions represent the combined effects of parallax, significant for nearer stars, and proper motions. Observed radial velocities need corrections for the Earth's rotation and orbital motion and, possibly, motion of the Sun about the center of mass of the solar system. Other small corrections are relevant. Other definitions of the space motion of stars are used for studies of stellar kinematics, including origins located at the average motion of stars in the solar neighborhood, the Local Standard of Rest (LSR), or at the galactic center (galactocentric motion). Transformation formulae enable conversions of space motions amongst these origins and axes.

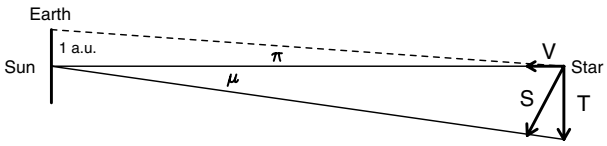

Figure 1. Space velocity (S) with components radial velocity (V) and tangential velocity (T). Proper motion displacement (μ) corresponds to the tangential velocity and parallax (π) is the angular change in direction of a star as seen from ends of a baseline of length one astronomical unit.

The proper motions for galactic stars reflect the wide range of their space velocities. The open clusters and the bulk of the stars near the galactic plane have heliocentric motions of low tens of kilometers per second, with some well over 100 km s^{-1}. Large motions prevail for globular clusters and many halo stars, which reach several hundred kilometers per second. Internal motions in globular clusters are typically around 5 km s^{-1}, while in open clusters it is only one-tenth of this.

BARNARD'S STAR, the second nearest after the α Centauri system, has the largest known proper motion of 10.36 arcsec per year and lies at a distance of 1.82 pc. It traverses an angle corresponding to the diameter of the Moon in only 175 yr. Interestingly, among the nearby stars, there is the RED DWARF Gliese 710 with an annual proper motion of only 0.003 arcsec (or 3 mas). Now at a distance of 19.3 pc, it is approaching the solar system with a radial velocity of about -18.6 km sec^{-1} and should pass at a miss distance of only 0.3 pc in about 1 million years. When closest to the Sun, its radial velocity becomes zero, while its tangential velocity equals its space velocity and its proper motion reaches a maximum of 13 arcsec per year. This change in size of proper motion illustrates the effect of *perspective acceleration*, now detectable for very few stars. Future astrometry from space, with sub-milliarcsecond levels of accuracy, will be able to measure this effect for many stars.

Historical background

In 1718 the English astronomer Edmond HALLEY discovered that stars exhibit proper motions, when he compared recent positions observed by TYCHO BRAHE and others in the 1580s and 1590s with those in the Almagest, the early Middle Age Arabic version of the Greek PTOLEMY's star

catalog (AD 138). The positions listed by Ptolemy may actually be much older and refer to those observed by the Greek astronomer HIPPARCOS (ca. 130 BCE), corrected for PRECESSION to AD 138. Halley found that some stars showed large residual shifts in excess of expected errors, two of these being the bright stars Aldebaran and Betelgeuse. The discovery of the proper motions had no immediate impact. It was only in 1738 that Halley's proper motion of Arcturus was confirmed by JACQUES CASSINI. The first catalog containing proper motions for many stars came a few years later with the work of Tobias Mayer, who compared RØMER's observations of 1706 with those made by himself and LACAILLE in the 1750s. Positional astronomy grew over the following 250 years with ever-improving instrumentation and observing techniques.

The legacy from this long period is the many star catalogs containing the equatorial coordinates right ascension and declination, based on meridian circles and related devices for observing positions for the brighter stars to magnitude 8–9. Unfortunately, this limit was too bright to include the remote galaxies, which would have provided fixed anchor points against which to measure positions of moving stars. Instead, fundamental observations used the Sun and some relatively nearby stars to locate the positions of the moving celestial equator and equinox point, as a practical way of defining the equatorial coordinate system and its progressive change with time. The secular effect of precession and the periodic effect of NUTATION measure this change. The practice of correcting for systematic differences among catalogs was begun by Auwers after 1865. It led to a series of catalogs, each defining a new version of the Fundamental System of reference with improved precision and accuracy, culminating with the final *Fundamental Katalog FK5* (1988), containing nearly 5000 stars around the sky. A new level of accuracy and precision was achieved in 1995 by the Hipparcos catalog, which is linked to the extragalactic frame and adjusted to the framework of the FK5 at epoch J2000.

Determination of proper motion

The tools of astrometry take various forms. The photographic plate has dominated direct imaging for over a century. The final decade of the 20th century saw electronic imaging sensors, such as the charged-coupled device (CCD), infrared detectors, and others, singly or in mosaic form, becoming the detectors of preference. Their advantages include high quantum efficiency, direct digital recording, and rapid real-time data processing by computers. Imaging detectors sensitive to the infrared domain offer great opportunities as astrometric probes in optically opaque regions of the Galaxy. Infrared observations take advantage of 'windows' in the electromagnetic spectrum, where the Earth's atmosphere is relatively transparent, such as those at near-infrared wavelengths 1.25, 1.65, and 2.20 microns (μm) for the J, H, and K bands, respectively. The HUBBLE SPACE TELESCOPE (HST) provides capabilities in optical and near-infrared regions for the measurement of proper motions and parallaxes with precisions at least comparable to the *Hipparcos Catalog*, but reaching to much fainter magnitudes. Optical INTERFEROMETRY shows the feasibility of differential astrometry to very high precision (tens of μas) in very small fields, with further advantages expected by observing in the near-infrared region using large telescopes.

The determination of proper motions is based on the comparison images of a star field obtained at suitably spaced epochs of observation. The images may be photographic plates or frames from electronic detectors. Precision coordinate measuring machines provide rectangular coordinates from photographic plates, while software associated with electronic detectors provides coordinates directly. The term plate is used below for images.

Basically the proper motion is resolved into components, nominally aligned along right ascension and declination, expressed by coordinate differences divided by epoch difference Δt, as $\mu_x = \Delta x/\Delta t$ in x and $\mu_y = \Delta y/\Delta t$ in y. In practice, the case is more complex. Each plate is exposed and measured with small differences in centering and alignment of axes. The telescope contributes effects from guiding errors, optical distortion, flexure, plate tilt and others, which are not precisely the same for each exposure. Variations in atmospheric refraction and chromatic effects, depending on the color of the star, contribute to the imaging on each plate. The plates may even be taken with different telescopes. These effects must be accounted for in astrometric reductions.

In order to map precisely each plate of a series of two or more plates into one selected as a standard frame, we use a model that accounts for the above-cited effects. For a pair of plates ($\Delta t = t_2 - t_1$), we have in each coordinate the form

$$x_2 - x_1 = \mu_x \, \Delta t + F(x, y, m, c; a_i) + \epsilon \qquad i = 1, n$$

where the model F is some function of position (x, y), stellar magnitude (m), and color (c). The n unknown parameters a_i are called plate constants, while ϵ is a residual error.

The simplest case is a linear model, often adequate for small fields, where we have for the x coordinate (similarly in y)

$$\Delta x = \Delta t \, \mu_x + a_1 \, x + a_2 \, y + a_3 + \epsilon_x$$

with unknown plate constants (a_1, a_2, a_3). Two basic approaches exist for finding the plate constants. If a subset of the measured stars is also contained in a star catalog of positions and proper motions, they may be used as reference stars to evaluate the plate constants and, hence, permit the calculation of proper motions, close to the astrometric system of the parent catalog, for the other stars in the field.

If no external astrometric data exists, then we fall back to a solution for *relative* proper motions, which has an unknown zero-point offset. In practical terms, we use all

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

(or part) measured stars as reference stars and, assuming their average proper motion is zero, solve for *relative* plate constants and then compute relative proper motions for all stars. However, if the measurements include faint, compact galaxies, we may compute their mean 'fictitious proper motion', taken with opposite sign, and apply it as a zero-point correction to convert from relative to absolute proper motions for the stars. An alternative statistical method (*mean secular parallaxes*) may be used to estimate the zero-point correction—the parallactic motion component of the reflex effect of solar motion—evaluated in the direction of the field and at the mean apparent magnitude and mean distance of the reference stars.

Techniques for evaluating the plate constants include a simple least squares adjustment for a pair of plates. The more complex method of plate overlap, pioneered by Eichhorn (1960) and now used extensively, solves simultaneously by least squares for both plate constants and star constants (proper motion and parallax) for a series of plates.

Some applications

Cluster membership

Proper motions provide a means for isolating members of open and globular clusters from foreground and background field stars. Goals include the construction of color–magnitude diagrams or studies of individual members. The internal motions in clusters are generally very small. This translates into very nearly equal and parallel proper motions, in contrast to the wide range of motions displayed by the surrounding field stars. The proper-motion vector point diagram, a plot of the two components of (usually) relative proper motion, forms the basis for estimating stellar membership in star clusters. The diagram displays two distributions of points with centroids representing the cluster (usually smaller dispersion) and the field stars. Estimates of membership have been made for some 100 open clusters and about 15 globular clusters. Recent observations with large ground-based telescopes and with the Hubble Space Telescope (HST), focusing on small regions, particularly the cores of globular clusters, are raising the astrometry to new levels of precision and magnitude limits unattainable by traditional photography (see CLUSTER MEMBERSHIPS).

Space motions of clusters

The trajectories of clusters around the galactic center may be computed from their space motions. These orbits provide clues to the origin and evolution of the Galaxy. For globular clusters the issue concerns correlations between cluster metallicity, as age indicator, and cluster kinematics—whether the motion supports membership in the halo or disk population. Motions have been traced back over the age of the Galaxy, to expose the changing character of the orbits with time. For the generally much younger open clusters the trajectories provide information about their places of origin in the framework of spiral structure as it was in the past and correlations of their atmospheric metal contents with galactocentric distance.

The number of globular clusters with measured absolute proper motions of quality ranging from useful to submarginal is about 35 and growing. Many are measured on photographs using galaxies or stars from the *Hipparcos Catalog* as reference frame, while others are based on a statistical reduction for conversion to absolute motion. Absolute proper motions have been measured on photographs for more than 200 open clusters, using photographic star catalogs for the reference frame, as most clusters lie in the Milky Way. The *Hipparcos Catalog* provides astrometric and photometric data for 241 clusters, ranging from one star per cluster to over 100 stars (Hyades).

Astrometric distances of clusters

The history of estimating distances to star clusters, using various astrophysical methods, is a long one. An alternative astrometric method for estimating distance involves the comparison of dispersions in proper motion and radial velocity, using the simple expression

$$d = \frac{\sigma_v}{4.74\,\sigma_\mu}$$

where σ_v and σ_μ are the error-corrected dispersions in radial velocity (km s^{-1}) and proper motion (arcsec yr^{-1}), respectively. The astrometric method provides an independent way for finding distance that is insensitive to the interstellar medium. A more realistic approach that accounts for omissions in the simple method uses dynamical models of the cluster. Few clusters have been calibrated by these methods so far.

Space motions of nearby galaxies

Our Galaxy belongs to a clustering of some 30 known members called the LOCAL GROUP. First steps towards measuring the trajectories for some nearer members have been made. These reveal the complex nature of interactions of our Galaxy with the MAGELLANIC CLOUDS and other neighbors. The absolute proper motion measured for the LMC in 1994 reveals it is gravitationally bound to the Galaxy and now lies at perigalacticon on a strongly eccentric orbit. Results using the *Hipparcos Catalog* for both LMC and SMC provide independent measurements of the motions. These indicate that more precise absolute proper motions are still needed to firmly establish the nature of the motions of the Clouds.

Absolute proper motions measured for other satellite galaxies (the nearer dwarf spheroidal systems Ursa Minor, Draco, and Sculptor) show them to be generally moving along one of two great circles on the sky, either the MAGELLANIC STREAM or a second stream with the Fornax dwarf spheroidal galaxy. The motion for the SAGITTARIUS DWARF SPHEROIDAL galaxy, discovered in 1994, shows that it is a tidally distorted system now near perigalacticum, only 16 kpc from the galactic center. The motions of galactic satellite systems provide evidence for the mass and mass distribution in the Galaxy.

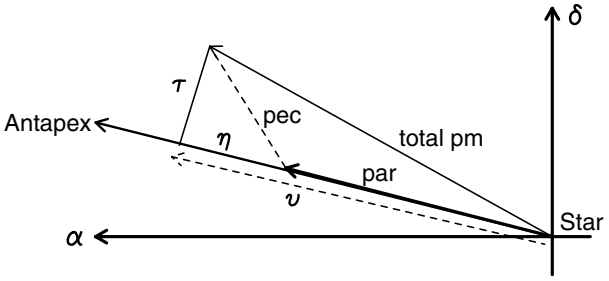

Figure 2. Total proper motion resolved along (υ) and normal (τ) to great circle from star to antapex of Solar Motion. Peculiar motion (pec) is resolved into τ and η components. The parallactic motion (par) is the reflex solar motion.

Solar motion and galactic rotation

The effect of galactic rotation is that *on average* stars closer to the galactic center than the Sun move faster around the center, while stars farther from the center than the Sun orbit more slowly. This differential galactic rotation effect, measured with respect to the average motions of stars in the Sun's neighborhood, called the Local Standard of Rest (LSR), may be expressed by mathematical models as a function of absolute proper motions and radial velocities. The simplest is the linear Oort model, valid for nearer stars with circular orbits in the galactocentric plane. It provides the Oort constants A and B, which enable computing the angular velocity and circular velocity in the solar neighborhood.

Statistical luminosity calibration

The observed total proper motion is resolvable onto orthogonal axes, one aligned along (υ) and the other at right angles (τ) to the great circle passing through a star and extending from apex to antapex defined by the solar motion (figure 2). The two proper motion components form the basis of two variations of statistical methods for finding mean parallaxes and distances for specific classes of stars, usually applied to those with narrow range in luminosity, and, therefrom, the calibration of their mean absolute magnitudes. Certain classes of stars have too few members near enough for the accurate measurement of individual parallaxes. Consequently, statistical methods based on proper motions provide alternative approaches.

The mean *parallactic motion* for a stellar sample is found from averaging the υ components. For the special case of a small region at angular distance λ from the Solar apex, we have the mean $\langle\upsilon\rangle = \langle\mathrm{par}\rangle + \langle\eta\rangle = \langle\mathrm{par}\rangle$, because, by definition of solar motion, the average peculiar motion of the stars (here η component) is zero with respect to their LSR. The mean parallax for the region, where $V_\odot$ is the solar motion, is

$$\langle\pi\rangle = \frac{4.74\,\langle\mathrm{par}\rangle}{V_\odot \sin\lambda}.$$

The *statistical parallax* is based on τ components, which represent pure peculiar motions of stars. It is measured by the ratio of mean $\langle|\tau|\rangle$ and mean peculiar radial velocity $\langle|V|\rangle$ components. The practical determination of mean parallax by either method is more complex, in that the distribution of peculiar space velocities is generally ellipsoidal. This means that forming averages of proper motions and radial velocities for stars located over the sky must be done carefully using the tools of statistical astronomy.

Nebular astrometry

Normally we regard proper motions as properties of stars and stellar systems. Proper motions can also refer to the angular movement of material in the stellar environment. Nebular astrometry has its roots in photographic imaging extending back to the early years of the 20th century, with observations of expanding shells and light echos of NOVAE. Observed proper motion expansions prevail in several classes of objects, including novae, SUPERNOVAE, PLANETARY NEBULAE, YOUNG STELLAR OBJECTS (Herbig–Haro), and various classes of luminous stars undergoing mass loss. These motions are observable in the optical and other wavebands.

Measurements of proper motion expansion provide timescales and evidence for underlying stellar processes. Proper motions combined with radial velocities of shells, or other features, provide a valuable geometrical method for measuring distances and luminosities of central stars that is independent of corrections for intervening interstellar absorption. Moreover, observations of supernovae provide an independent measure of distances to galaxies. The advent of exceptional resolution provided by HST and ground-based CCD imaging of non-stellar features is leading to a new level of precision unattainable by the older photographic technique.

Infrared astrometry and catalogs

Historically color-sensitized photographic plates have recorded beyond the visual wavelength limit near 0.7 micron up to a near-infrared limit of about 1.1 micron. The record shows scant precision photographic astrometry in this wavelength domain. However, infrared astrometry is emerging as cameras are being developed with electronic detectors possessing sensitivity, imaging characteristics, and field size suitable for precision measurements. The ability to penetrate deeply into a variety of optically highly opaque regions of the Galaxy is their prime advantage. These include star-forming regions, enabling studies of the kinematics of stars in the process of formation. Fields are now being exploited through proper motions of both stars and associated non-stellar matter, such as jets, streams, shells, and other parts. An outstanding success of near-infrared K-band astrometry is the measurement of relative proper motions of stars near the optically highly opaque galactic center using the Keck 10 m telescope. The motions support a massive BLACK HOLE candidate. Systematic large-scale infrared sky surveys are unveiling now-hidden populations throughout the galactic disk and bulge and to the far side of the Galaxy.

Infrared surveys, such as *IRAS*, provide large numbers of sources, including many galactic stellar objects. The large positional uncertainty at a single epoch precludes their use for measuring accurate proper motions. However, cross-identifications with large optical catalogs, containing proper motion and other data, enables these catalogs to be used for kinematical studies. An example is the *Infrared Astrometric Catalog (IAC)*, based on space observations made with the Mid-Course Space Experiment telescope Spirit III at a wavelength of 8 microns. It forms a new infrared database of 177 860 stars, containing improved positions as well as proper motions and other data compiled from optical catalogs. Other surveys in progress, giving positions at the 0.5–1.0 arcsecond level for over 100 million objects, include the Sloan Digital Sky Survey (SDSS), Deep Near Infrared Survey (DENIS), 2 Micron All Sky Survey (2MASS), and Infrared Space Observatory (ISO). Eventually observations for high-precision proper motions will enable greater exploitation of these databases.

Astrometric catalogs

The precision of a catalog is characterized by the standard errors of its (equatorial) coordinates (ϵ_c) at its mean epoch t_c and its proper motions (ϵ_μ). The inexorable temporal degradation in accuracy of positions computed at some epoch t away from the catalog epoch ($\Delta t = t - t_c$) is given by the law of error propagation

$$\epsilon_t = [\epsilon_c^2 + (\epsilon_\mu \, \Delta t)^2]^{1/2}.$$

For the *Hipparcos Catalog* with errors of 0.8 mas in positions and proper motions at 1991.25, the error in computed positions grows to 8 mas after 10 years. This tells us that catalogs have finite useful lifetimes, as a source of positions projected to distant dates.

During the preparation of the *Hipparcos Catalog* it became apparent that binary and multiple stars could affect both the derived proper motions and the estimates of the total errors. This comes from the fact that the observations for the Hipparcos program spanned only ~3.5 years, while many binary stars have Keplerian orbital periods ranging from much shorter to much greater values. The measured instantaneous positions on the sky are the sum of the proper motion of the center of mass of the system and the location of each stellar component on a sky-projected orbit. The picture is more complex. The Hipparchos detector measures the equivalent of a photocenter, which at one extreme senses only the brighter component of a system where the fainter one lies below the detection limit. At the other extreme the measured photocenter senses the partially merged light of two components of comparable brightness. Moreover, one or more components may be variable in brightness, thus complicating the interpretation of the displacement of the photocenter with time. If observations of photocenters are made in different wavebands, for stars of different colors, a color-induced effect may also be significant. Therefore, the total positional error in star positions projected to other epochs may be dominated by an orbital-motion-induced cosmic error, in excess of the measuring error. Conversely, a comparison of Hipparcos proper motions with those based on traditional decades-to-century-long baselines provides an independent way of discovering close binary stars. New techniques of statistical astrometry were developed to complement high-precision space astrometry made over short time baselines.

The following sections describe major astrometric programs and star catalogs currently available or in progress. Table 1 summarizes these catalogs and provides references. Data centers or observatories providing these catalogs usually include detailed information for the user.

Surveys for large proper motions

Surveys to faint limits have uncovered many stars of large proper motion, mainly nearby red and white dwarfs and subdwarfs. These are useful collectively for stellar statistics of the solar neighborhood and individually for astrophysical observations. Stars of larger proper motion, typically over about 0.1–0.2 arcsec per year, are discovered by comparing photographs taken a decade or more apart. Major recent surveys include those of Luyten (Minnesota), Giclas group (Lowell Observatory), Wroblewski group (Cerro Calan Observatory), and others. About 70 mainly bright stars have proper motions over 2.0 arcsec per year. Some 4000 stars have annual motions over 0.5 arcsec (over half found by Luyten), while 60 000 stars exceed 0.2 arcsec (70% found by Luyten). An estimated 500 000 stars have annual motions over 0.10 arcsec. Digitized Schmidt and other sky surveys will provide a full count of proper motions above their error thresholds.

Astrograph surveys

The Lick Northern Proper Motion (NPM) and Yale/San Juan Southern Proper Motion (SPM) programs provide absolute proper motions for large numbers of faint stars, based on photographs exposed 2–4 decades apart. These use faint galaxies to approximate an inertial frame for the non-Milky Way sky and the Hipparcos system in the Milky Way zone. The NPM program covers the sky northward of declination -23°, while the SPM program extends southward from -17°, with a some fields north of this. Both programs, still in progress, have produced large astrometric catalogs: *NPM1* with 149 000 stars for the non-Milky Way sky and *SPM 1.0* with 59 000 stars in a 720 deg^2 region around the south galactic pole. Both programs include large numbers of special stars selected for their astrophysical and kinematical importance.

Similar surveys include the Faint Star Catalog (*KSZ*) plan (Pulkovo), involving photography at several observatories for 205 fields north of declination -25°. The separate parts, when completed at Kiev, will form the *General Compiled Catalog of Absolute Proper Motions (GPM)*. The Main Meridional Section of the Galaxy (MEGA) program at Kiev, including contributions from Potsdam, contains fields along an arc linking the galactic poles

for studies of stellar distributions and kinematics. The Potsdam program uses the Tautenburg Schmidt telescope for deep photography in numerous regions over the northern sky.

Hipparcos/Tycho catalogs

The Hipparcos and Tycho Catalogs provide positions, proper motions, photometry, and other data in the Hipparcos system, which is regarded as a representation of the ICRS system in optical wavelengths. This is a large catalog of unprecedented astrometric precision in optical wavelengths. For the brighter Hipparcos stars ($H_p \leq 9$) the median precisions are 0.8 mas for position, 0.8 mas yr^{-1} for proper motion, and 1.0 mas for parallax. For the much larger *Tycho Catalog* the median precisions for brighter stars ($V_t \leq 9$) is 7 mas, while for all stars it is 25 mas. A new version *Tycho2 Catalog* will have 2.5 million stars, including proper motions derived from re-reduced *AC* positions.

The adopted astrometric reference system is now the International Celestial Reference System (ICRS). The ICRS is that astrometric system that closely approximates the conventional equatorial coordinate system for mean equator and equinox of J2000 and the fundamental FK5 system. It is represented by the *Hipparcos Catalog* for stars and by the nearly inertial extragalactic frame defined at radio wavelengths by a special set of more than 200 (later 600) faint quasars and compact galaxies uniformly distributed around the sky. The ICRS system is used

hereafter for both optical and radio observations to ensure compatibility of their reference systems.

Extensions of Hipparcos system

The *Astrographic Catalog (AC)*, also known as *Carte du Ciel (CdC)*, was a massive program started in 1887 by some 22 observatories to photograph and measure positions for stars to magnitude about $B = 12.5$. The resulting observatory catalogs contain rectangular coordinates of varying precision for over 4.5 million stars, spanning a very wide range of epochs around the average near 1905. These positions, now in computer-readable form, have been reduced to equatorial coordinates nominally in the Hipparcos (ICRS, J2000) system. One of several versions, completed or in progress, is the *AC2000*.

The *ACT Reference Catalog (ACT)* and *Tycho Reference Catalog (TRC)* are parallel catalogs based on the same material, the *Tycho* and *AC*, but using different strategies for reducing the *AC* into the Hipparcos system for deriving improved proper motions for the Tycho and other stars. The *ACT* uses *AC2000*, while *TRC* uses its own version.

The *Twin Astrographic Catalog (TAC) Version 1.0* is based on photography at the US Naval Observatory (USNO) for the sky north of declination -18° with epochs 1977–1986. It is an independent catalog with higher density than *Tycho*, where proper motions are found by comparison with the *AC* reduced to the (FK5, J2000) system. A new version *TAC 2.0* reduced to the Hipparcos system is in progress. The *US Naval Observatory CCD Astrometry Catalog (UCAC-S)* represents a CCD survey in progress to produce a very high density catalog in the Hipparcos system for the southern sky to magnitude 16.

The high-density *Starnet Catalog* and *Four-million Star Catalog of Positions and Proper Motions (4M Cat)* are parallel in using the *HST Guide Star Catalog 1.0* and reduced *AC*, referred to the *Positions and Proper Motions Catalogue (PPM)*.

Schmidt telescope surveys

The digitization of northern and southern photographic surveys obtained at several epochs with Schmidt telescopes forms massive databases of positions and photometry, and (in progress) proper motions, to faint magnitudes.

The Minnesota *APS Catalog* is based on copies of the *Palomar Observatory Sky Survey I (POSS-I)* plates for galactic latitude $|b| > 20^\circ$. The *APS-Luyten Proper Motion Catalog*, in progress, includes red Palomar plates taken by Luyten in the 1960s to derive absolute proper motions with respect to galaxies.

The *USNO A2.0* catalog provides positions in the ICRS system from scans of POSS-I, UK(SRC), and ESO Schmidt plates made at the USNO (Flagstaff). The Space Telescope Science Institute (STScI) digitized the POSS-II and UK Schmidt plates intended for the second generation *Hubble Guide Star Catalog (GST-II)*, containing positions, proper motions, and photometry. It is organized on the sky (32 768 equal areas) for efficient cross-matching with other optical surveys and data from other wavebands. The *DPOSS* (Caltech) is the digitized POSS-II for two billion stars and 50 million galaxies.

Future prospects: space astrometry

The success of the Hipparcos Mission in reducing errors to the milliarcsecond level has emphasized the decisive advantages of astrometry from space. Discussions for future missions now center on the scientific and technical aspects for achieving astrometric accuracy in the microarcsecond domain, some 1–3 orders of magnitude smaller than from the Hipparcos Mission. More optimistic scenarios envision measuring proper motions and parallaxes for objects throughout the Galaxy and deep into extragalactic space. Such a success would impact profoundly on problems that today are only imperfectly understood. Beneficiaries would extend from the solar system to stellar kinematics and galactic rotation, distance scale and luminosity calibrations, galaxy trajectories and their implications on the formation and evolution of the Galaxy, and much more. The needed metrology to achieve this goal is technologically challenging. Discussions envision a Space Interferometry Mision (SIM) and a German interferometer for a multichannel photometry and astrometry (DIVA) mission sometime after 2000. Some concepts include GAIA (ESA), POINTS (Center for Astronomy: Cambridge), OSI (Jet Propulsion Laboratory (JPL)), NEWCOMB and FAME (JPL, USNO, SAO, NRL). Direct imaging with HST and future space telescopes in optical and other spectral regions offer alternative options for space astrometry.

Protogalaxies

The term protogalaxies or sometimes primeval galaxies (hereafter PGs) has been used in the literature with a range of different meanings, but a general definition may be something like this: progenitors of the present-day (normal) galaxies, in the early stages of formation; also, many, but not all, authors would also add to that the words 'at high redshifts'. The key phrase is 'the early stages of formation', which is fundamentally not well defined.

The ambiguities are mainly due to the fact that our understanding of what GALAXY FORMATION means has been evolving over the past few decades. Moreover, even at any given time, experts of different technical orientations (e.g. observers versus n-body simulators) who would otherwise agree about the general picture of galaxy formation would have different and equally legitimate definitions in mind. For example, an observer may mean 'the first major burst of star formation in a progenitor of a present-day elliptical galaxy', whereas a theorist may mean 'the peak merging epoch of dark halos of the fragments which assemble to produce an average galaxy today'; others would define a PG as a still gaseous body before any STAR FORMATION has taken place or as an overdense region of DARK MATTER in the very early universe, destined to become gravitationally bound and to collapse. In some sense all of them are right.

It may be useful here to offer a brief account of our present understanding of galaxy formation and then describe some of the relevant observations, thus defining PGs in an implicit way. While the subject is still evolving rapidly as of this writing (late 1999), most cosmologists would agree that the basic picture we now have is likely to be essentially correct. Instead of seeking a hypothetical magic epoch when PGs appear and then evolve into the familiar types of galaxies today, the focus is now on understanding of the complete history of galaxy and large-scale structure assembly, as well as the history of star formation in all galaxies and the chemical enrichment of gas in the universe at large. It is then almost a matter of taste which slice of formative history would be called the epoch of galaxy formation and which objects or which evolutionary stages of normal galaxies would be called PGs.

In what follows, we outline a broad-brush picture and give general arguments and order-of-magnitude estimates, which are likely to be at least roughly correct, however much our understanding of galaxy formation evolves in the forthcoming years. Ever more detailed models will be producing more precise predictions, which can then be tested by future observations.

From density fluctuations to protogalaxies

The basic paradigm of structure formation is that it takes place through the gravitational instability of bound, overdense regions in the early universe. The distribution of such regions in mass (or, equivalently, density) is quantified by the initial density perturbation spectrum, which is produced by some type of quantum fluctuation processes in the early universe. Sufficiently overdense regions separate from the universal expansion and collapse under their own self-gravity, roughly on the free-fall time scale:

$$t_{\rm ff} = \left(\frac{\pi^2}{8G}\right)^{1/2} R_{\rm init}^{3/2}\, M^{-1/2}$$

$$\approx 5\times 10^8\ {\rm yr} \times \left(\frac{R_{\rm init}}{100\ {\rm kpc}}\right)^{3/2} \left(\frac{M}{10^{12} M_\odot}\right)^{-1/2}$$

$$\approx\ 1.6\times 10^9 {\rm yr} \times \left(\frac{R_{\rm init}}{10\ {\rm Mpc}}\right)^{3/2} \left(\frac{M}{10^{15} M_\odot}\right)^{-1/2}$$

where $R_{\rm init}$ is the initial radius of the bound region and M is the enclosed mass. It can be seen that for a galactic or subgalactic mass fragment the corresponding cosmic epochs ($\sim 10^8$ yr) imply high REDSHIFTS of collapse, whereas CLUSTERS OF GALAXIES or larger structures may be still collapsing today. The free-fall time scale is a lower limit to the formation time scale, its duration and the cosmic epoch: in practice, it may take several free-fall times for a given mass overdensity to be assembled through a process of hierarchical merging and virialization. To a first order, this simple argument implies that the peak epoch of galaxy formation is likely to be found at the cosmic epochs of a few $\times 10^8$ to a few $\times 10^9$ yr, or roughly in the redshift range $z \sim$ 2–20 or so, whereas the epoch of cluster formation lasts many billions of years and is still going on now.

Collapse

Since the non-baryonic dark matter appears to dominate the total mass, the overdense regions, i.e. proto-dark-halos, can start collapsing even while the universe is still ionized, e.g. at $z \sim 10^4$, with the baryonic matter following. The smallest mass fluctuations collapse the fastest; however, they are also most readily erased by a variety of damping processes operating in the early universe, such as the streaming of matter and photons, sound waves, etc. It is now believed that the smallest structures which survive at the recombination epoch are similar in mass to GLOBULAR CLUSTERS or DWARF GALAXIES, i.e. $(10^5$–$10^8)M_\odot$. They may be the basic building blocks of galaxies.

Images of the COSMIC MICROWAVE BACKGROUND (CMB) photosphere show a snapshot of overdense regions at the recombination epoch at $z \sim 1100$. At the present time, the resolution of such observations corresponds to physical scales of large clusters and superclusters of galaxies rather than galaxies themselves. Nevertheless, these observations support the basic picture of structure formation via gravitational instability.

Any energy dissipation in the baryonic component of the mass (also called the cooling of PGs) would of course accelerate the collapse and lead to the formation of denser objects, since systems which dissipate energy at a fixed mass become more tightly bound. The distinction between galaxies and large-scale structures such as galaxy groups or clusters (or larger) is that the galaxies (or

their protogalactic fragments) can cool faster than the free-fall time. Physical mechanisms which enable this energy dissipation in collapsing PGs include the inverse-Compton cooling of hot gas on the CMB radiation (CMBR) photons and shocks in the infalling and colliding gas clouds.

Thus galaxies (or their building blocks) become distinct concentrations within the overall large-scale structure, whose evolution is dominated by the gravity of the dark matter. Simple arguments based on the mean density of galaxies, the spin-up of galaxy disks, etc all suggest that they collapsed by about a factor of 10 or 20 in radius, whereas pure dissipationless collapse can produce only a factor of 2 (this is a direct consequence of the virial theorem for systems bound by gravity). Given the ratio of the comoving rms separation of galaxies today and their typical radii, this must have happened at $z < 20$ or so. It is also hard to have an effective cooling of PGs at redshifts much higher than that.

There are two fundamental aspects of galaxy formation: assembly of the mass (mostly dark), and conversion of the primordial gas (see GAS IN GALAXIES) into stars, and the subsequent chemical enrichment through SUPERNOVA explosions. The former is easier to model numerically; the latter is what is actually observable. The two may be connected, as bursts of star formation are likely to result from mergers of gas-rich PG fragments.

Assembly of protogalaxies

At every spatial (or mass) scale, there is a gradual, hierarchical merging of fragments into ever larger structures. This process operates first at the smaller scales, and moves to ever larger ones as the age of the universe increases and as the smaller fragments are consumed in mergers. While mergers of galaxies are relatively rare (yet readily observed) in the present-day universe, such processes must have been much more common at higher redshifts, when galaxies and their initial building blocks were closer together, with less developed peculiar velocities, and when there were more fragments to merge with (see GALAXIES: INTERACTIONS AND MERGERS). However, this process of hierarchical assembly never really ceases, and today it is the principal mechanism of galaxy transformation.

In 1960s and early 1970s, a simple picture of galaxy formation as a monolithic collapse of a single large PG cloud was promoted by Eggen, Lynden-Bell and Sandage, with a majority of the POPULATION II (bulge and halo) STARS formed more or less during a single free-fall time. This picture has now been completely replaced by the hierarchical formation scenario. The remaining issue is when and where did most of the stars form? A merger of a large number of PG fragments on a time scale comparable with the free-fall time of the entire system, and accompanied by a rapid star formation activity, is in practice indistinguishable from the old monolithic collapse picture. It is quite possible that massive ELLIPTICAL GALAXIES in clusters formed in such a manner. In another extreme scenario, mergers of large fragments occur over a more protracted time scale, comparable with the Hubble time, with most of the stars already formed in the merging units and some formed in merger-induced starbursts. It is likely that there was a full spectrum of galaxy assembly scenarios or formation histories at work.

The interplay of mass assembly and star formation fundamentally determines the galaxy morphology and the origin of disks in SPIRAL GALAXIES. In general, random merging of fragments leads to the formation of spheroidal (or, more accurately, triaxial) systems such as the bulges, stellar halos and dark halos, where kinetic energy needed to support the system against its own gravity is in random motions. In contrast to that, if protogalactic gas settles into a dark halo potential well gradually, it radiates away its kinetic energy, but retains most of the angular momentum (which can be only mechanically transferred away). PGs acquire their angular momenta through tidal interactions in the early universe, as passing-by mass concentrations exert tidal torques on each other. The gas then assumes the lowest-energy configuration possible for a given amount of angular momentum, which is a centrifugally supported, rotating thin disk (similar arguments apply to the origin of any disks in astronomy, including PROTOPLANETARY DISKS, ACCRETION DISKS, etc, not just DISK GALAXIES). Any stars formed within the gaseous disk then inherit the same kinematics.

Disks are dynamically fragile: major mergers would disrupt their orderly rotation and convert them to random motions. Thus, any disk galaxy is unlikely to have had a major merger since its disk was formed, but accretion of smaller satellites is still possible. Conversely, one often hears assertions that (some) ellipticals are made by merging spirals, which is indeed observed in the nearby universe. Obviously this is not the only possible path: a young elliptical may be made by merging a thousand small fragments early on. While some ellipticals may be formed in late, major mergers, many studies of elliptical galaxy properties in clusters at low and moderate redshifts suggest that most of their star formation was completed at high redshifts, $z > 3$ or higher, although some fraction of their stars may have formed since then.

At large redshifts, the merging was much more rapid and frequent, and the formation of durable, massive galactic disks was not likely. As the merging subsided and galaxies were carried apart by the universal expansion, the necessary gradual assembly of disks increased (incidentally, the same argument is used to explain the morphology–density relation in clusters and groups of galaxies: spirals are found mainly in low-density regions, and vice versa for ellipticals). Thus, we expect that the epoch of halo and bulge formation in galaxies in general preceded the epoch of disk formation, which is consistent with their star formation histories: bulges and ellipticals show little or no star formation today, and have spectra and colors characteristic of old stellar populations, where the bulk of the stars formed ∼6–12 billion years ago, whereas the disks are actively forming stars now,

and apparently had similar star formation rates over their entire history.

To summarize, the expected history of galaxy formation may be something like this. The first PG fragments (gravitationally bound clumps in the early universe) may have had masses comparable with those of dwarf galaxies, $M\sim(10^6$–$10^8)M_\odot$ at the epoch of recombination, at $z \sim 1100$. Over the subsequent few billion years they merged hierarchically into ever more massive structures, stimulating star formation in the process. The first stars may have formed within a few hundred million years, at redshifts $z \sim 20 \pm 10$. The process of hierarchical assembly of PGs reached a peak maybe 1–3 billion years later, at redshifts $z \sim 2.5 \pm 1$. At subsequent epochs, this activity subsided as galaxies were carried apart by the universal expansion, and the supply of fragments and gas to merge with was diminished. Galaxy formation became GALAXY EVOLUTION. Most of the early star formation was in proto-ellipticals and bulges, with the disks forming on longer time scales.

Assembly of the mass into the present-day galaxies is one fundamental aspect of galaxy formation, but since most of the mass is dark this process is not readily observable. The other fundamental aspect is the conversion of primordial gas into stars and the early evolution of stellar populations, which is what we can observe. Let us then examine the sources of luminosity in PGs.

Luminosity of protogalaxies

The first is the release of excess binding energy, since PGs have collapsed. This is true regardless of the details of mass assembly, be it hierarchical merging or a monolithic collapse. A variety of arguments suggest that the PGs collapsed by about a factor of 10. First, the mean densities of galaxies exceed the extrapolated densities of the large-scale structure down to the typical radial scales of galaxies (a few kpc) by about a factor of $\sim 10^3$, suggesting a collapse by about a factor of 10. Second, the spinup of galactic disks requires a collapse by a similar radial factor. We can estimate the amount of the binding energy released by assuming that the present-day galaxies are in a virial equilibrium and estimating their total intrinsic kinetic energy. According to the virial theorem, this is equal to the amount of the excess binding energy lost in the process of virialization: a PG starts as a marginally bound system, with the kinetic energy equal to the potential one, but ends up as a virialized system where the kinetic energy is one half of that, with the other half presumably radiated away or carried out by galactic winds. An estimate of the kinetic energy of a normal, average galaxy today can be written as

$$|E_{\rm k}| \simeq \frac{1}{2} M_{\rm cool} \langle V_{\rm 3d}^2 \rangle$$

$$\simeq 6.2 \times 10^{58}\ {\rm erg} \times \frac{M_{\rm cool}}{10^{11} M_\odot} \left(\frac{V_{\rm 3d}}{250 {\rm km\ s^{-1}}} \right)^2$$

where $M_{\rm cool}$ is the total mass which can cool radiatively and $V_{\rm 3d}$ is the typical rms velocity. This estimate represents a minimum amount of energy released by a PG, even with no star formation. A comparable amount of binding energy is released in the collapse of protostars within a PG.

There are several possible mechanisms for release of this energy. The gas may be cooling via the inverse Compton effect on the photons of the CMBR. It may be radiated away in the shocks from colliding, still gaseous PG clouds and fragments. If the collapse happens on a free-fall time scale, $t_{\rm ff} \sim 10^8$ yr, the corresponding mean luminosity is $L_{\rm coll} \sim 2 \times 10^{43}$ erg s^{-1} $\sim 5 \times 10^9\ L_\odot$.

However, a much more energetically important process is nuclear burning in stars. It has been estimated that about a half of the STELLAR MASS in galaxies today is in the old populations, bulges and stellar halos, and thus about a half of all star formation in the universe's history can be associated with PGs (this is admittedly dependent on how one wishes to define PGs). The key to estimating this energy is through the resulting chemical enrichment: the same stars which produce the energy also produce the heavier elements. Most of the energy comes from hydrogen burning into helium, ~7 MeV per nucleon, i.e. ~0.7% or the initial rest mass of the processed hydrogen. The rest of the nucleosynthetic chain up to iron adds <0.1% to that.

Unfortunately, it is practically impossible to measure directly the accurate abundance of helium in the old STELLAR POPULATIONS today. Instead, we can use the observed abundances by mass of heavier elements and a conversion from chemical evolution models: $\Delta Y/\Delta Z = f$, where ΔY is the increase in the fractional mass abundance of helium, ΔZ is the increase in the fractional abundance of heavier elements (i.e. the mean metallicity), and f is typically found to be ~2–5. Since the initial abundance of heavier elements is essentially zero, $\Delta Z = Z$, which is observable. Estimates of the mean metallicity of old stellar populations are of the order of solar, i.e. $\langle Z \rangle \approx 0.01$–$0.02$. Thus the fraction of the rest mass of the primordial gas converted into energy during this initial chemical enrichment is

$$\Delta X \approx\ 0.07 f \langle Z \rangle \approx (4 \pm 2) \times\ 10^{-4}.$$

We can then estimate the total energy release from nuclear burning in stars responsible for this initial chemical enrichment:

$$E_{\rm nuc} \simeq M_\star\, c^2 \Delta X$$

$$\simeq 7.2 \times 10^{61} {\rm erg} \times \frac{M_\star}{10^{11} M_\odot} \frac{\Delta X}{4 \times\ 10^{-4}}$$

where $M_\star$ is the total mass burned in stars during the protogalactic starburst. This is much larger than the release of the binding energy and would thus be the dominant signal in detection of PGs. It may be a lower limit, since some of the produced metals must have been ejected in the resulting galactic winds and are not counted in our estimate of the mean metallicity of stellar populations today. Direct evidence for these ejected metals is in the intracluster gas seen in x-rays.

If this energy is released over a free-fall time scale, $t_{\rm ff} \sim 10^8$ yr, the corresponding bolometric luminosity would be $L_{\rm nuc} \sim 2 \times 10^{46}$ erg s^{-1} $\sim 5 \times 10^{12}\, L_\odot$, comparable with the luminosities of bright QUASARS and utraluminous IRAS STARBURST GALAXIES today. Some authors have indeed proposed that such PG starbursts are the source of luminosity of quasars, but a majority belief is that quasars are powered by accretion onto massive BLACK HOLES. The mean star formation rate would be several hundred $M_\odot$ yr^{-1}. Even if this process proceeded on a more extended, hierarchical merging time scale $t_{hm} \sim 10^9$ yr, the resulting luminosities would still be an order of magnitude higher than the mean galaxy luminosity today (L_*) and comparable with that of the brightest cluster ellipticals today.

Finally, if formation of AGN accompanied some or all of these PG starbursts in young ellipticals and bulges, a comparable amount of energy may have been contributed by these early AGN. There is now growing evidence that massive black holes exist in the centers of most ellipticals and bulges, with the mean mass proportional to that of the stars, $M_{\rm bh} \sim 0.002 M_\star$. If about 10% of the rest mass of the black hole is radiated away in dissipative processes during its formation and growth (this is a typical estimate), then a comparable fraction of the bulge rest mass is radiated in the production of these ubiquitous black holes as in the nuclear burning in stars. It would be hard to separate observationally the effects of primordial starbursts in PGs housing quasars at large redshifts in terms of the energetics alone.

Thus, a 'generic' PG would have a typical bolometric luminosity $L_{\rm PG} \sim 10^{11\pm1} L_\odot$. To make an order-of-magnitude estimate of the observable fluxes, we note that in the relevant range of redshifts, $z \sim$ 3–10, and for a reasonable range of cosmological models, the luminosity distances are $D_{\rm L} \sim$ a few $\times 10^{29}$ cm, so that the expected bolometric fluxes are of the order of $\sim 10^{-15\pm1}$ erg cm^{-2} s^{-1}. Assuming for simplicity $L \sim \nu P_\nu$, the corresponding observed R band magnitudes would be $R \sim 25$ mag, or $F_\nu \sim 0.1$ mJy at $\lambda_{\rm obs} \approx 0.3$ mm, give or take an order of magnitude in flux. Much of this flux range is detectable with present (or soon forthcoming) instruments.

Detection of protogalaxies

The key question about detectability of PGs is that of obscuration. Most of the energy is released in the restframe UV, either from the photospheres of massive stars or from accretion disks in AGN, and would be now redshifted in the visible regime. On the other hand, if these PG starbursts were obscured by dust, the captured energy would be reradiated in the far-IR and would now be observable in the sub-mm regime (the AGN may also be detectable in x-rays). Approximately a third of all star formation in the present-day universe is obscured by dust, and perhaps a similar fraction applied to PGs (note, however, that some tens of millions of years of stellar evolution and chemical enrichment are needed before any dust can be produced, and the early PG phases must have been unobscured). This dichotomy of energy release channels leads to a dichotomy of detection strategies. We will discuss the two cases in turn.

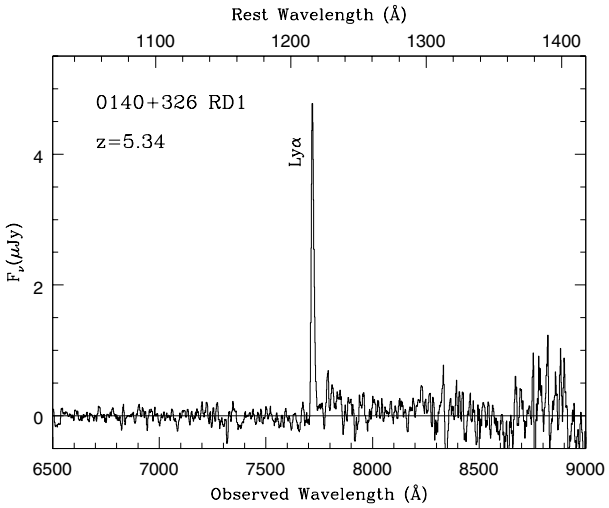

Figure 1. An example of a spectrum of a galaxy at $z = 5.34$, discovered serendipitously in a long-slit spectroscopic search. The Lyα emission line is very prominent. Objects like this can also be found in a narrow-band imaging search, provided that the line falls within the narrow filter bandpass. Reprinted with permission from Dey A *et al* 1998 *Astrophys. J. Lett.* **498** L93. © The American Astronomical Society.

Most of the early, and some of the modern searches for PGs were based on the detection of recombination emission lines, and most notably the Lyα λ 1215.7 Å line of the ionized hydrogen. For an unobscured, young stellar population with a normal IMF, several per cent of the total bolometric luminosity should emerge in this line. A useful rule of thumb is that about two Lyα photons are produced for every three ionizing (i.e. $\lambda < 912$ Å) photons. The line is readily detected (and is very luminous) in quasars, but its detection from galaxies powered by star formation was only achieved in 1990s. An approximate conversion is that unobscured star formation rate of $1 M_\odot$ yr^{-1} would produce the Lyα line luminosity of about 10^{41} erg s^{-1} in the restframe, but this number is highly sensitive to the form of the stellar initial mass function, since most of the ionizing photons are produced at the high-mass end but most of the mass is in the low-mass stars.

There are two observational approaches to detection of high-redshift, emission line objects, including PGs: narrow-band imaging and slit spectroscopy. Most of the emission line PG searches in the visible light have targeted the Lyα line, but exactly the same methodology was also used in the near-infrared, where searches targeted the Balmer lines of ionized hydrogen (mainly Hα λ 6563 and Hβ λ 4861) and the nebular lines of ionized oxygen, [O II] λ 3727 or [O III] λ 5007.

In the former, deep images are obtained in a narrow-band filter (usually an interference filter, or a Fabry–Perot tunable filter) and compared with images in a

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

broad bandpass with a comparable central wavelength. Objects with a strong emission line falling in the narrow bandpass would appear much brighter than in the broad band, where this line flux would be averaged out. This method can cover a relatively large area, but only a very narrow slice of redshift, corresponding to the redshifted line traversing the width of the filter, i.e. $\Delta z = \Delta\lambda/\lambda_c$, where $\Delta\lambda$ is the filter width and λ_c its central wavelength. Typically, $\Delta z \approx 0.01$–0.02 is used in PG searches.

The second approach is to obtain deep long-slit spectra of 'blank' patches of the sky, hoping that an emission line object would be covered by the slit. This method covers only a small area but a large range in redshift. One benefit of this approach is that almost any deep spectra taken for some other purpose can be used for a serendipitous search for PGs (figure 1).

The first detections of Lyα emission from GALAXIES AT HIGH REDSHIFT were from powerful RADIO GALAXIES, which are ostensibly ionized mainly by an active nucleus, and from quasar companion galaxies. However, no clear population of 'ordinary' PGs, i.e. powered by star formation, was found despite considerable efforts until the late 1990s. The early limits and the more recent detections correspond to modest star formation rates, up to a few $M_\odot$ yr^{-1}.

This conspicuous absence of a large population of Lyα luminous PGs was readily explainable by invoking extinction: both Lyα photons and the ionizing UV photons which produce them are absorbed by interstellar dust, which is likely to be present at some level in all but the most primordial star-forming regions. To complicate things further, Lyα photons are resonantly scattered by the interstellar hydrogen, which greatly increases their probability of being absorbed before escaping the PG.

The real breakthrough in the detection of high-redshift, star-forming galaxies came with the use of a different technique, the Lyman-break method (figure 2). Actively star-forming PGs would have relatively featureless, flat continua, except for one very significant feature: a strong drop in flux shortward of the Lyman limit, at 912 Å in the restframe, as the more energetic photons are readily absorbed by interstellar hydrogen. Thus, by imaging in at least three filters, one of which would cover the part of the spectrum shortward of the redshifted Lyman break, and two of which would sample the relatively flat continuum longward of the break, one can select candidate high-redshift galaxies through the resulting color signature. Actual spectra are then obtain to verify the candidates and measure their redshifts. This method is very efficient, and to date many hundreds of high-redshift galaxies (i.e. at $z > 2$ or so) have been identified in this manner.

At somewhat higher redshifts, i.e. $z > 4$ or so, a variant of this technique is used to detect both galaxies and quasars. There the net absorption by the intergalactic Lyα forest clouds along the line of sight decreases the flux shortward of the Lyα line in the object itself and sufficiently so as to produce a similar color signature. For example, quasars and PGs at $z \sim 4$–4.5 or so are very red in the $B-R$ or a similar color owing to this absorption effect, yet blue in the $R-I$ color, which is intrinsic and is not affected by the Lyα forest. This is actually the principal discovery technique for $z > 4$ quasars, but it works equally well for galaxies at comparable redshifts. The effectiveness of this technique increases with redshift, as the optical depth of the Lyα forest increases.

What if the star-forming regions are effectively completely hidden by dust? The absorbed energy is then reradiated in the restframe far-infrared and would now be observable in the sub-mm and mm region of the spectrum. Adequate detection technology in these wavelength regimes is just maturing, and first detections of high-redshift sub-mm sources (intrinsically very luminous ones) are just starting as of this writing (late 1999). This is clearly a very promising area of research, and it is likely that future observations in this regime will uncover a more substantial, optically obscured component of PG population.

We note that the integrated emission of unobscured and obscured galaxies, both forming and evolving, is observable in the form of diffuse optical and far-infrared backgrounds. Discussion of this fascinating topic is beyond the scope of the present article, but suffice it to say that the data so far indicate that the two components (obscured and unobscured) are roughly comparable in terms of the energy content.

A complementary approach to a direct detection of PGs in emission is to detect them in absorption, in the spectra of unrelated background quasars. Metallic line absorbers and high column density hydrogen absorbers are now believed to originate in galaxies or their halos, which at high redshifts may still be in the process of assembly. This approach eliminates all selection biases inherent in direct photometric detection, but it is limited in the information it can provide, primarily the gas column density, metallicity (an indicator of the chemical evolution) and perhaps rudimentary kinematics. Direct detections of a small number of high-redshift galaxies responsible for absorption systems have been made, and the data suggest that they are very similar to the general field population detected with the Lyman-break technique at comparable redshifts.

Formation of galaxies and that of the large-scale structure are closely related at early epochs. It is plausible that the first galaxies form in the densest spots of the primordial density field. These 'density peaks' are expected to be intrinsically highly clustered, as they would be mainly located within the larger overdensity regions. The first PGs may thus be found in the cores of future rich clusters, and then galaxy formation would gradually spread to ever lower density environments. This concept of so-called biased galaxy formation is generic to almost all models of structure formation. There is now some evidence that galaxies and quasars at $z > 3$ or 4 may indeed be strongly clustered. It should be noted that this primordial large-scale structure derives from initial conditions, with the first PGs and quasars lighting up

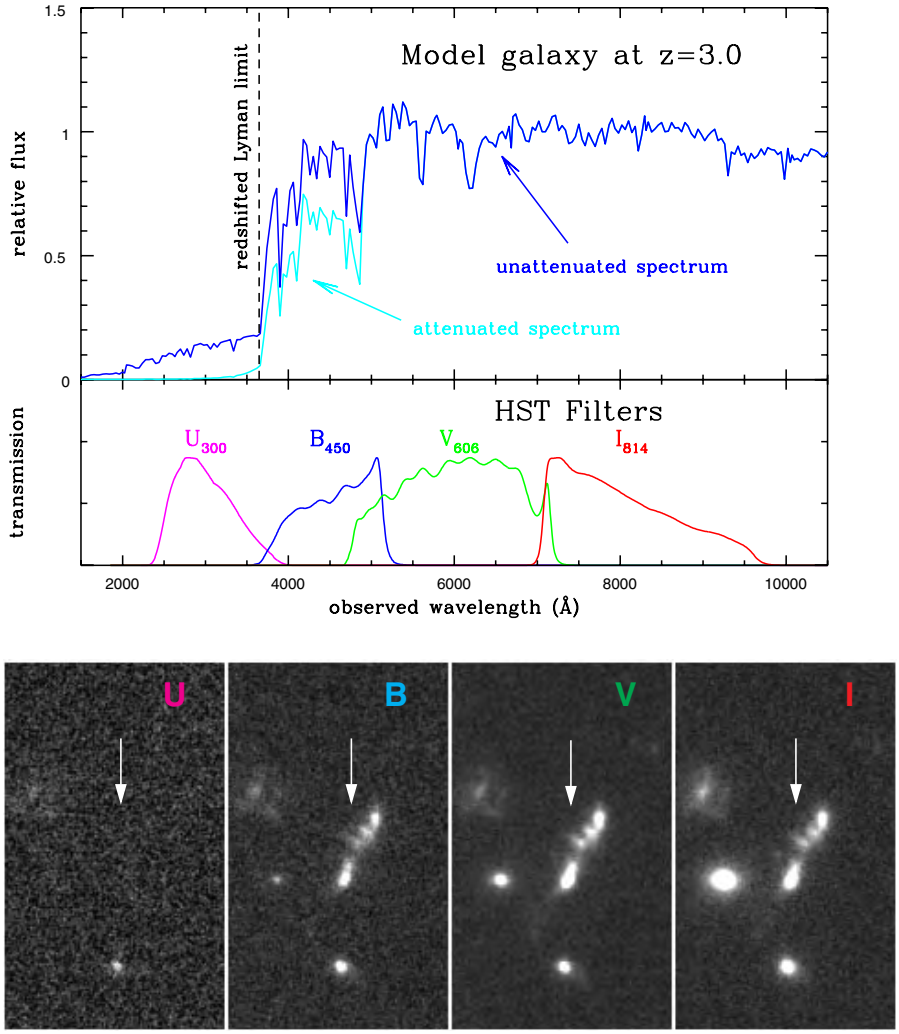

Figure 2. An illustration of the Lyman-break technique at work. The top panel shows a population synthesis model spectrum of an actively star-forming galaxy redshifted to $z = 3$, with and without attenuation due to the Lyα forest. Note the sharp drop in the continuum shortward of the Lyman break, at the observed wavelength of 912 Å $\times(1 + z)$. A set of transmission curves of filter used in the imaging of the Hubble Deep Field is shown below the spectrum. One would expect that such a galaxy would appear about equally bright in the B, V and R filters, but be practically undetectable in the U filter. This is indeed observed in the actual images of a galaxy at $z = 2.8$ found in the Hubble Deep Field images, shown in the bottom row. Reprinted with permission from Dickinson M 1998 *The Hubble Deep Field* ed M Livio *et al* (Cambridge: Cambridge University Press) p 219. © (The Cambridge University. Press).

the highest peaks of the primordial density field. This is distinct from the large-scale structure seen in the local universe, which grows gradually over the Hubble time through the gravitational instability.

The net result of the studies to date is at least a broad-brush understanding of the history of galaxy formation and evolution since $z \sim 5$ or so. The average star-forming activity has a broad maximum around $z \sim 2$ or 3, with a rapid decline since $z \sim 1$ or 2 towards the present day, $z \sim 0$. However, it is not clear whether we have yet seen the onset of galaxy formation. From absorption line studies we know that the universe was already fully ionized at $z \sim 5$, presumably by some combination of PGs and early AGN. While most of the stars may have formed since $z \sim 5$, clearly the first stars and thus PGs must have formed earlier.

We know that the universe entered 'dark ages' after the recombination at $z \sim 1100$, a few hundred thousand years after the big bang. Current theory suggests that the first protogalactic fragments started forming at $z \sim 10$–20 or so, a few hundred million years after the big bang. This 'cosmic renaissance' ended the dark ages and marked the onset of galaxy formation. The challenge for the future is to map this critical era, from $z \sim 20$ to $z \sim 5$, where the first PGs were forming.

Bibliography

This is a rapidly developing field, and perhaps the best way to learn about the up-to-date results is by browsing recent conference proceedings on cosmology, high-redshift universe, etc, of which there are many. However, the following reviews give more details on the subject of this article.

A good review of PG searches, problems, and techniques up to the mid-1990s is

Pritchet C 1994 *Publ. Astron. Soc. Pac.* **106** 1052–67

An updated review of searches for distant galaxies up to 1999 is

Stern D and Spinrad H 1999 *Publ. Astron. Soc. Pac.* **111** 1475–502

A good overview of the Lyman-break technique and some of the results is

Steidel C 2000 *Proc. Pritzker Symp. on the Status of Inflationary Cosmology* (Chicago, IL: University of Chicago Press)

S G Djorgovski

Proton

A positively charged elementary particle that is composed of three quarks. It has a charge of +1, equal in magnitude to the charge on the electron (1.602×10^{-19} coulomb), and a mass of 1.6725×10^{-27} kg, 1836 times greater than the mass of the electron. In terms of energy, its mass is equivalent to 938.3 MeV. It has an intrinsic angular momentum, or spin, of 1/2 (expressed in units of the Planck constant, h, divided by 2π).

The proton is a nucleon, one of the two basic constituents of an atomic nucleus (the other being the marginally heavier neutron). The number of protons in an atomic nucleus (its atomic number) determines its net charge and, therefore, the chemical element of which that atom is an example. For example, a hydrogen nucleus contains one proton, a helium nucleus, two, and a uranium nucleus, 92. Although it has a lifetime of at least 1032 years, and may be completely stable, some versions of grand unified theory predict that protons eventually decay into leptons and photons.

Protoplanet

An object representing an intermediate stage in the process of planet formation. A protoplanet is formed by the accretional collision of planetesimals, the primary products of accretion, themselves formed initially by the coalescence of dust grains and then the gradual aggregation of further material. Protoplanets collide with one another to form larger objects; the end result of this stage is a system of planets—a small number of still larger objects which have swept up most of the debris from collisions and occupy orbits which have long-term stability.

See: accretion, planetesimal, solar system: formation.

Protoplanetary Disks

Protoplanetary disks are disks of dust and/or gas orbiting very young stars. Based upon what we know about the formation of our own solar system, these objects are deemed to be very likely to evolve into solar systems like our own.

This is a very fast-paced field of study and many of the scientific advances have occurred within the past 15 yr. In 1983, a satellite was launched to study the infrared emissions from the sky. This satellite, called the Infrared Astronomy Satellite or *IRAS*, revealed that about one-fifth of the main-sequence A stars near the Sun exhibited an excess infrared emission that could only be explained by warm dust orbiting these stars. This suggested that a significant fraction of all A stars, and presumably other young stars as well, have dust orbiting them. Since A stars have lifetimes of 10^8–10^9 yr, their implied ages overlap with the era of planet formation and heavy meteoritic and cometary bombardment of planets in our early solar system.

Shortly after this discovery, attempts were made to image the dust surrounding these stars. This was very tricky, since one must see the dust against the glare of the bright star. A small disk was placed inside the camera to block out the light coming from the star. In this way, it was hoped that the light scattered by the dust surrounding the star could be seen. One star, β Pictoris, an A star at a distance of 62.5 light-years, revealed a very flat disk of dust extending over 500 astronomical units (AU) from the star. (An astronomical unit is the distance defined by the distance between the Earth and the Sun.) For comparison, Pluto has an average distance of 39 AU from the Sun. This was the first evidence for truly solar system sized disks of dust orbiting nearby stars. The size of this dust disk is comparable to that of the KUIPER BELT of our own solar system. The Kuiper Belt is thought to extend from just inside the orbit of Neptune to beyond 200 AU from the Sun. The Kuiper Belt is the home of an estimated 100 million to 1 billion COMETS. A small fraction of these comets have orbits that penetrate into the inner solar system near the Earth and the Sun.

Spectroscopic studies of β Pictoris using the International Ultraviolet Explorer (IUE) satellite and the Hubble Space Telescope (HST), as well as ground-based telescopes, revealed an even more complicated picture. These spectra showed red-shifted spectral absorption lines of low-ionization atoms, varying with time, indicating gas possibly from comets falling onto the the stellar surface. The age estimates for β Pictoris are typically less than 100 million years. β Pictoris and other stars similar to it show spectral signatures of ice. These data, collectively, suggest that large numbers of comets are present around many young A stars. Hopefully, by studying these objects we can gain some understanding of how our early solar system evolved.

Thanks to a variety of observations, using both ground-based and space-borne instruments, we are beginning to get a consistent picture on how young protostars and disks representing PROTOPLANETARY NEBULAE evolve. The process starts with the gas on an interstellar cloud collapsing to form stars. The gas and dust forming an individual star fall inward and produce a star and an envelope which contains a large fraction of the angular momentum. An outward flow of gas, or 'wind', develops that clears the gas and dust of the inner envelope away from the young stellar object along the rotational axis of the star. The polar winds, or jets, can extend to very large distances. These extended bipolar flows can have distinct 'knots' of emitting gas along the flow. These flows can interact with the dense nebulosity typically found around these objects and produce shock-heated boundaries. These objects, if enough obscuring dust is removed so they can be seen at optical wavelengths, are sometimes called HERBIG–HARO OBJECTS.

The youngest obscured systems

Recent HST images have been acquired of YOUNG STELLAR OBJECTS (YSOs) in the constellation Taurus with the Near Infrared Camera and Multi-Object Spectrometer (NICMOS). These young systems are typically only observable at infrared (IR) wavelengths because the thick veil of dust absorbs all the visible light. However, the dust re-radiates this light energy at infrared wavelengths. The NICMOS infrared images at wavelengths from about 1 to 2 μm indicate YSOs with masses similar to our Sun and ages $\leq$1 Myr. These objects show dark obscuring dust lanes with diameters of 500–900 AU perpendicular to the bipolar flows emanating from the YSOs. The HST observations indicate these dust lanes are somewhat-flattened disks with equatorial extents of 500–900 AU and vertical thicknesses of 50–350 AU. The central protostar and the surrounding disk are completely obscured at optical wavelengths.

Other presumably young objects are the 'proplyds'. These objects are very compact knots of ionized gas that are seen near the core of the ORION NEBULA. The Orion Nebula is also a well-known site of active star formation. The proplyds appear to be very small with radii on the order of 50 AU. All observations suggest that they are a distinct class of very young objects. Proplyds appear to be flattened circumstellar clouds of gas and dust that surround stars collapsing toward the main sequence. Just how these objects fit into the observational scheme of the evolution of protoplanetary disks is not at all clear.

Ages from 1 to 10 million years: the young stars are unveiled

At ages from 1 Myr to 10 Myr, the envelope disperses, the disk continues to flatten and the central pre-main-sequence star becomes visible. Although much of the stellar radiation is absorbed by dust and re-emitted at IR wavelengths, the star itself shows very strong emission lines of ionized gas. The emission is produced by the gaseous infall onto the stellar surface and by the strong magnetic activity in these young objects. These young

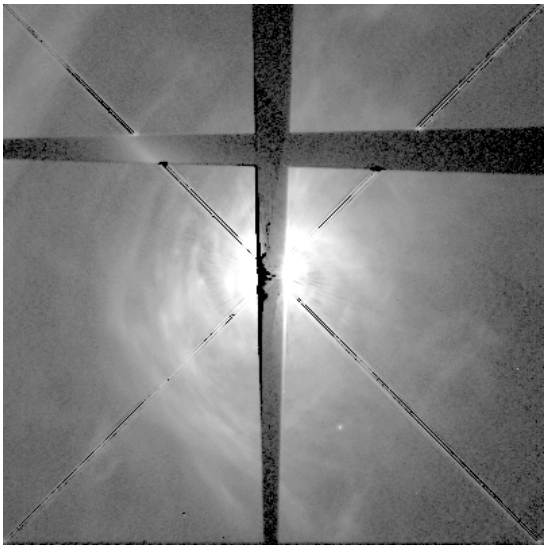

Figure 1. HST/STIS image of the circumstellar disk of the pre-main-sequence star, AB Aurigae (after Grady *et al* 1999). This image obtained with the STIS shows stellar light reflected from dust of the circumstellar disk. Notice the crossbar structure that blocks the direct light of the central star. The circumstellar disk appears to have a clumpy band or spiral structure centered on the star.

emission-line stars are called T TAURI STARS and are named after their prototypical example.

HST images of protoplanetary disks have been acquired with both the NICMOS camera in the near-IR and the Space Telescope Imaging Spectrograph (STIS) at visual wavelengths using techniques to dramatically reduce the contributions of the central stars. These techniques enhance the visibility of the surrounding circumstellar dust disk. These images have provided important glimpses of what happens at ages from 4 to about 10 Myr. These observations are very important because they can be used to limit the time scale of the protoplanetary disk phase. At later times, if a massive, Jupiter-sized planet is present, its gravitational perturbations can act to clear away dust from the region interior to the planet's orbit.

Recent STIS images of the star AB Aurigae, at a distance of about 470 light-years, show a dust disk with a radius of about 1300 AU (figure 1). Age estimates are generally not highly accurate, but determinations for AB Aurigae yield an age of about 2–4 Myr. This star also displays a gas disk that has been seen in line emission from molecular CO. The images do indicate a nebulosity that is circularly symmetric about the star with some spiral or band-like structure superposed. In general, there is a uniform drop-off in surface density with distance from the star. No definite evidence of clearing due to a massive planet is seen.

Near-IR images obtained by the NICMOS camera aboard the HST show annular dust rings instead of uniform dust disks about two young stars, HR 4796A and HD 141569. Both stars are hotter and much more massive than our Sun. The spectral types are A0 Ve and B9.5 Ve for HR 4796A and HD 141569, respectively. The 'e' in both spectral types indicates that these stars have detectable hydrogen Balmer lines in emission.

The age for HD 141569 is ill defined. All that can be said is that it has an age between 1 Myr and 10 Myr. The NICMOS images reveal a disk with a gap at a distance of approximately 250 AU from the star. In addition the brightness of the dust disk peaks at about 185 AU from the star and falls off in brightness at both smaller and larger distances. If recent modeling efforts are correct, the gravitational perturbations of a Jupiter-sized planet at a distance of 250 AU could produce the observed gap. This planet would be far too faint to be detected with the available ground-based and space borne instruments.

The NICMOS imagery of the star HR 4796A is even more revealing (figure 2). The near-IR images at 1.1 and 1.6 μm of this star clearly show a sharply defined annular ring. The inclination on the plane-of-the-sky implies that the ring brightness peaks at a distance of about 70 AU from the star. The resolved width of the ring further shows that it is sharply delineated with a width of 17 AU. The sharply defined morphology of the annular disk implies one, possibly two, unseen planets near 70 AU from the star, HR 4796A. The age estimate for HR 4796A suggests that it is 8$\pm$ 3 Myr old.

The HST observations for HD 141569 and HR 4796A impose strong constraints on the theory of planet formation. Based upon theories attempting to explain how planets form in our own solar system, it would be extremely surprising to see massive, Jupiter-sized planets at such great distances (70–250 AU) from the central star, a region where the density in the protoplanetary disk should be far lower than at distances corresponding to the realm of the giant planets in the solar system. Also, these observations suggest the formation time needed to form giant planets is quite short ($\leq$8–10 Myr) and poses strong constraints on theories for planetary formation.

The end of the protoplanetary phase

At times greater than 10 Myr, if planets are, indeed, forming at times shorter than 10 Myr, we may not be seeing protoplanetary disks, but debris disks, representing the residues of planetary formation. Although meteoritic and cometary impacts will continue the planetary growth process, the protoplanetary part of the evolution of the circumstellar disk has come to an end. There are several physical processes that act to destroy and disperse circumstellar dust. Observations of stars older than 10 Myr can place important constraints on these processes.

The most notable stars which appear to have circumstellar dust disks and that have ages $\geq$10 Myr are the so-called 'big three', β Pictoris, α Piscis Austrini (Fomalhaut) and α Lyrae (Vega). Based upon their deduced positions in the H–R diagram and theoretical evolutionary tracks, the ages of these three stars are thought to be near 100, 200 and 400 Myr, respectively. However, there is some indirect evidence which suggests

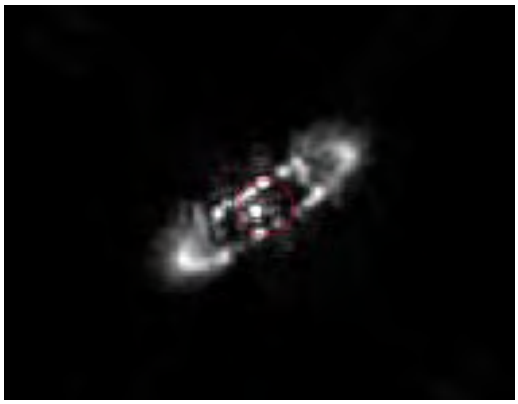

Figure 2. HST/NICMOS image of the circumstellar dust ring of HR 4796A (after Schneider *et al* 1999). This is the processed image of the disk as seen in the infrared at 1.1 μm. The central star has been placed in a 0.3″ radius hole in an attempt to minimize the light seen from the star. Note the sharply defined dust ring. Its infrared brightness peaks at ∼70 AU from the star. The sharply defined nature of the ring may indicate the presence of one or more unseen Jupiter-sized planets.

that β Pic might be as young as 20 Myr. All of these stars have significant IRAS infrared excesses as has been known since the mid-1980s.

The processes that lead to the destruction of the dust disk are (a) expulsion by pressure of starlight, (b) Poynting–Robertson drag and (c) sublimation of icy grains. Small grains have a high cross-sectional area relative to their mass and can be preferentially blown away when the force due to radiation exceeds that of gravity. The smaller grains, with sizes $\leq$2–10 μm, are quickly expelled even at early ages. The larger remaining grains, because they orbit the star, have a component of the radiation force, Poynting–Robertson drag, that opposes the orbital velocity of the grains. This causes the orbiting grains to eventually spiral into the star. This preferentially clears the inner disk, but the outer regions at distances of 1000 AU can be cleared on time scales comparable with the evolutionary time of the A stars.

However, it is still unresolved how such extensive dust disks remain in these older systems. Perhaps this dust and the presence of massive planets inferred at larger distances suggest that the protoplanetary disks are quite massive and dense at very large distances from the protostar. Recent models even suggest that planets can form at much greater distances and then, through interactions with the disk, migrate inward toward the star. This is a controversy that hopefully will be solved with future observations of other young forming planetary systems and extrasolar planets (EXOPLANETS).

Bibliography

Comprehensive reviews of the research on protoplanetary disks are regularly presented in scientific conferences. The best source of these compilations can be found in the series published by The University of Arizona Press called *Protostars and Planets I–IV*. These published books detail the proceedings of regular meetings held every few years in this field.

Much of what has been presented here comes from very recent observational results obtained with instruments aboard the Hubble Space Telescope. More exciting results are sure to come. Some of the recent observations and theoretical models can be found in the following references.

Protoplanetary Nebulae

Protoplanetary nebulae (or pre-planetary nebulae, PPNs) are defined as objects that are in transition between the asymptotic giant branch (AGB) and planetary nebula phases of STELLAR EVOLUTION. Stars on the AGB lose mass at a high rate ($(10^{-7}$–$10^{-4})M_{\odot}$ yr^{-1}) in the form of a stellar wind. Such mass loss eventually depletes the hydrogen envelope of the star and exposes the electron-degenerate carbon–oxygen core. This leads to an increase of the effective temperature of the star and the termination of mass loss. As the small amount of remaining hydrogen above the core continues to be consumed by hydrogen shell burning, the effective temperature of the star will gradually increase. When the stellar temperature reaches approximately 30 000 K, the amount of stellar photons with energies above the Lyman limit (13.6 eV) will be large enough to photoionize the surrounding material. The emergence of strong recombination lines of hydrogen (e.g. Hα) and helium and collisionally excited lines of metals (e.g. the [O III] line at 5007 Å) signifies the beginning of the planetary nebula phase. The evolutionary phase between the end of AGB mass loss and the beginning of photoionization is referred to as the PPN phase.

Observational properties

PPNs are primarily identified by their large infrared excesses. Such excesses originate from dust in the remnant of the stellar wind ejected during the AGB. As the wind disperses, the dust cools and the thermal radiation shifts to longer wavelengths. Most of the PPNs are discovered by finding IRAS sources that have dust temperatures intermediate between those of AGB stars and planetary nebulae. A typical PPN shows an infrared excess peaking at $\sim$20 μm, corresponding to a dust temperature of $\sim$150 K. Some examples of PPNs are given in table 1.

Table 1. Examples of protoplanetary nebulae.

Object	Spectral type	Chemistry	[s/Fe]
IRAS 04296 + 3429	G0 Ia	C	+1.4
IRAS 07134 + 1005	F5 I	C	+2.0
IRAS 18095 + 2704	F3 Ib	O	−0.1
IRAS 19500 − 1709	A2–3 I	C	+1.2
IRAS 22272 + 5435	G5 Ia	C	+2.5

[s/Fe] denotes the abundance of s-process elements.

Molecular emission is also a characteristics of PPNs. Molecules (e.g. CO, HCN) in the remnant AGB envelope emit line radiation as the result of rotational transitions. These molecular lines have typical linewidths of 20–40 km s^{-1}, implying expansion velocities of 10–20 km s^{-1} for the envelope. From these velocities, we can estimate the dynamical ages of PPNs to be $\sim 10^2$–10^3 yr. The total lifetime of the PPN phase is $\sim 10^3$ yr, depending on the mass of the star.

The central stars of most PPNs are of spectral types between G and B (corresponding to effective temperatures of 5000–15 000 K) and luminosity class I. The high luminosity class of PPNs is a manifestation of the low surface gravity ($\log g \sim 1$) in these objects. Because of their spectral class, PPNs are sometimes referred to as yellow supergiants.

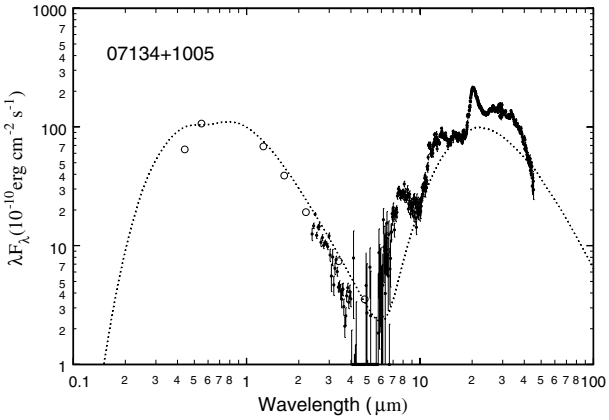

Figure 1. The spectral energy distribution of the PPN IRAS 07134 + 1005. The dust component (right) is clearly separated from the photospheric component (left). The fact that the dust shell is detached from the photosphere is confirmed by a radiation transfer model (shown as a dotted curve).

Evidence for the end of AGB mass loss and the detachment of the AGB envelope from the photosphere can be found in the spectral energy distribution. As the envelope expands, the decrease in circumstellar extinction allows the central star to become more prominent. This results in a double-peaked spectral energy distribution made up of a cool dust component and a photospheric component reddened by circumstellar extinction (see figure 1).

The morphology

Optical and infrared imaging has found that many PPNs have asymmetric envelopes. For objects that are viewed edge on, two bipolar reflection lobes can be seen. These lobes are the result of light from the central star scattered off the dust in the circumstellar envelope. An example of such bipolar structure is shown in figure 2. The dark region between the bipolar lobes is believed to be due to extinction from an equatorial disk. With the use of mid-infrared cameras on new large ground based telescopes, such disks can be directly resolved and imaged (see INFRARED IMAGERS, INFRARED TELESCOPES).

PLANETARY NEBULAE are found to have diverse morphologies including bipolar (or butterfly) shapes. When and how the spherical AGB envelopes are shaped into such bipolar forms are topics of high current interest. The detection of bipolar nebulosity in PPNs suggests that the shaping of planetary nebulae occurs early, possibly only a few hundred years after the end of the AGB.

Some PPNs show two pairs of searchlight beams and a series of concentric arcs (figures 2 and 3). The beams can be explained as light reflected off a cavity in the polar directions, but the origin of the arcs is not known. The cavity is probably created by a collimated fast outflow

that developed during the PPN phase. Support for the existence of a collimated outflow can be found in PPNs such as Hen 401 (figure 4) which have an elongated shape.

Masses and luminosities

The central star of a PPN represents the core of its AGB progenitor. Since the envelope mass is very small ($<10^{-3}M_{\odot}$), the total mass of the central star is approximately equal to the core mass (M_c). The typical

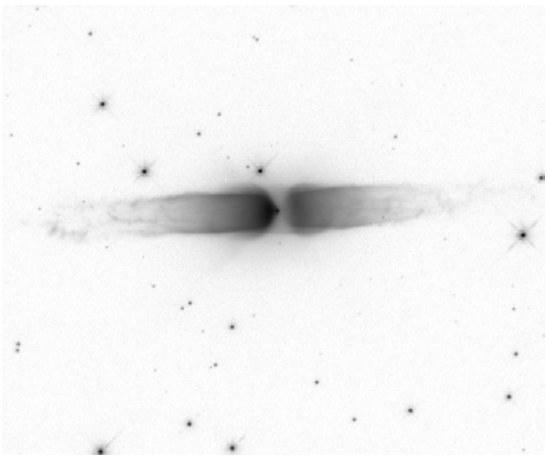

Figure 4. *HST* V-band image of the PPN Hen 401. **This figure is reproduced as Color Plate 42.**

mass of the central star is $0.6M_{\odot}$, but theoretically it can be as high as $1.4M_{\odot}$, the maximum mass limit for a WHITE DWARF (the Chandrasekhar limit). The luminosity of a hydrogen-burning PPN is directly proportional to the mass of the core:

$$L_* \sim 60\,000(M_c/M_{\odot} - 0.5)L_{\odot}.$$

For example, PPNs with $M_c = 0.60M_{\odot}$ and $0.64M_{\odot}$ will have luminosities of $\sim 6000L_{\odot}$ and $8300L_{\odot}$ respectively. PPNs are therefore among the most luminous stars in the Galaxy (see also HIGH-LUMINOSITY STARS).

Which stars will become PPNs?

The discovery of white dwarfs in young open clusters suggests that stars with initial (main-sequence) mass as

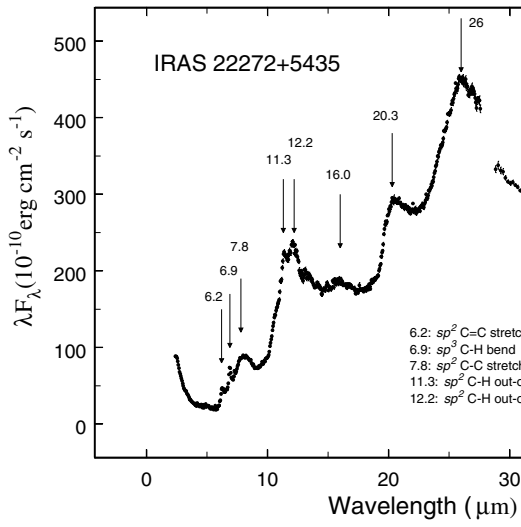

Figure 5. *ISO* spectrum of the PPN IRAS 22272 + 5435 showing various stretching

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

high as (8–10)$M_\odot$ will become white dwarfs. This implies that approximately 95% of stars will end their lives as white dwarfs. However, not all white dwarfs necessarily passed through the planetary nebula stage. Specifically, post-AGB stars with low core masses ($M_c < 0.57 M_\odot$) are believed to be evolving too slowly to cross the HERTZSPRUNG–RUSSELL (H–R) DIAGRAM in time to ionize the circumstellar envelope before it disperses. These post-AGB stars without surrounding nebulae will be observed as blue hot stars radiating primarily in the ultraviolet. Such stars have been suggested to be responsible for the ultraviolet excesses observed in ELLIPTICAL GALAXIES.

Variability

As PPNs evolve across the H–R diagram at constant luminosity, the radii of the central stars will decrease. Consequently, their pulsation periods are also expected to decrease from the several hundred days observed for AGB stars. Pulsations of PPNs have been observed through both spectroscopic (radial velocity) and photometric variations, with periods ranging from 25 to 150 days.

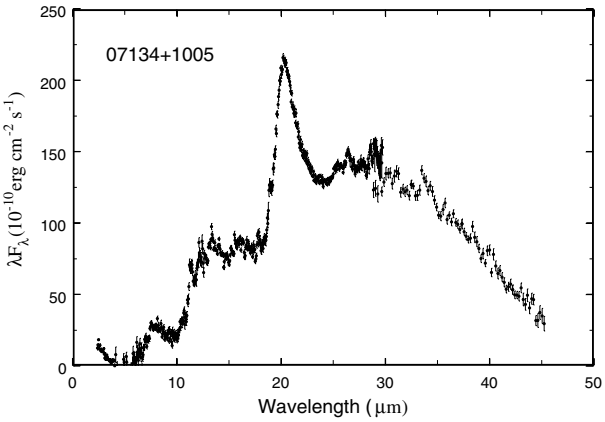

Figure 6. *ISO* spectrum of the PPN IRAS 07134 + 1005 showing the unidentified 21 μm emission feature.

Chemical abundances

PPNs can be classified as oxygen or carbon rich depending on whether the O/C abundance ratio is larger or less than unity. Since the less abundant element is tied up almost exclusively in CO, it is not available to form other molecules. Oxygen-rich PPNs can be identified by the presence of the 9.7 μm circumstellar silicate feature whereas carbon-rich PPNs show molecular absorption bands of C_2, C_3 and CN.

Stars on the AGB undergo hydrogen and helium shell burning as well as neutron capture processes. Some PPNs show a large overabundance of s-process elements (Y, Zr, Ba, La, Ce, Pr, Nd, Sm and Eu), confirming that these objects have indeed evolved through the AGB phase (see table 1).

Chemistry of the circumstellar envelope

Infrared spectroscopy of PPNs has revealed the presence of organic compounds with aromatic and aliphatic structures. A series of infrared emission features at 3.3, 6.2, 7.7 and 11.3 μm due to aromatic C–H and C–C stretching and bending modes are commonly seen in carbon-rich PPNs. In addition, features at 3.4 and 6.9 μm due to stretching and bending modes of aliphatic subgroups are also detected (see figure 5). These features, as well as the underlying broad emission plateaux around 8 and 12 μm, can be found in the laboratory infrared spectra of polycyclic aromatic hydrocarbons, quenched carbonaceous composites, hydrogenated amorphous carbons and coal.

In addition, strong unidentified emission features at 21 and 26 μm are also seen in carbon-rich PPNs (see figures 5 and 6). In particular, the 21 μm feature is unique to PPNs and has not been seen elsewhere in stars in other phases of evolution or in the interstellar medium.

The detection of these carbonaceous compounds suggests that complex organic molecules can be formed over a short ($\sim 10^3$ yr) timescale. This process is believed to first begin during the late AGB phase, where simple organic molecules such as acetylene (C_2H_2) are formed

in the AGB wind. Chemical reactions in the envelope can lead to the formation of benzene (C_6H_6) and possibly other aromatic hydrocarbons. PPNs are therefore useful laboratories for the study of ASTROCHEMISTRY.

Proxima Centauri

The star α Centauri C, a red dwarf member of the Alpha Centauri gravitational system, spectral type M5Ve, apparent magnitude 11.01. The separation from the principal stars of the system, the binary pair (Cen A and B, is so great (2.2°) that although its similar distance from the Sun confirms that it is a member of the system no orbital motion can be detected. It is a star of very low luminosity indeed, absolute magnitude 15.4, and is also a flare star which frequently brightens briefly by about one magnitude. It is a good example of a main-sequence star nearing the end of its life. With a parallax of 0.772″, equivalent to a distance of 4.22 light-years, it is 0.17 light-years closer than the central pair and is thus the closest known star to the solar system.

Ptolemaic System

The geocentric view of the universe as expounded by Ptolemy (Claudius Ptolemaus, *c*. AD 100–170, librarian at Alexandria) in the second century AD. According to this view, the Earth lay at the center of the universe and around it, in order of distance, moved the Moon, the planets Mercury and Venus, the Sun, and the planets Mars, Jupiter and Saturn. Beyond the outermost planet lay the sphere of the stars. The Sun and Moon were envisaged as moving around the Earth in circular paths while, in order to account for their observed motions, each planet was considered to move around a circle or epicycle, the center of which moved around a larger circle, the deferent, which was itself centered on the Earth.

The system required additional complex devices in order to account fully for planetary motions and was never entirely satisfactory (although surprisingly successful predictions of planetary positions were achieved). At that time it was felt that the circle was the perfect geometrical form, and that only perfect motion was possible in the heavens. It was not until the work of Kepler (1571–1630) that it was appreciated that the planets move around the Sun in elliptical orbits.

Ptolemy

The last important astronomer of classical antiquity, Ptolemy is also the only one whose works have come down to us substantially intact. His *Almagest*, a comprehensive empirical and mathematical deduction of models to explain the motions and phenomena of the heavenly bodies, laid the methodological foundation for the Islamic and European mathematical astronomy of the Middle Ages and Renaissance.

Biography and writings

Claudius Ptolemaeus (Ptolemy) worked at or near Alexandria in Egypt during the middle decades of the 2nd century AD. He began making astronomical observations at least as early as AD 127. By 147, he had completed a preliminary version of his system of planetary models, which he described in outline in a public inscription that was later preserved in manuscript copies. The full presentation of the system, incorporating some significant revisions, was given in a large treatise entitled *Mathematical Composition*, which much later came to be universally called the *Almagest* (from an Arabic title meaning 'the greatest'). Ptolemy wrote several other works on physical science, most of them after the *Almagest*. Those that are directly concerned with astronomy include the *Phases of the Fixed Stars*, the *Handy Tables*, the *Planetary Hypotheses* and brief works on stereographic projection and sundial theory. The original Greek texts of the *Almagest* and *Handy Tables* have been preserved in medieval copies, whereas the other works are incomplete, or extant only in Arabic versions.

The *Almagest*

The purpose of the *Almagest* is to establish quantitative geometrical models based on uniform circular motion for the Sun, the Moon, the five known planets and the fixed stars (see also PLANETARY THEORY FROM EUDOXUS TO COPERNICUS). Ptolemy attempted to make the work thoroughly empirical, deductive and demonstrative, following a course that he succinctly delineates in the introduction to his planetary theory: 'anyone who was to convince himself and his future audience must demonstrate the size and the period of each of the two anomalies [in a planet's motion] by means of well-attested phenomena which everyone agrees on, must then combine both anomalies, and discover the position and order of the circles by which they are brought about, and the type of their motion; and finally must make practically all the phenomena fit the particular character of the arrangement of circles in his hypothesis'. This is an axiomatic approach, resembling Greek geometry, rather than a heuristic one. The starting points are (a) hypothetical model types for the heavenly bodies, (b) approximate values for the periodicities, taken over from earlier astronomers, and (c) records of observations and measurements.

Ptolemy's plan also resembles a Greek geometrical treatise in being cumulative, building demonstrations on prior demonstrations. He begins with arguments, chiefly from qualitative observation, that the Earth and heavens are spheres with a common center, and that the Earth is stationary and negligible in size relative to the celestial sphere. This is followed by a table of the lengths of chords in a standard circle (used for trigonometrical calculations), a measurement of the obliquity of the ecliptic using a meridian ring and a group of geometrical theorems useful for solving problems in spherical astronomy, which Ptolemy immediately applies to deducing tables for declinations and right and oblique ascensions.

The natural frame of reference for planetary positions in ancient astronomy was the backdrop of fixed stars. Because he knew from Hipparchus' work (see HIPPARCHUS) that the stars have a precessional motion relative to the equinoctial points, and considered it necessary to demonstrate the nature of that motion before using the stars as reference points in observations, Ptolemy instead chose to build his chain of deductions from a solar theory demonstrated from observations of the dates of solstices and equinoxes. Drawing heavily on Hipparchus' writings on solar theory, Ptolemy argues that the tropical year, i.e. the interval measured between observed equinoxes or solstices of the same kind, is constant, and approximately 365;14,48 days (where the numerals after the semicolon represent sixtieths, sixtieths of sixtieths, and so forth). Hence it also follows that the lengths of the astronomical seasons do not change, and Ptolemy claims to have confirmed by 'very precise observations' that Hipparchus' values ($94\frac{1}{2}$ days for astronomical spring and $92\frac{1}{2}$ days for astronomical summer) were valid in his own time. On this basis Ptolemy took over (with acknowledgment) Hipparchus' solar model, according to which the Sun travels with a period of 365;14,48 days on a circle whose center is displaced from the Earth's center by 1/24 of the orbit's radius in a fixed direction $65\frac{1}{2}^\circ$ east of the vernal equinoctial point.

Ptolemy's handling of the solar theory calls for several remarks. First, without a constant tropical year his rationale for giving priority in the *Almagest* to the solar theory would have been undermined. Secondly, while there is no obvious reason why Ptolemy should not have been able to observe equinoxes and solstices generally within the quarter-day tolerance that Hipparchus correctly claimed for his own observations, consistent results unambiguously confirming the constancy of the seasons would have been much harder to achieve. Thirdly, Ptolemy's observations of the equinoxes and summer solstice in AD 139 and 140, on which his demonstration rests, are not genuine, since they are consistently about a day too late. Why Ptolemy introduced falsified observations at this point, whether he made real ones and whether his proceedings were justifiable are topics of controversy. Since Ptolemy reckons longitudes from the vernal equinoctial point rather than relative to the stars, the error of a day introduces a systematic and gradually increasing error into all longitudes derived from his models, and the false observation reports continued

to bedevil later astronomers' solar theories for centuries afterwards.

The lunar theory in the *Almagest* begins along the same lines as Hipparchus', with a calculation of the radius of the Moon's epicycle (or, equivalently, the eccentricity of its orbit) from sets of three observed lunar eclipses on the hypothesis of a simple epicyclic model. Unlike Hipparchus, Ptolemy obtains a consistent result, namely an epicycle radius of $5\frac{1}{4}$ units where the deferent circle's radius is 60 units; the consistency is enhanced, however, by small 'fudgings' in Ptolemy's arithmetic. Ptolemy revises Hipparchus' lunar periodicities after finding the dimensions and configuration of the model, so that he is able to use for this purpose very widely spaced eclipse observations subject to fewer restrictions than Hipparchus required.

From a study of observations recorded by Hipparchus, Ptolemy discovered that the lunar anomaly predicted by this model was too small in situations other than syzygy, with the maximum discrepancy when the Moon was elongated 90° from the Sun. He therefore modified the model by replacing the Moon's deferent circle with a rapidly revolving eccentric circle so as to draw the epicycle closer to the Earth at quadrature than at SYZYGY. The revised model, which is quite successful in predicting lunar longitudes, has the defect of falsely implying that the lunar disk ought to appear much larger at half Moon than at full Moon. Ptolemy does not mention the problem, although he can hardly have been unaware of it.

Ptolemy was now in a position to calculate lunar positions accurately and to compare these with observed positions to measure the Moon's parallax and hence its distance from the Earth. The calculation is marred by errors, yet arrives at a fairly accurate result (mean distance at syzygy of 59 Earth radii), a clear illustration of Ptolemy's contriving to make a derivation arrive at an answer that he already knew by other means. In this instance, an inaccurate parallax would have shown up in the prediction of solar eclipses, and Ptolemy also could have been influenced by previous estimates by Hipparchus and others. Ptolemy uses Hipparchus' eclipse diagram (see HIPPARCHUS, figure 1) in reverse to find a solar distance from his lunar distance, disregarding the extreme sensitivity of this calculation to small variations in the data.

After the Moon Ptolemy turns to the fixed stars, showing from observations spanning more than four centuries that the configurations of stars do not vary (that is, they have no proper motion), and that the entire 'sphere of fixed stars' revolves about the poles of the ecliptic. Ptolemy finds too small a rate of precession (1° in 100 yr instead of in about 72 yr), but this almost exactly cancels out the error in his tropical year, so that the mean sidereal year implicit in his theory is unexpectedly good. A catalog of 1022 fixed stars, with longitudes (normed for AD 137), latitudes and numerical magnitudes ranging from 1 to 6, follows at this point. Ptolemy describes this as the product of his own observations; historians are in disagreement about the truth of this assertion, and whether the catalogue actually incorporates an older catalogue by Hipparchus adjusted by Ptolemy for precession.

Ptolemy's planetary models impose an epicycle (to exhibit the synodic cycle of direct and retrograde motion) on an eccentric orbit (to exhibit the variations in the synodic cycle). For the INFERIOR PLANETS the epicycle's center revolves about the Earth with the same period as the Sun, whereas the SUPERIOR PLANETS revolve about their epicycles with a period such that they are approximately at the perigee of the epicycle when in opposition to the mean Sun. Ptolemy further modified the eccentric model by introducing the so-called equant point, a point twice as distant from the Earth as the center of the eccentric deferent along the same line; the revolution of the epicycle around the deferent is postulated as uniform as seen from the equant point rather than from the deferent's own center. The effect of this model is roughly to make the planet's deferent appear to have twice as great an eccentricity at opposition and conjunction as at situations half-way between.

The procedure for measuring the components of the models is different for the inferior and superior planets. In the case of Venus and Mercury, Ptolemy is able, so to speak, to observe the edges of the epicycle directly when the planet is at its greatest elongation from the Sun; hence he can straightforwardly establish the apogee of the deferent and the size of the epicycle. In the case of the remaining planets Ptolemy selects sets of three observations of oppositions with the mean Sun, when the planet is theoretically seen along the same line with the epicycle's center, and applies the same Hipparchian method of determining an eccentricity and apogee as in the solar and lunar models. The procedure is made much more difficult here by the equant motion, to account for which Ptolemy carries out a sequence of iterative corrections to his first calculation. The epicycle is then measured using an observation of the planet at intermediate elongation from the Sun. The verification of the periodicities is carried out after the determination of the radii and apogee, as was the case with the Moon. In contrast to the closely reasoned treatment of the planetary models so far as they concern motion along the ecliptic, Ptolemy's rather complicated system of wobbles to produce their latitudinal motion is presented as a *fait accompli*, unsupported by specific observations.

Other writings

Ptolemy concluded the *Almagest* with a theory of the limits of planetary visibility, which served by its agreement with the accepted planetary phenomena as a confirmation of the validity of Ptolemy's models. The essential concept here was the *arcus visionis*, a critical arc by which the Sun must be below the horizon along an altitude circle if the planet is to be visible. In his *Phases of the Fixed Stars* (the theoretical part of which has not survived) Ptolemy extended this visibility model to the stars, taking into account the effects of the observer's latitude and the latitudes of the stars. The extant part of the book applies this information to produce

Dirac House, Temple Back, Bristol, BS1 6BE, UK

a calendar correlating computed dates of appearance and disappearance of stars with regular patterns of weather in different localities.

Interspersed in various parts of the *Almagest* are many tables for computing positions and phenomena of the heavenly bodies, derived from the models. These have an internal application in the deductions of the *Almagest*, but also were potentially useful for other purposes, especially ASTROLOGY. After completing the *Almagest* Ptolemy revised the tables, and published them separately as the *Handy Tables*. In addition to many improvements in the format of the tables, Ptolemy tacitly simplified the underlying models for planetary latitude and reworked the tables for planetary visibility. The *Handy Tables* was widely disseminated in antiquity.

The *Planetary Hypotheses* represents Ptolemy's last word on the celestial motions. In this work he treats the models of the *Almagest* in a more physical way, as a system of rotating spheres. Most of the *Planetary Hypotheses* exists only in an Arabic translation (see also MEDIEVAL COSMOLOGY) that is often difficult to interpret, and there is some ambiguity about the extent to which Ptolemy meant to delineate the actual structure of the heavens, since he also evidently has in mind the construction of a sort of ORRERY. A feature of this book that was profoundly influential in medieval astronomy was Ptolemy's presentation of the models as a series of nested spheres, with the outermost sphere of the Moon directly continguous with the innermost sphere of Mercury, and so on outwards to the sphere of the fixed stars (see ISLAMIC ASTRONOMY). By a remarkable coincidence, as Ptolemy discovered, such a packing is almost perfectly in agreement with the solar and lunar distances that he determined in the *Almagest*.

Pulsar Backends

Present-day pulsar astronomers require equipment which will perform two main tasks. The first of these is to search for new PULSARS and the second is to make observations of known ones, primarily to make precision timing measurements, but also to study the polarization and morphology of the pulses. These require rather different capabilities from the equipment, but the two things they have in common are the necessity for high time resolution and high sensitivity. The signal-to-noise ratio, which is the main measure of the quality of a pulsar observation, is approximately

$$\mathrm{SNR} = K\left[NBT\left(\frac{P}{W}-1\right)\right]^{1/2} \qquad (1)$$

where K is a constant which depends on the size and performance of the radiotelescope, N is the number of polarization channels (usually 2), B is the total receiver bandwidth, T is the duration of the observation and P and W are the period and width of the pulses. This equation clearly indicates that the use of a receiver with a large bandwidth is important. Moreover, we see that the sensitivity is greatest for small values of the width of the observed pulses W. Thus any instrumental process which broadens the pulses reduces the sensitivity.

Dispersion

What makes the tasks non-trivial is the dispersion of the signals caused by the weak frequency dependence of the velocity of the pulses during their passage through the interstellar medium. The gas in the interstellar space is ionized to a greater or lesser extent by ultraviolet and x-ray emission from stars. The pulsar signals travel through the resultant electron plasma at a radiofrequency ν with the group velocity of

$$v_\mathrm{g} = c\left(1-\frac{n_\mathrm{e}e^2}{2\pi m\nu^2}\right) \qquad (2)$$

where n_e is the free-electron plasma density, c is the free-space velocity of light and e and m are the charge and mass of the electron. The effect of this can be seen most clearly in figure 1 which shows the dispersion of the radio pulses from the pulsar B1356 − 61, the pulses at low frequencies being delayed relative to those at higher ones. Clearly, if one uses a receiver with bandwidth exceeding a few of these frequency channels, the observed pulse will be much wider than the true pulse, so reducing the sensitivity.

The amount of frequency drift is determined by the column density of free electrons along the line of sight to the pulsar, a quantity known as the dispersion measure.

Dedispersion

Of course one could combat the broadening effects of this dispersion simply by using a very narrowband receiver but this would be at the penalty of much reduced sensitivity as can be seen from equation (1). However, there are several ways in which the effects of dispersion may be removed from the data, while retaining full sensitivity, using processes which come under the generic name of dedispersion.

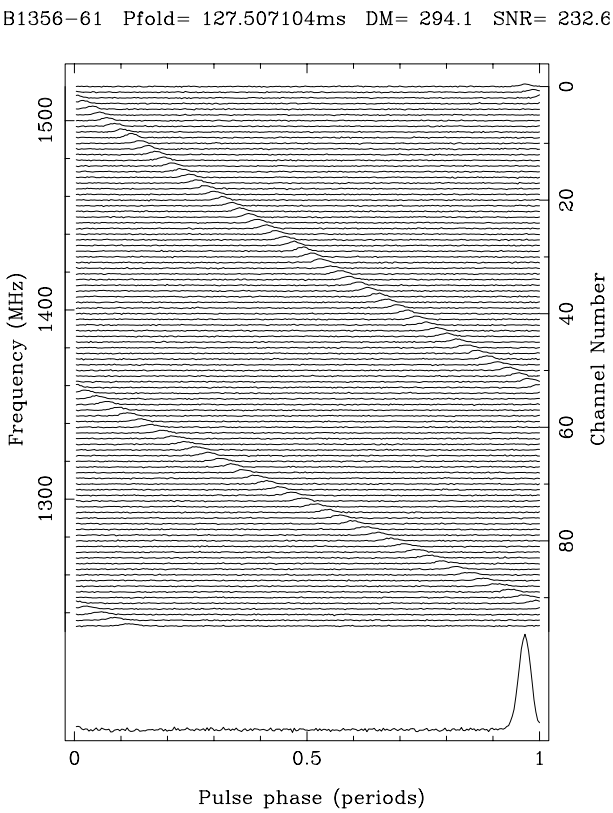

Figure 1. Frequency dispersion in the pulses from PSR B1356 − 61. Each horizontal trace shows the pulse profile recorded in one of 96 adjacent frequency channels, each 3 MHz wide, centered on 1380 MHz. The pulse profile at the bottom is the result of correcting the individual profiles for the drift in frequency and then adding them together.

The most widely used technique is to segment the receiver band into a number of much smaller bands in which the dispersion broadening is small and to record the power from each (see figure 1). If the dispersion measure is known, the outputs from the individual channels may be delayed by appropriate amounts before adding them all together to give a 'dedispersed' time sequence with a resolution determined by the broadening arising in the single channels.

There are two main practical ways of achieving this—by the use of FILTERBANKS or the use of autocorrelation spectrometers. The former essentially requires a bank of separate contiguous, narrowband receivers, with bandwidths equal to their frequency separation. These can often be constructed simply and cheaply using simple LC-tuned circuits. These have the disadvantage of inflexibility and more expensive digital filters have been employed in which the bandwidth and frequency are programmable.

The alternative digital autocorrelation spectrometers (CORRELATORS) form the basis of most spectral analysis in modern RADIO ASTRONOMY and are also used in pulsar astronomy. These first involve the computation of the autocorrelation function (ACF) of the data. Fortunately, the ACF is easily calculated digitally and accumulated over a period of time. Its Fourier transform may be calculated in a computer to provide the power spectrum (from a relationship known as the Wiener–Khinchin theorem). This is essentially the output of a filterbank and, as before, after the application of appropriate delays and additions, a dedispersed time sequence may be obtained.

Unfortunately there is a fundamental limit to the achievable time resolution of such post-detection, or incoherent, dedispersion techniques. As the bandwidth of the individual channels is reduced, the dispersion broadening is reduced. However, the use of a filter of bandwidth b limits the response time of the output to roughly $1/b$ and hence there is a critical bandwidth below which the time broadening starts increasing again.

There is only one technique which can overcome this limitation; pre-detection, or coherent, dedispersion. This requires sampling the voltages of the full receiver bandwidth digitally and then applying exactly the inverse of the filter which has been applied by the interstellar medium, which essentially rotates the phase of the signals as a function of frequency according to the dispersion law. This is usually achieved by performing a Fourier transform of the data, rotating the phases of every element in the transform and then performing the inverse Fourier transform. The result is a time sequence which is essentially the output of a receiver which was very close to the pulsar. In this case, the time resolution is as little as $1/B$, the inverse of the full receiver bandwidth. For example, with a bandwidth of 100 MHz, time resolution of only 10 ns is possible.

This of course is the ideal process but requires very large computational resources and, while it is used for a number of studies of millisecond pulsars, it is not worthwhile for most slower pulsars.

Searching for pulsars

Most modern searches for pulsars are based on the identification of signals which are dispersed and periodic in nature. These searches are usually conducted by recording the output of a filterbank or spectrometer, using a sampling interval which is small compared with the intrinsic width of the pulses of the target pulsars. If this is not so, the effective pulse width will be increased and the sensitivity of the search will be reduced according to equation (1). The recorded data are then dedispersed for a number of trial dispersion measures, each trial producing a time sequence which is then searched for pulse trains of unknown periodicity and pulse width. This search is usually carried out by performing a fast Fourier transform of the data and seeking large spikes in the resultant spectrum. The search sensitivity can be improved by summing up to $P/2W$ harmonics of the fundamental period P, where W is the pulse width; the sensitivity is then improved by a factor $(P/2W)^{1/2}$ and is consistent with that given by equation (1).

While these computations can in principle be carried out in real time, the required computing resource is considerable and there is no possibility of reprocessing the data, for instance if the data from some filterbank channels are spoilt by interference. For these reasons, data are usually recorded directly onto magnetic tape and processed later on off-line computers in a more leisurely fashion. The volume of recorded data in modern searches is often large. It is not unusual for 512 filterbank channels to be sampled every 100 μs, requiring the storage of 5 million data elements per second. Recording say 8 bits for each element requires a sustained data rate of 5 Mbytes s^{-1}. However the number, and hence cost, of tapes can be reduced by representing each element by a smaller number of bits, resulting in a somewhat reduced sensitivity. In fact, in the extreme case of the small signals expected from undiscovered pulsars, single-bit sampling provides a sensitivity which is reduced by a factor of only $(2/\pi)^{1/2} = 0.80$ for an eight-fold reduction in data volume. Such digitization simply requires the recording of a '0' or a '1' depending on whether the signal level is less than or greater than the long-term mean level. The simplicity and economy of such sampling make it widely used (see also SOFTWARE: RADIO PULSAR SOFTWARE).

Timing measurements

Much of the most interesting astrophysics in pulsar astronomy arises from the ability to monitor the rotation of pulsars through very high-precision measurements of their arrival times. This is usually achieved by dedispersing and folding the data at the known period of the pulsar over a sufficiently long interval of time, typically 10 min, to give a high signal-to-noise ratio profile. Such folding may be carried out within special-purpose hardware or in general-purpose computers.

In order to perform this operation, the pulsar dispersion measure and the instantaneous period must be known. The latter requires an accurate model of the rotation of the pulsar, as it would be observed at the BARYCENTER of the solar system, together with an ephemeris for the rather complicated motion of the telescope around the barycenter. This then allows calculation of the phase of the data samples within the pulse period so that they may be added into one of a number of hardware or software registers, each containing data for a single pulse 'phase'.

The input data for this process is usually the output of a filterbank or spectrometer or a coherent dedispersion process. The data may be dedispersed completely, partially or not at all prior to folding, in which case the dedispersion is completed afterwards. The reason for this is that the dispersion measure may not be well determined at the time of observation, and incorrect dedispersion may lead to distortion, or smearing, of the pulse. Likewise, an incorrectly known period may lead to smearing of the pulse. To combat this, an observation is usually

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

divided into a number of subintegrations within which the distortion is small. These may be combined subsequently when the period is better determined.

In order to use such data for timing measurements, the local observatory clock must be synchronized with UTC or some other atomic time standard. This is usually carried out using the Global Positioning Satellites (GPS) with an accuracy of better than 0.1 μs. The profile must then be appropriately time tagged and, from this, a time of arrival is usually obtained by convolution with a template, which is a standard, noise-free profile. The time of arrival is taken to be the peak of the resulting function.

Single pulses

Most pulsars show a considerable amount of detail and variation from pulse to pulse, revealing much about the details of the emission process. The acquisition of such data uses most of the principles discussed in the previous sections and usually involves the recording of dedispersed time sequences. Sometimes, the amount of data recorded can be reduced by storing only the data lying within narrow 'windows' centered on the pulse, rather than the whole period.

Polarization measurements

The measurement of the polarization of the radio pulses is important in establishing the configuration of the pulsar rotation axis and the NEUTRON STAR magnetosphere. Most modern telescopes have receivers providing two channels, A and B, which are sensitive to either left-hand and right-hand circular polarizations or to orthogonal linear polarizations. These pairs of signals can be combined to provide the four Stokes parameters, I, V, Q and U, which completely specify the polarization state of the radiation. For incoherent dedispersion systems, these are obtained electronically for each element of the filterbank and each of the four Stokes parameters is then dedispersed separately. For coherent dedispersion systems, the phase information is still available in the dedispersed time sequences so that only A and B need be recorded and dedispersed, the full Stokes parameters being calculated digitally from the resulting dedispersed time sequences.

Pulsars

Pulsars are the lighthouses of the Galaxy—rapidly spinning NEUTRON STARS whose strong magnetic fields produce conal beams of electromagnetic radiation that sweep past the Earth with each rotation of the star, producing the eponymous pulses that are observed primarily at radio wavelengths.

Like other neutron stars, radio pulsars are born in the SUPERNOVA explosions that accompany the collapse of massive stars. The nascent pulsars are born rotating at up to about 100 times per second. It is this stored rotational kinetic energy that powers the pulsar, so like a spinning top the pulsar gradually slows, reaching spin periods of about a second within a few million years. Eventually, within about 100 million years, the pulsar is spinning too slowly to maintain its radio emission, and it fades from view. Some old pulsars that have binary companions can be 'recycled', or spun back up to fast rotation periods by mass transfer from their companions. Because the resulting 'millisecond pulsars' have relatively low magnetic field strengths and hence low energy loss rates, they can continue to spin rapidly for times that are long compared with the age of the galaxy.

Just over 1000 pulsars are now known, all in our own galaxy except for a few pulsars detected in the MAGELLANIC CLOUDS. They are studied because neutron stars are intrinsically interesting astronomical objects, but also because the study of pulsars is deeply intertwined with many different branches of both astronomy and physics. Pulsars are, for example, very useful astrophysical probes. For example, a sharp radio pulse emitted by a pulsar is delayed and broadened during its propagation through the dispersive, turbulent interstellar medium, in a way that depends on the frequency and polarization of the signal as well as the properties of the medium. Multifrequency studies of pulsar signals have been used to map the distribution and turbulence structure of ionized material in the Galaxy, as well as the average Galactic magnetic field.

Pulsars are also, by virtue of their very regular, clocklike pulses, useful probes of the gravitational environments in which they are found. The Doppler shifts of the signals from pulsars in binaries can be used to study the binary properties, just as spectral lines are used with normal stars. Some very close pulsar binaries have orbits that are substantially deformed from Keplerian ellipses by general relativistic effects; in these systems, very precise tests of 'post-Keplerian' gravity theory have been possible.

Discovery and early history

Pulsars were discovered in 1967 by a Cambridge University graduate student, JOCELYN BELL (now Jocelyn Bell Burnell), working under the supervision of her thesis advisor, ANTHONY HEWISH. Hewish, Bell and their collaborators had designed and built a new telescope near Cambridge that was designed to study the rapid SCINTILLATION, or twinkling, of radio signals from QUASARS as they propagated through the SOLAR WIND. Studying the thousands of feet of chart recorder paper produced their receivers, Bell noticed some unusual 'scruff', from a direction well away from the Sun, that recurred on several nights at a fixed sidereal time. Follow-up observations showed that the signal had the form of a series of short radio pulses, repeated every 1.337 s. The extreme regularity of the pulsations was puzzling. After ruling out terrestrial interference sources, the team briefly considered the possibility of an artificial extraterrestrial origin—leading Bell to jokingly call the source LGM, for 'little green men'—but her quick discovery of three more pulsating radio sources demonstrated that they must arise from some natural source. A distance estimate of 65 pc was obtained for the first object, from measurement of the DISPERSION of the signal in the ionized interstellar medium, placing the source far beyond the solar system.

The rapid variability of the signal required a source that was much smaller than a light-second across: smaller, that is, than an ordinary star. The name 'pulsar'—pulsating star—enshrines the original model put forth by Hewish and his collaborators in which the pulses were produced by radial oscillations of a WHITE DWARF or neutron star. Models involving rotation rather than pulsation were, however, strongly favored by observations that the pulsation periods were gradually lengthening. (A top, as it loses energy, slows down; a bell rings with a constant frequency but a decreasing amplitude.) The identification of pulsars with neutron stars rather than white dwarfs came with the discovery in 1968 of pulsars in the Vela and Crab supernova remnants. Not only were neutron stars thought to be born in supernovae, but the Crab pulsar had a period of only 33 ms, much faster than allowed by any white dwarf model. (Remarkably, Franco Pacini had predicted that rotating, highly magnetized neutron stars were a potential source of electromagnetic radiation just a few months before pulsars were discovered.)

Hewish was awarded the 1974 Nobel Prize in Physics for his 'decisive role in the discovery of pulsars' and his pioneering work in radio astronomy. Bell's key role in the discovery has been widely recognized: among other awards, she has received the Michelson Medal of the Franklin Institute in Philadelphia (jointly with Hewish), the Tinsley Prize of the American Astronomical Society and the Herschel Medal from the Royal Astronomical Society.

The pulsar population

There are just over 1000 known radio pulsars (March 1999), with pulse periods ranging from 1.557 ms to over 8 s. This known sample represents fewer than 1% of the active pulsars in the Galaxy, with the others either too faint or too distant to detect, or with radio beams whose sweeps do not intersect the Earth. Most known pulsars lie within a few kiloparsecs, although some very luminous pulsars are observed in the distant reaches of our Galaxy and a few in the Magellanic clouds. No known pulsar is bright

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

enough to be detectable if it were placed in our neighbor galaxy M31.

A new pulsar is born in the Galaxy every 50–300 yr. This rate is somewhat lower than the estimated rate of core collapse supernova explosions (type II and type Ib/c) in the Galaxy, thought to be one every 20–50 yr. Both rate estimates are subject to many uncertainties, so the significance of the discrepancy is unknown. It is possible, however, that many core collapse supernovae do not produce active pulsars.

Pulsars in supernova remnants

Only a relatively small number of known SUPERNOVA REMNANTS harbor known radio pulsars. There are perhaps eight secure associations, and another dozen proposed associations where the possibility of a chance line-of-sight coincidence between the pulsar and remnant cannot be ruled out. Because pulsars remain active for over 10 million years, and their remnants fade within a hundred thousand years, the absence of remnants around most pulsars is easily understood. Remnants without pulsars may result from type Ia supernovae, may have pulsars that are too faint to be seen or are beaming in a direction away from Earth, or may contain neutron stars that are not active as pulsars for some reason (e.g. the soft gamma repeaters).

The association between the CRAB NEBULA, a plerionic supernova remnant, and the pulsar PSR B0531+21 has been particularly important. Chinese records of the supernova, which was first detected by Sung astronomers on 4 July 1054 and which remained visible in daylight for 3 weeks and at night for nearly 2 yr, have given modern astronomers a precise age for the pulsar. Tracing the motion of the filaments in the nebula backwards in time, they converge nearly a century after the supernova took place, implying an acceleration of the expansion after the original explosion. The pulsar provides the long-lived energy source for this acceleration.

Pulsar ages and magnetic fields

Observations of pulsars over extended periods of time allow the measurement of both the pulsar period P and the rate at which the period is lengthening $\dot{P}$ (or equivalently the frequency Ω and $\dot{\Omega}$). Often, it is assumed that the braking torque on the pulsar is proportional to some power of the pulsar spin frequency, so $\dot{\Omega} \propto \Omega^n$ where n is the 'braking index' ($n = 3$ for braking by magnetic spin-down radiation). If the original spin frequency was Ω_0, then the current age of the pulsar is

$$t = -\frac{\Omega}{(n-1)\,\dot{\Omega}}\left[1 - \left(\frac{\Omega}{\Omega_0}\right)^{n-1}\right]. \qquad (1)$$

A 'characteristic age' is often defined by assuming that $\Omega \ll \Omega_0$ and $n = 3$, so

$$\tau = -\frac{\Omega}{2\dot{\Omega}} = \frac{P}{2\dot{P}}. \qquad (2)$$

In a few cases, the braking index can be directly determined from measurements of the second derivative of the pulsar frequency, since $n = \Omega\ddot{\Omega}/\dot{\Omega}^2$. Measured values are between 1.4 and 3, slightly lower than prediction of the magnetic dipole model.

With this caveat in mind, the assumption that magnetic dipole radiation dominates the pulsar energy loss rate leads to an estimate of the surface magnetic field strength:

$$B \approx \left(\frac{3Ic^3P\dot{P}}{8\pi^2R^6}\right)^{1/2} \qquad (3)$$

where I is the moment of inertia of the neutron star and R its radius. For typical values from neutron star models, and P in seconds, we have

$$B \approx 3.2 \times 10^{19}(P\dot{P})^{1/2}\ G. \qquad (4)$$

In figure 1, we show the known pulsars with measured P and $\dot{P}$, including lines of constant characteristic age (equation (2)) and surface magnetic field (equation (4)). The pulsars in supernova remnants are shown by stars; as expected, they are among the youngest known pulsars. The pulsars in the lower left region of the figure are the 'recycled' pulsars; they will be discussed further below. The great majority of known pulsars are seen to have inferred magnetic field strengths of 10^{11}–10^{13} G and ages of 10^3–10^8 yr.

After pulsars are formed, pulsar spin periods lengthen and individual pulsars move from left to right in the figure. The precise shape of their tracks depends on the evolution of their magnetic fields, and hence the spin-down torques. For many years it was assumed that fields would decay owing to ohmic losses on timescales of 10^6–10^7 yr, but the current understanding is that the high conductivity interior to the star prevents field decay at least on 10^8 yr timescales. Pulsars would then move along lines of constant magnetic field. Eventually, pulsars reach the region in the lower right of the figure and are lost from the sample, either fading below detectable luminosity or crossing a 'death line' below which the radio emission process does not function.

The pulsar velocity distribution

Pulsars have high space velocities. This is observed directly, with interferometric measurements of PROPER MOTIONS corresponding to typical transverse speeds of around 300 km s^{-1}. Although most pulsars are born in the explosions of massive stars that are found near the Galactic plane, their high velocities carry them to a large observed scale height above (and below) the plane, $z \sim 500$ pc.

The origin of the pulsar velocities is still uncertain. Many pulsars are born in binaries, and binary disruption during a supernova explosion can leave the individual stars with large velocities. Binary disruption cannot account for the highest observed velocities, however. A more promising source of a large 'kick' is anisotropy in the supernova birth event. Even a small asymmetry in the neutrino emission from a supernova explosion is sufficient to leave the neutron star moving at 1000 km s^{-1} or faster.

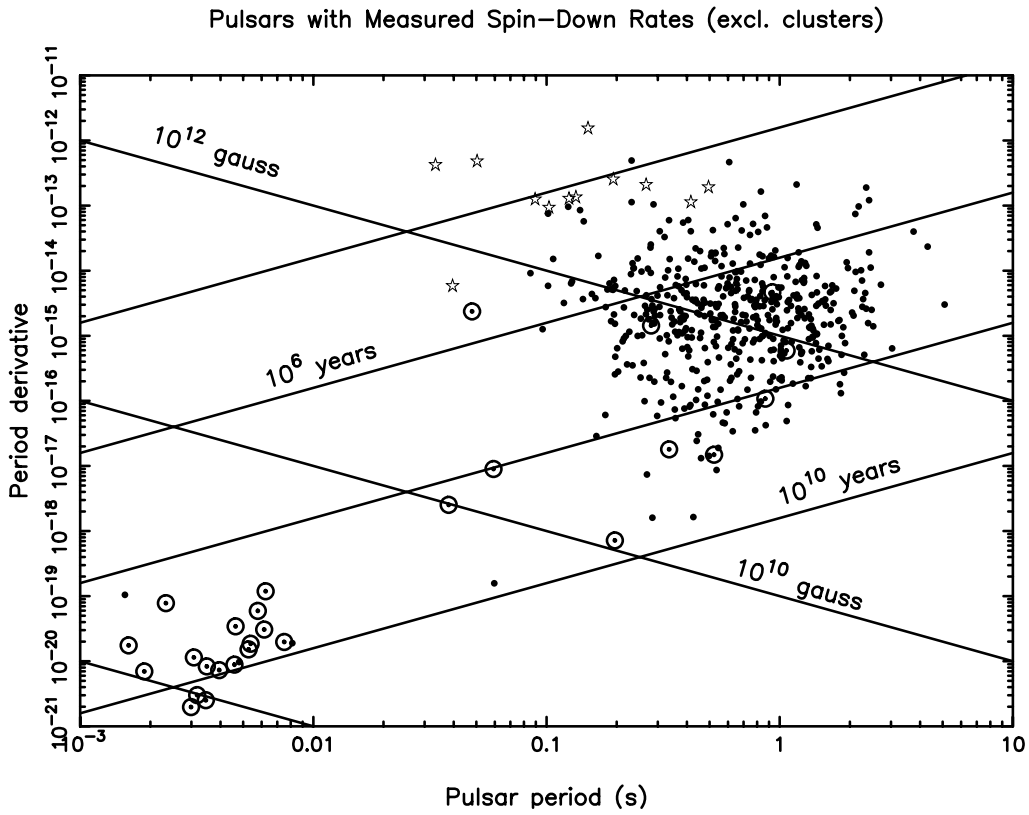

Figure 1. Pulsars with measured spin-down rates (excluding pulsars in globular clusters). Binary pulsars are marked with open circles, pulsars in supernova remnants with stars.

Radio and high-energy emission from pulsars

Although a basic physical model of pulsars was developed within a few years of their discovery, the pulsar radiation source itself remains rather mysterious. Astronomer Jon Arons has observed that we know why pulsars pulse, but not how they shine.

Some aspects of the emission process are straightforward. The neutron star is very strongly magnetized, with a field that is at least roughly dipolar and whose axis is misaligned with the rotation axis of the star. The rotating magnetic field produces a strong induced electric field which accelerates charged particles off the surface of the star into an ionized 'magnetosphere'. The conductivity is high along the magnetic field lines but very low perpendicular to the lines, so the charged particles are forced into corotation with the star. At a radial distance $r_c = c/\Omega$ a corotating particle would travel at the speed of light, so corotation must break down within this 'light cylinder'. Magnetic field lines that close back to the star within this radius can support a static charge distribution, but the 'open' field lines that cross the light cylinder define a conal region above the pulsar's magnetic polar cap in which particles can be accelerated to high energies. It is this polar cap region where pulsar radio emission is probably generated. Particle acceleration may also occur in a depleted region that develops just inside the light cylinder; this 'outer gap' is frequently invoked as the source of high energy (optical, x-ray and γ-ray) emission observed from some pulsars.

This simple picture remains incomplete, with such questions as 'current closure' (global charge conservation) remaining unsolved. It is remarkable that the seemingly straightforward electrodynamical problem of a non-aligned, magnetized rotator has so far defied analysis.

The radio emission mechanism

Observed pulsar radio luminosities, together with the small source size, imply extraordinarily high brightness temperatures—as high as 10^{31} K. To avoid implausibly high particle energies, coherent RADIATION processes are invoked. A maser-like mechanism, involving particles bunched in momentum space, is attractive, if only because maser action has been observed elsewhere in astrophysics, but models with coherent emission from bunches of particles have also been widely discussed, with a bunch of N particles localized in physical space radiating power proportional to N^2. Coherence by bunching is seen in terrestrial lightning flashes. In detail, severe problems remain in understanding pulsar emission by either the maser or the bunching models, and no consensus has emerged.

The emission mechanism itself also remains uncertain. Charged particles gyrating around magnetic field

lines produce SYNCHROTRON RADIATION. In the strong magnetic fields of the pulsar magnetosphere, a particle will quickly radiate aways its components of momentum that are perpendicular to the field lines, so will be confined to the lowest Landau level. Roughly, the charged particle can be pictured as a bead on a wire, along which the bead is free to move. As a particle moves out along a curved field line, it will produce synchrotron-like radiation that is conventionally called 'curvature radiation'. Coherent curvature radiation is currently the most widely accepted model for pulsar radio emission, but many other possible models have been discussed, including models based on relativistic plasma instabilities that are varients of the mechanisms proposed for type III solar radio bursts (see SOLAR FLARES: RADIO BURSTS).

Polarization

The radio emission from pulsars is frequently highly polarized, with linear polarization fractions reaching nearly 100% in some cases. In most emission models, the electric vector in the radiation can be associated with a preferred direction: either in the plane of the curving magnetic field lines or perpendicular to that plane. In many cases, there is evidence for radiation in both of two orthogonal modes of linear polarization. This can be observed, for example, by monitoring the pulse-to-pulse variations in the polarization vector. The position angle of the linear polarization often swings smoothly across the pulse period, as expected from the changing projection on the plane of the sky of the magnetic field direction. With the assumption that the field geometry is roughly dipolar, this position angle swing can be modeled to produce estimates of the angles between the spin axis and magnetic axis, and between the spin axis and the observer's line of sight.

Significant circular polarization ($\gtrsim$10%) is also often observed. Often, the circular polarization changes handedness near the center of the pulse profile. It is not known whether the circular polarization is intrinsic to the pulsar radiation processes or arises as a linearly polarized signal propagates, for example, through a birefringent region in the pulsar magnetosphere.

Radio phenomenology

The observed radio beam of a typical pulsar is quite narrow, with the pulsar 'on' only a few per cent of the time. When averaged over hundreds to thousands of pulse periods, the radio emission pattern is usually very stable. Some pulsars confine their radiation to a single Gaussian beam; others have complex pulse shapes, or show 'interpulses' that most likely arise from the second magnetic pole. A few pulsars have two or more stable emission patterns, and switch, apparently at random, between the two emission 'modes'.

From one pulse to the next, pulsars display a bewildering array of complex behaviors, both random and highly structured. A histogram of pulse strengths is generally roughly exponential in form, with the strongest pulses about 10 times the mean. Some pulsars undergo extended stretches, called 'nulls', with no detectable radio emission at all. Two pulsars, the Crab pulsar and the millisecond pulsar B1937+21, exhibit a power-law tail of 'giant pulses' that extends to hundreds of times the mean pulse intensity.

Individual pulses are often composed of one or more 'subpulses', which are usually significantly narrower than the length of the average pulse window. These subpulses occasionally show highly organized behavior from pulse to pulse, drifting across the pulse window. On much shorter timescales, 'micropulses' with widths as short as a microsecond are seen.

Rotation-powered X-ray and γ-ray pulsars

The coherent radio emission from pulsars is a nearly insignificant fraction of the total luminosity inferred from their spin-down rates. A handful of radio pulsars, primarily the youngest, also have pulsed emission at optical, x-ray and γ-ray energies. The Crab pulsar, for example, has a spectrum that has been measured all the way from 10 MHz radio waves to at least 5 GeV γ rays; the emitted power peaks in the hard x-ray band. The pulsar in the Vela supernova remnant has a spectrum that peaks in the γ rays, where it is the brightest object in the sky. (These rotation-powered high-energy pulsars should not be confused with X-RAY BINARY STARS that are accreting material from a companion.) One pulsar is known, GEMINGA, that appears quite ordinary except that it is seen only at high energies and not in the radio. It is believed that Geminga is a very nearby radio pulsar whose radio beam does not intersect the Earth. As noted above, some models place generation of the high-energy emission from pulsars in an outer gap, rather than the polar cap region where the radio emission probably originates.

Binary and millisecond pulsars

There are about 50 pulsars now known in binary systems. Most of these pulsars are clustered in the lower left of figure 1, with shorter pulse periods, larger characteristic ages, and lower magnetic fields than the general pulsar population. Only a handful of ordinary pulsars have binary companions, certainly a far smaller number than might be expected from studies of BINARY STARS. Although most pulsar progenitors were originally in binaries, most of these binaries were gravitationally unbound by the mass loss that accompanied supernova explosions, leaving the pulsars isolated.

Recycling

Under normal circumstances, the more massive component of a binary star system will evolve most rapidly, resulting, if the star is above about $8M_\odot$, in a supernova explosion. If the binary remains bound, the system may appear as a young pulsar with a main sequence companion. Eventually, the second star will finish core hydrogen burning and move off the main sequence, gradually

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

swelling. If the binary is sufficiently wide, the companion will continue its evolution as if it were an isolated star. However, if the binary is sufficiently compact, the surface of the companion will eventually come into contact with its Roche surface and begin transferring mass (and angular momentum) to the neutron star, spinning it up to shorter rotation periods. During this stage, the system will be visible as a luminous x-ray binary.

The fate of the system depends on the mass of the companion. A massive companion will evolve quickly, exploding as a supernova after a relatively short mass transfer period (as a high-mass x-ray binary). The result will be a pulsar with spin period around 30–50 ms, with a neutron star companion or no companion at all if the system becomes unbound. A light companion will evolve slowly, with a long mass transfer period (as a low-mass x-ray binary), leaving a pulsar with period 1–10 msec and a light, helium white dwarf companion. An intermediate-mass companion will leave a pulsar with intermediate spin period and a massive, carbon–oxygen white dwarf companion.

It is observed that the magnetic fields of these 'recycled' pulsars are significantly smaller than those of young pulsars. (The reason is not well understood, but is probably related to the mass accretion.) The resulting torques are very small, so recycled pulsars can spin down much more slowly than ordinary pulsars and remain active for billions or even tens of billions of years.

Selected binary pulsars

A few binary pulsars of particular interest are described here.

The Hulse–Taylor binary. The first binary pulsar was discovered by RUSSELL HULSE and JOSEPH TAYLOR in 1974, during a survey for new pulsars done at the ARECIBO OBSERVATORY as part of Hulse's PhD thesis work. Follow-up observations showed that the pulsar is in a high-eccentricity ($e = 0.6$), short-period ($P_b = 8$ h) orbit with another star, which is almost certainly a second neutron star. It was immediately realized that the high velocities and strong gravitational fields in this binary make it an extraordinary laboratory for studying fundamental physics, as described below. In 1993, Hulse and Taylor were awarded the Nobel Prize in Physics 'for the discovery of a new type of pulsar, a discovery that has opened up new possibilities for the study of gravitation'.

Two other close, double neutron star binaries are now known. Loss of energy to GRAVITATIONAL RADIATION causes the neutron stars in these binaries to slowly spiral together; on timescales of 10^8–10^9 yr, the neutron stars will collide and coalesce, probably forming a BLACK HOLE and possibly powering a GAMMA-RAY burst.

The eclipsing binaries. In 1988, a pulsar (B1957+20) was discovered with a $0.025M_\odot$ companion. The pulsar was eclipsed by its companion for about 10% of each orbit. The eclipse region is significantly bigger than the companion's ROCHE LOBE, leading to the conclusion that the eclipse is caused by a wind of material streaming off the companion. Although the mass loss rate inferred for this system is fairly small, the excitation of a wind by pulsar radiation has been suggested as a means of ablation or evaporation of a companion. The handful of known millisecond pulsars without binary companions may have emerged from such 'black widow binaries', of which several examples are now known. (See also ECLIPSING BINARY STARS.)

Pulsars with main sequence companions. Two pulsars are known with massive main sequence companion stars. Both are young pulsars that have not yet been recycled during companion evolution. The pulsar B1259−63 is in a very wide (3.4 yr), high-eccentricity orbit around a $10M_\odot$ Be star; J0045−7319 orbits a $\sim 9M_\odot$ B1 V star whose radial velocity curve has been measured with optical observations, making it the only known 'double-line' spectroscopic pulsar binary. Quadrupolar distortions of the companions in these systems lead to classical spin–orbit coupling and hence to measurable perturbations of the pulsar orbits, providing a test of stellar structure models of these massive stars.

A pulsar with planets. PSR B1257+12, a pulsar with a 6 ms spin period, has two planetary companions of roughly terrestrial mass, $3.4M_\oplus$ and $2.8M_\oplus$, orbiting with periods of 66.5 and 98.2 days. A third body, of roughly lunar mass, orbits in a 1 month orbit. This was the first planetary system detected outside the solar system, and these remain the lightest known extrasolar planets. The planets are in nearly circular orbits, suggesting that they were formed after the supernova that created the pulsar. It is possible that they formed from a disk left by a companion star that was destroyed by the ablation processes seen in the eclipsing binary pulsars.

A triple pulsar system. The pulsar PSR B1620−26, in the globular cluster M4, has a $\sim 0.3M_\odot$, white dwarf companion in a low-eccentricity, half-year orbit. An observed acceleration of this binary has been interpreted as the reflex motion of the binary around its center of mass with a second, more distant companion. The outer body is light, probably either a planet or a brown dwarf, and the orbital period is most likely a few centuries.

Isolated millisecond pulsars

There are a few pulsars known that have short spin periods and low magnetic fields that place them with the binary pulsars in figure 1 but which have no observed binary companion. These include the first millisecond pulsar discovered, PSR B1937+21, which is still the fastest known pulsar, with spin period $P = 1.557$ ms. It is generally thought that B1937+21 and similar pulsars were recycled in binary systems but later lost their companions, perhaps to a process like the evaporation that appears to be occurring in the eclipsing binary systems.

Pulsars in globular clusters

Over 40 pulsars are now known in the Galactic GLOBULAR CLUSTERS, 20 in 47 Tucanae alone. Most have low magnetic fields and short spin periods and are probably products of recycling in a binary system. About half are now in binary systems. Since globular clusters contain very old stellar populations and no active star formation, no core collapse supernovae are currently producing young pulsars. The apparent presence of a few relatively young pulsars in clusters has led to the suggestion that some neutron stars could be created in 'accretion-induced collapse' of white dwarfs that are pushed over the Chandrasekhar mass limit by accretion from a binary companion.

The stellar density in the core of a globular cluster is sufficiently high that stellar interactions, including star–binary interactions and binary–binary interactions, are an important dynamical process. Thus clusters contain a relatively high fraction of isolated millisecond pulsars, whose companions have been unbound in three or four body interactions. (See also BINARY STARS IN GLOBULAR CLUSTERS.)

Pulsar timing

Because of their great rotational inertia, the rotation of pulsars is extremely stable. The individual pulses from pulsars are the ticks of celestial clocks that are, in the best cases, as precise as the best terrestrial atomic time standards (long-term frequency stability of about a part in 10^{14}). Measuring the differential light travel time of the pulsar signal as the Earth moves around its orbit allows, for example, the position of the pulsar in ECLIPTIC coordinates to be precisely determined. Similarly, the pulsar signal will be periodically advanced or delayed as the pulsar travels in a binary orbit. Pulsar timing experiments—clock comparison experiments that compare the pulse arrival time with a reference atomic time standard—can thus be used to make very precise estimates of the orbital parameters of binary pulsars. (For further details, see also RADIO PULSAR BACKENDS and SOFTWARE: PULSAR SOFTWARE.)

Tests of general relativity

The most famous application of pulsar timing techniques has been to tests of experimental gravitation. In most cases, binary orbits are well approximated as Keplerian ellipses. The high velocities ($\sim 10^{-3}c$) and strong gravitational fields in some binary pulsar systems cause relativistic deviations from Keplerian motion to be significant. Five relativistic corrections have been measured: the advance of the angle of periastron of the elliptical orbit (as is seen in the orbit of Mercury); the combined effect of the transverse Doppler shift and the changing gravitational redshift as the eccentric orbit carries the pulsars closer and further from its companion; two parameters describing the Shapiro time delay of the pulsar signal as it propagates through the gravitational potential well of the companion; the decay of the binary orbit due to gravitational radiation back reaction. The measurement of any two of these effects allows the amplitude of the other three to be predicted, making possible very precise tests of general relativity and alternative gravity theories. This was the subject of the 1993 Nobel Prize in Physics, discussed above. (See also GENERAL RELATIVITY TESTS: BINARY PULSARS.)

Pulsars and nuclear physics

The average density of a neutron star is comparable with the density in heavy atomic nuclei, and the density reaches several times this value at the core. Neutron stars are thus useful laboratories for studying nuclear materials at densities beyond what can be reached in the laboratory. One topic of considerable interest is the maximum neutron star mass, above which the star becomes unstable to collapse to a black hole. Pulsar timing measurements allow, in some cases, very accurate stellar mass estimates. The most massive known neutron star in a radio pulsar binary is $1.44M_{\odot}$, considerably below the $\sim 2M_{\odot}$ limit of a typical nuclear equation of state.

A more direct probe of neutron star interiors comes from the study of timing 'glitches', that are observed in some young pulsars. During a glitch event, the pulsar period decreases in a step function, with amplitude from a few parts in 10^9 to a part in 10^6. At the same time, the spin-down rate increases, and the pulsar recovers over a time period of weeks to months to a period close to the pre-glitch value. Smaller glitches may be caused by a sudden cracking of the crust of the neutron star and its relaxation to a more spherical shape; larger glitches are probably due to variations in the coupling between the superfluid interior of the star and its independently rotating crust.

Bibliography

The most recent introductory textbook is

Lyne A G and Smith F G 1998 *Pulsar Astronomy* 2nd edn (Cambridge: Cambridge University Press)

A more advanced, classic textbook, now dated, is

Manchester R N and Taylor J H 1977 *Pulsars* (San Francisco, CA: Freeman)

A collection of more advanced review articles on a variety of topics have been published in book form as

Blandford R D, Hewish A, Lyne A G and Mestel L (eds) 1993 *Pulsars as Physics Laboratories* (Oxford: Oxford University Press)

A good introduction to the problem of the pulsar emission mechanism is

Michel F C 1991 *Theory of Neutron Star Magnetospheres* (Chicago: University of Chicago Press)

An annotated guide to the pulsar literature has been compiled:

Pulsating and Chemically Peculiar Upper Main Sequence Stars

There is a natural astrophysical division of the main sequence which occurs for early F stars. Stars cooler than this have deep surface convection zones, radiative cores, generate their energy by the proton–proton cycle, rotate relatively slowly and any global magnetic field present is weak, although strong fields may exist in tangled flux tubes, as in sunspots in the Sun. Stars hotter than early F have thin or no surface convection zones, convective cores, generate their energy by the CNO cycle, rotate relatively rapidly and, if they have magnetic fields, those fields are strong, global and approximately dipolar. Given this natural division this article concerns the stars of the Upper Main Sequence, from early F to the O stars. A guide through the names of most of the types and classes for these stars is provided.

Mostly, the peculiar stars do not pulsate, and the pulsating stars (see STELLAR PULSATION) are not peculiar. However, there is a small overlap; the relationship between pulsation and peculiarity is discussed, and the most widely accepted model, the diffusion hypothesis, is introduced and explained, with examples given of its wide applicability to many fields of stellar astrophysics.

Nomenclature for the peculiar stars

On and near the main sequence for $T_{\rm eff} > 6600$ K there is a plethora of spectrally peculiar stars and photometric VARIABLE STARS with a bewildering confusion of names. Table 1 shows some of the subgroups of chemically peculiar (CP) stars as a function of temperature. These stars all show spectral peculiarities. Members of the magnetic group are known to have global magnetic fields which are roughly dipolar with strengths of hundreds to tens of thousands of G. (The global magnetic field of the Sun is about 0.5 G; the magnetic field in sunspots is about 1500 G.) The magnetic stars are mostly known as Ap stars (for A peculiar), but many of the 'Ap' stars are B stars, so sometimes those are called Bp stars. Other A stars which have peculiar spectra, but not the same peculiarities as the Ap stars, and are non-magnetic, are called Am stars (for A metallic-lined).

Table 1. Magnetic and non-magnetic peculiar stars of the upper main sequence.

$T_{\rm eff}$ (K)	Magnetic stars	Non-magnetic stars
7000–10 000	Ap SrCrEu	Am, λ Boo
	A3 – F0	A0 – F1
10 000–14 000	Ap Si	Ap HgMn
	B8–A2	B6–B9
13 000–18 000	He-weak Si, SrTi	He-weak PGa
	B3–B7	B4–B5
18 000–22 000	He-strong	
	B1–B2	

Am stars are given three spectral classifications: one based on the Balmer lines which gives a good measure of the effective temperature; one based on the Ca II K-line which, because of its weakness relative to normal stars, gives an earlier spectral type; and one based on the metal lines which, because of the enhanced strength of the metal lines, gives a later spectral type. 'Classical Am' stars have K-line and metal line spectral types that differ by five or more spectral subclasses; this difference is less than five subtypes in 'marginal Am' stars (designated 'Am:'). Classical Am stars have H-line types that lie between A3 and F1. For hotter stars the Am phenomenon is harder to recognize, but continues to A0 (Sirius is an Am star), so Am stars with H-line spectral types between A0 and A3 are known as 'hot Am' stars. Evolved Am stars with luminosity classes IV and III are classified as δ Del stars, or as ρ Pup stars (see also CLASSIFICATION OF STELLAR SPECTRA).

To rationalize this situation another system of nomenclature was devised in which there were four subtypes of chemically peculiar (CP) stars: CP1 ≡ Am stars, CP2 ≡ magnetic Ap, Bp stars, CP3 ≡ HgMn stars, and CP4 ≡ He-weak B stars. This system is widely used—principally, but not exclusively, in Europe—whereas North Americans seem to prefer the Ap–Bp terminology.

There are also the λ Bootis stars which have H-line types between A0 and F0, a Ca II K-line type of A0, or slightly later, and *weak* metallic lines, particularly Mg II 4481 Å. Abundance analyses show marked *under*-abundances of the Fe-peak elements, with lighter elements essentially normal.

The oblique rotator model

The magnetic field strengths, spectra and luminosities of the magnetic CP stars all vary synchronously on timescales of about a day to over a century. These variations are well-understood in terms of the oblique rotator model. Figure 1 shows the geometry of this model. The line-of-sight to the Earth is to the right. The inclination of the rotation pole is i, the obliquity of the magnetic axis is β, and the variable angle between the magnetic pole and the line-of-sight is α. As the star rotates, the magnetic field is seen from varying aspect, so its effective strength is observed to be variable. Because the stars have anomalous abundance patches at their magnetic poles, the spectrum also varies with rotation as does the luminosity—both of these in phase with the magnetic variations. These rotational variables are known as α^2 CVn stars.

For a centered dipolar magnetic field the measured effective magnetic field strength is:

$$H_{\rm eff} = \frac{1}{20}\frac{15+\mu}{3-\mu} H_{\rm p}(\cos i \cos\beta + \sin i \sin\beta \cos \Omega t)$$

where $H_{\rm p}$ is the polar magnetic field strength, i and β are the rotational inclination and magnetic obliquity, μ is the limb-darkening coefficient and Ω is the rotation frequency. It can be seen from this equation that dipolar magnetic fields give rise to magnetic variations which are sinusoidal, with amplitudes proportional to $\sin i \sin\beta$ and zero points proportional to $\cos i \cos\beta$; this immediately constrains the values of i and β.

© Astronomical Society of the Pacific 2000

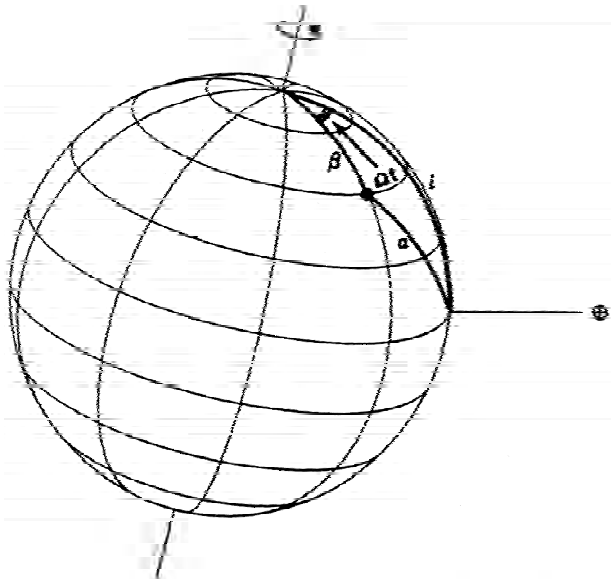

Figure 1. The geometry of the oblique rotator model. Earth is in the direction marked.

Nomenclature for the variable stars

There are many kinds of pulsating stars near the upper main sequence:

- The δ Sct stars lie in the instability strip, which ranges from A2 to F0 on the main sequence and from A3 to F5 at luminosity class III. They pulsate primarily in low-overtone radial and non-radial p modes with periods between about 30 min and 6 h, and amplitudes ranging from the detection limit of a few mmag up to 0.8 mag. Some δ Sct stars may also pulsate in g modes.
- The high-amplitude δ Scuti stars are known as HADS and as dwarf Cepheids if they are POPULATION I STARS. Low metallicity, POPULATION II subdwarfs with δ Scuti pulsation are called SX Phe stars.
- The rapidly oscillating Ap (roAp) stars are mid-A to early-F main sequence Ap SrCrEu (CP2) stars which pulsate in high-overtone p modes with periods in the range 5–16 min and amplitudes $\leq$0.016 mag—generally much less. The pulsation modes are aligned with the oblique magnetic axis, so the geometry of the oblique rotator model in figure 1 applies to the pulsation of these stars in the similar oblique pulsator model. They mostly lie within the δ Sct instability strip, but a few of them are cooler. The driving and mode selection mechanisms are not known. Asteroseismic study of the pulsation frequencies of these stars provides information about their pulsation modes, rotational inclination, the inclination of the magnetic field to the rotation axis, atmospheric structure, luminosity, internal structure and internal magnetic field strength and configuration. Asteroseismically, they are the most studied main sequence stars other than the Sun.
- The Herbig Ae and Be stars, known collectively as HAeBe stars, are PRE-MAIN SEQUENCE A and B STARS which show emission lines from strong stellar winds and from cocoons of remnant gas from which they collapsed. These are massive counterparts of the T TAURI STARS. Two Herbig Ae stars are now known to be δ Sct stars.
- The γ Dor stars are multi-periodic, non-radial g-mode main sequence pulsators with periods in the range 0.3–3 days, and amplitudes of a few hundredths of a magnitude. They are confined to an instability strip which partially overlaps the δ Sct stars in the HERTZSPRUNG–RUSSELL (HR) DIAGRAM, ranging in temperature from 7200–7700 K on the main sequence, and 6900–7500 for $\log g \approx 4$.
- The slowly pulsating B (SPB) stars (also known as 53 Per stars) are multi-periodic, non-radial g-mode main sequence pulsators with periods in the range 0.6–3 days and amplitudes typically less than a few hundredths of a magnitude. They lie in a narrow instability box in the HR diagram which ranges from B2 to B9, thus they do not overlap with the δ Sct stars.
- The β Cephei stars are giant and sub-giant, p-mode pulsators with periods in the range 2–7 h. Some are singly periodic, some are multi-periodic; they pulsate in both radial and non-radial modes of low degree, $\ell \leq 3$, and low overtone, n. Their photometric amplitudes are $\leq$0.1 mag, except for the star BW Vul.
- Even hotter than the β Cep stars there are (possibly) pulsating O stars known as α Cygni variables. Their periods are typically of the order of 1 to 2 months, and their amplitudes are less than a few tenths of a magnitude. They are thought to be pulsating in g modes, or in so-called 'strange modes'—modes associated with a sound-speed inversion, caused by a density inversion, caused by an opacity bump, most likely from Fe, H and/or He.
- Amongst the B stars there are emission-line Be stars which have periodic variations with periods between 0.3 and 3 days and amplitudes between 0.01 and 0.3 mag. These are known as λ Eri stars. It is contentious as to whether their variability is caused by g-mode pulsation or by some rotational effect.

Non-pulsating variables near the upper main sequence include:

- Eruptive LUMINOUS BLUE VARIABLES (LBVs) called S Doradus stars with variations of about 0.2 mag on time-scales of weeks to months. If there is thought to be periodicity in the variations, then these are called α Cyg stars as discussed above. LBVs also have eruptions of 0.5–2 mag on a time-scale of years to decades, and giant eruptions on the time-scale of a millennium, η Car being the best known, most spectacular example of this.

© Astronomical Society of the Pacific 2000

- WOLF–RAYET STARS which show non-periodic variations with amplitudes of the order of 0.02 mag caused by variable winds and possibly by rotation.
- Non-periodic, long-time-scale light variable Oe and Be stars known as γ Cas stars which are in addition to the periodic Be stars (λ Eri stars) mentioned previously. They range from spectral type O6 to B9 and through luminosity classes V to III. Their light variations are caused by variable winds.
- α^2 CVn stars which are magnetic stars with spots associated with their magnetic poles. These spots are seen from varying aspect as the stars rotate, causing photometric variability with the rotation period. The amplitudes are typically a few hundredths up to (rarely) a few tenths of a magnitude.

In general, there is an exclusion between the CP stars and the pulsating δ Sct stars. But there are some CP stars that do pulsate! The diffusion hypothesis is the favored explanation for this. It also has important implications in many other fields of stellar astrophysics.

The diffusion hypothesis

There is no universally accepted model that explains all of the observed characteristics of the CP stars. Models involving anomalous atmospheres, nucleosynthesis and dredging, surface spallation, magnetic accretion, planetesimal impacts, binary mass transfer and element separation (diffusion) have all been tried with varying success. The most successful model, the *diffusion hypothesis*, is the working model of choice for the majority of investigators.

The idea is simple in principle: if there are layers in a star which are stable against turbulent mixing, then elements heavier than H will tend to sink gravitationally, unless they have many absorption lines near the local flux maximum, in which case the asymmetry in the flux arising from the temperature gradient will mean that ions absorb more radiation from below than above, hence are radiatively driven towards the surface. These two competing effects can cause some elements to sink and other to rise, thus producing peculiar atmospheric abundances.

In the CP stars the diffusion hypothesis accounts for:

- Overabundances of the Fe peak, rare earth and lanthanide elements: these elements, which are principally in their neutral and first-ionized states, have many absorption lines near the flux maximum, hence they are driven upwards to the surface layer.
- Underabundances of Ca, Sc, C, He in Am stars: the principal atmospheric ionization states of Ca and Sc are Ca III and Sc IV which leave each of these elements, numbers 20 and 21, with 18 electrons so that they are in closed electronic shell configurations similar to Ar. With tightly bound electrons the absorption lines have high excitation potentials, hence lie in the UV where there is insufficient flux to levitate these ions. Thus they sink and are deficient.
- Isotopic ratios of Hg in HgMn stars: there are seven observable isotopes of Hg in the HgMn stars—196, 198, 199, 200, 201, 202 and 204—which show drastically different abundances from the terrestrial mixture, and which show large variation from star to star. Radiative levitation preferentially lifts the less abundant isotopes to the surface. Because their lines are less saturated, they absorb more flux per ion than the more abundant isotopes, and thus the isotopic ratios are altered. This same effect is seen in the He^3/He^4 ratio embedded in Moon rocks from the solar wind. He^3 is preferentially driven off the Sun in the solar wind because its lines are less saturated than the more abundant He^4.
- Ages of CP stars: calculations indicate that diffusion can produce observable anomalies in 10^6 years, the age of the youngest Am stars.
- Disappearance of anomalies in RED GIANTS with CP precursors: all models of CP stars can account for this, because it is known that the abundance anomalies must be confined to a thin atmospheric layer. One strong demonstration of this is the overabundance of some rare earths and lanthanides in Ap stars by a factor of 10^4–10^5. More than one in a hundred thousand stars is a member of this group. Hence, if the abundance anomalies were global, the Ap stars would contain almost all the rare earths and lanthanides in the universe, a clear absurdity. In all models, the growing depth of the surface convection layer with age, as stars move to the right in the HR diagram towards the zone of completely convective stars, leads to mixing away of the surface anomalies.
- Slow rotation in Am and Ap stars: A-type stars may show equatorial rotational velocities up to $v_{\rm eq}\sin i \approx$ 250–300 km s^{-1}, whereas Am stars have $v_{\rm eq}\sin i \leq$ 125 km s^{-1} and Ap stars have $v_{\rm eq}\sin i \leq 100$ km s^{-1}, although for the latter $v_{\rm eq}\sin i \leq 10$ km s^{-1} is not unusual. Rotation generates meridional circulation currents which flow faster with higher $v_{\rm eq}\sin i$. At some value of $v_{\rm eq}\sin i$ they become turbulent; that value is calculated to be about 50–100 km s^{-1}, in good agreement with the observations. The resultant turbulent mixing inhibits diffusion.
- Binary nature of Am stars: nearly 100% of Am stars are BINARY STARS with $1 \leq P_{\rm orbital} \leq 10$ days. Tidal synchronism locks the rotational and orbital periods and slows the rotation. A 2-$R_\odot$ star rotating with a period of 1 day has $v_{\rm eq}\sin i \approx 100$ km s^{-1}. Binary stars with $P_{\rm orbital} < 1$ day rotate too quickly; those with $P_{\rm orbital} > 10$ days do not become rotationally synchronized, thus tending to rotate too quickly.
- Magnetic braking of Ap stars: The very low rotational velocities of the Ap stars are considered to be the result of magnetic braking.
- Concentration of elements in spots near the magnetic poles in Ap stars: Ap stars have 'spots' or 'rings' of overabundant elements near their magnetic poles. Diffusion is thought to concentrate certain elements

© Astronomical Society of the Pacific 2000

in these regions, perhaps because quadrupole magnetic field components may produce magnetic loops arranged in rings which halt radiative levitation and trap rising elements.

- Near-exclusion of CP and δ Sct stars: about 30% of the stars in the lower instability strip are δ Sct stars. Most of the non-pulsating stars in this part of the instability strip are Am and Ap stars. Only a few Am and Ap stars pulsate, and it is a strength of diffusion theory that it can explain this: in stable A- and early F-star atmospheres helium settles gravitationally. This shuts off the κ-mechanism operating in the He II ionization zone which drives δ Sct pulsation.

There are problems for the diffusion hypothesis in CP stars:

- Diffusion is at best semi-quantitative. Calculated diffusion velocities are very low—only 10^{-4} to 1 cm s^{-1}. Hence stars must be stable to turbulence at that level in the diffusive layers.
- Pulsation in peculiar stars which do pulsate must be laminar; i.e. it must not mix away the anomalies. In a few cases this demands no turbulence with pulsation velocities of the order of 10 km s^{-1}.
- The odd–even effect in abundances is apparent in Ap and Am stars. Opponents of the diffusion hypothesis say this argues for a partial role for nucleosynthesis. Proponents say diffusion does not erase completely the initial abundance patterns.

Thus, while the diffusion hypothesis is the most popular working model for the CP stars, it must be remembered that it has some weaknesses which are yet to be dealt with. That diffusion acts in CP stars is reasonably accepted; whether it is sufficient to explain all the peculiarities, or whether other mechanisms are working as well is still to be determined.

In other stars diffusion can also be important:

- WHITE DWARF STARS (see also DB PULSATING STARS) are layered by gravitational settling.
- The gravitational settling of He is an important part of the 'Standard Solar Model' changing the internal solar temperature gradient enough to decrease the calculated neutrino production rate by 7%. Helium and some metal settling have also been included in calculations of Li and Be mixing in the Sun.
- Gravitational settling of He in older stars converts gravitational potential energy to thermal energy, increasing core temperatures and nuclear reaction rates, hence shortening stellar lifetimes. This could possibly reduce GLOBULAR CLUSTER ages by 1–4 Gyr, a significant amount in the on-going cosmological conflict of low Hubble time, H_0^{-1}, and high stellar age from globular cluster evolutionary tracks.
- Gravitational settling also partially accounts for the Li-gap in F stars.

Thus the CP stars of the upper main sequence are the best laboratory in which to test diffusion theory which has many applications is stellar astronomy. The pulsating stars are being mined for rich asteroseismic information about stellar structure, and the small group of stars that are both peculiar and pulsate are providing particularly stringent tests of theory, plus a unique look at the interaction of stellar pulsation and strong magnetic fields.

Puppis

(the Poop or Stern; abbrev. Pup, gen. Puppis; area 673 sq. deg.) A southern constellation which lies between Canis Major and Vela, and culminates at midnight in early January. It was introduced by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2, from stars that formed part of the ancient constellation of Argo Navis (the Ship), which had been included by Ptolemy (*c*. AD 100–175) in the *Almagest*.

The brightest stars in Puppis are ζ Puppis (Naos), magnitude 2.2, π Puppis, magnitude 2.7, and τ Puppis, magnitude 2.9. There are seven other stars brighter than fourth magnitude, including σ Puppis, a double star with orange (K5) and yellow (G5) components, magnitudes 3.3 and 8.6, separation 22.3″, the former of which has an unseen companion which revolves around it in about 258 days. An interesting binary star is k Puppis (HR 2948–2949), which has two bluish-white (B5) components, magnitudes 4.5 and 4.7, separation 9.9″. Other interesting stars include L^2 Puppis, a semiregular variable (range 2.6–6.2, period about 140 days), and V Puppis, an eclipsing binary (range 4.4–4.9, period 1.45 days).

The Milky Way passes through Puppis and the constellation contains a number of open clusters, the brightest of which are M46 (NGC 2437), which has more than 150 stars fainter than eighth magnitude, M47 (NGC 2422), which has a few dozen stars, the brightest of magnitude 5.7, M93 (NGC 2447), which consists of about 80 stars fainter than eighth magnitude, and NGC 2477, which has about 300 stars fainter than ninth magnitude.

Purple Mountain Observatory

The Purple Mountain Observatory was built in 1934. It is situated on the Purple mountain in the eastern suburb of Nanjing, China.

At present it is engaged in the research of astrophysics, celestial mechanics, radio astronomy, space astronomy and practical astronomy. The programs consist of solar physics, stellar physics, planetary science, high-energy astrophysics, orbital theory of artificial satellites, etc.

The observatory has a staff of about 300 people, and has three observing stations outside Nanjing. A 13.7 m millimeter wave telescope was set up at the Qinghai station.

Pushchino Radio Astronomy Observatory

The Pushchino Radio Astronomy Observatory is 120 km south of Moscow. The staff consists of 45 astronomers and 42 engineers, supported by the Russian Academy of Sciences, Ministry of Sciences and Russian Foundation for Basic Research.

The most sensitive meter-wavelength radiotelescopes BSA and DKR-1000, as well as the 22 m dish of the Observatory are used for studies of galaxies, pulsars, interstellar and interplanetary plasma.

Discoveries and studies of Geminga's and Magnetar's (SGR1900+14) pulse radio emission are among the achivements of the last two years.

Pythagoras of Samos (*c*. 580–*c*. 500 BC)

Mathematician, born in Samos, Ionia, taught by Thales and Anaximander on Miletus, founded a philosophical and religious school in Croton (in southern Italy) whose members, as well as having various beliefs that we would recognize as religious, believed that at its deepest level, reality is mathematical in nature. Pythagoras observed that vibrating strings produce harmonious tones when the ratios of the lengths of the strings are whole numbers, and proved *Pythagoras's theorem*, and other geometrical theorems. In astronomy Pythagoras taught that the Earth was a sphere at the centre of the universe, and is credited as the first to realize that Venus as an evening star (Hesperus) was the same planet as Venus as a morning star (Phosphorus).

Pyxis

(the Compass; abbrev. Pyx, gen. Pyxidis; area 221 sq. deg.) A southern constellation which lies between Puppis and Antlia, and culminates at midnight in early February. It was introduced as Pyxis Nautica (the Mariner's Compass) by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2, from stars that formed the mast of the ancient constellation of Argo Navis (the Ship), but its name fell into disuse until resurrected in its shortened form by the American astronomer Benjamin A Gould (1824–96) in 1879. The shortened form was adopted by the IAU in 1922.

A small, inconspicuous constellation, the brightest stars in Pyxis are α Pyxidis, magnitude 3.7, β Pyxidis, magnitude 4.0, and γ Pyxidis, also magnitude 4.0. Interesting objects include T Pyxidis, a recurrent nova (range 7.0–15.8), which is normally about fourteenth magnitude but flared up to seventh to eighth magnitude in 1890, 1902, 1920, 1944 and 1966–7, and NGC 2818, an open cluster of about 40 stars fainter than eleventh magnitude which contains a twelfth-magnitude planetary nebula (PK261 + 08.1).

Quadrantids

A meteor shower that takes place in early January. It is one of the most prolific, with a peak zenithal hourly rate of 120 in a short, sharp maximum of about 12 hours. The brightest meteors show a blue or yellow-green tinge. The radiant lies in the constellation Boötes, near its border with Hercules. The shower is named after the obsolete constellation Quadrans Muralis (the Mural Quadrant) which used to occupy this region. Perturbations of the meteor stream by Jupiter cause it to oscillate up and down through the ecliptic; the current phase of Quadrantid activity began in the 1700s and will last until the 2200s.

Quantum Gravity

GENERAL RELATIVITY and QUANTUM MECHANICS are among the greatest intellectual achievements of the twentieth century. Quantum gravity is the theory that is being sought to unify them.

Each of the two theories has profoundly altered our understanding of the physical world. Furthermore, each has been successful in describing the physical phenomena in its own domain to an astonishing degree of accuracy. And yet they offer strikingly different pictures of physical reality. The world of general relativity is geometric, marked by precision and certainty. The world of quantum mechanics is fuzzy, marked by chance and uncertainty. Physicists can happily maintain a schizophrenic attitude and switch between the two because the natural domains of the two theories are distinct: while general relativity governs astrophysical and cosmological phenomena, quantum mechanics governs atomic and subatomic ones. But there do exist situations which straddle the two, in particular near the BIG BANG and the final stages of gravitational collapse. More importantly, everything in our past experience with physics tells us that such strikingly different descriptions of nature cannot both be fundamental. Since neither encompasses the other, they must both be special cases of a single, grander theory.

The search for this grander theory has therefore become a holy grail of theoretical physics. Indeed, some of the most distinguished personalities of this century have devoted many years of work to it. These include Peter Bergmann, Paul Dirac, Richard Feynman, Stephen Hawking, Roger Penrose, John Wheeler and Edward Witten, to mention just a few. The search for the theory began in the 1930s in the writings of Rosenfeld. However, the area remained dormant till the late 1950s. From then on, there has been a steady increase in activity. Over the last 10 years, this activity has intensified many fold. In particular, striking advances have occurred within two approaches. While the final theory still eludes us, many intriguing and suggestive results have been obtained which have provided glimpses of the desired theory. Therefore, there is now a heightened sense of optimism, enthusiasm and rapid progress in the field.

Why has the problem been so difficult? The most important obstacle has been the complete lack of experimental data with direct bearing on quantum gravity. The situation is thus very different from the evolution of quantum mechanics where the theory could be guided at critical junctures by masses of accumulated data from spectroscopy, radioactivity and solid state physics. But there also are, in addition, deep conceptual difficulties. Einstein taught us that gravity is a manifestation of curvature of SPACE-TIME. Unlike other forces of nature, gravity is geometry. A quantum theory of gravity is thus simultaneously a quantum theory of space-time structure. Therefore, in quantum gravity, geometry itself has to be subject to uncertainties, probabilities and fuzziness. Suddenly, the familiar arena of physics is no more and a host of fundamental questions arise. What happens to causality? To geodesics along which particles and lights rays travel? To differential equations obeyed by the electromagnetic waves? In short, how does one do physics without the familiar space and time?

Key issues

Although these difficulties seem enormous, we also have a number of hints. The first two come from the intrinsic limitations of the two theories themselves.

In the mid-1960s, Penrose, Hawking and others showed that Einstein's equations of general relativity themselves signal the limitation of the theory. More precisely, even if one begins with physically reasonable initial conditions, the resulting solutions to Einstein's equations often lead to singularities, regions in space-time where the gravitational field and other physical quantities become infinite. The theory predicts 'non-sense'. This is typically what happens when a theory is pushed beyond its domain of applicability. In the case under consideration, as the curvature of space-time increases, quantum effects which are ignored in the equations of general relativity are expected to become more and more important and make physical quantities finite. The challenge is to show that this does indeed happen.

Quantum field theory—the theory that results by unifying quantum mechanics with principles of SPECIAL RELATIVITY—also has its own limitations. Calculations of physical quantities often lead to infinities. These arise because one has to allow virtual processes of arbitrarily high energies, or equivalently, because the calculations of physical quantities involve integration over arbitrarily small distances. Thus, their origin can be traced back to the assumption that the continuum picture holds at arbitrarily small scales. From the very early days, it was conjectured by Planck, Heisenberg and others that the continuum hypothesis probably fails in the real world due to quantum gravity effects. This is because with the three fundamental constants of nature that quantum gravity would have—Newton's gravitational constant G, speed of light c and the Planck constant $\hbar$—one can construct a unique combination of length, $\ell_{\rm P} = \sqrt{G\hbar/c^3}$ whose numerical value is approximately 10^{-33} cm. This was noted by Planck in his seminal paper on quantum mechanics and $\ell_{\rm P}$ is now called the Planck length. The existence of a natural scale in a theory signals a transition; physics below that scale is generally quite different from that above the scale. It is widely believed that the familiar picture of space-time breaks down below Planck length. The quantum geometry effects become important. If they are ignored and the classical continuum approximation is pushed beyond the domain of its validity, one obtains infinities, i.e. non-sense. A satisfactory quantum gravity theory of gravity should be free of such infinities.

The clues provided by these limitations of the two theories have been valuable because they provide goals and general directions in the search of quantum

gravity. More concrete hints came from rather unexpected quarters in the early 1970s, namely the physics of BLACK HOLES. Through ingenious thought experiments, Jacob Bekenstein first pointed out that black holes can be assigned thermodynamic properties. This idea became more concrete in the work of James Bardeen, Brandon Carter and Stephen Hawking. They introduced a notion of 'surface gravity' κ of black holes, which is analogous to g on the surface of the Earth, and showed that within classical general relativity, black holes in equilibrium are subject to laws which are completely parallel to the standard laws of thermodynamics; a multiple of κ plays the role of temperature and a related multiple of the area A of the black hole horizon plays the role of entropy (see table).

Black hole mechanics	Thermodynamics
κ constant	T is constant
$\delta M = \dfrac{\kappa \delta A}{8\pi G}$	$\delta E = T \delta S$
$\delta A \geq 0$	$\delta S \geq 0$

However, within classical general relativity this could only be a mathematical analogy because, since black holes can only absorb energy, they must have zero physical temperature. This view changed dramatically with Hawking's discovery that, if quantum effects are included, black holes do in fact radiate due to the tunneling phenomenon and, furthermore, they do so exactly as if they were black bodies at temperature $T_{\rm bh} = \hbar\kappa/2\pi c$. The form of the first law of black hole mechanics then suggested that black holes carry an entropy $S_{\rm bh} = Ac^3/4G\hbar = A/\ell_{\rm p}^2$. Note that, as $\hbar$ goes to zero, $T_{\rm bh}$ tends to zero and $S_{\rm bh}$ tends to infinity as expected within classical general relativity. More importantly, subsequent and more detailed thought experiments by William Unruh, Robert Wald and others confirmed the precise expressions of $T_{\rm bh}$ and $S_{\rm bh}$.

These considerations led to concrete questions for potential quantum theories of gravity because Hawking's calculations included quantum matter but treated gravity classically. Indeed, the considerations outlined above contain an *ad hoc* mixture of classical and semiclassical ideas, reminiscent of the Bohr model of the hydrogen atom. However, because the final picture seems compelling and naturally brings together the three pillars of fundamental physics—general relativity, quantum mechanics and statistical mechanics—the general consensus is that the results must continue to hold for large black holes also in full quantum gravity. The challenge is to account for black hole thermodynamics from first principles.

Recent developments

The problem of quantum gravity has been approached from several directions. For examples, methods from quantum field theory which have been highly successful in the description of other forces of nature were adapted to general relativity by Feynman, Bryce De Witt and others. Unfortunately, the resulting theory has uncontrollable infinities. To cure these, theories with SUPERSYMMETRY—a new type of symmetry between bosons and fermions—were extended to include gravity. While some of the infinities were tamed by this process unfortunately, others continued to persist. Another avenue, developed by Hawking, James Hartle, Garry Gibbons and others, extends methods of quantum field theory in which the basic Green functions are first constructed in a four dimensional Euclidean space and the results are then used to calculate physical quantities of interest in the real, Lorentzian world. This approach was used especially in the cosmological context and also provided a unified description of black hole thermodynamics in the semiclassical regime. A completely new line of attack was adopted by Penrose and collaborators who developed twistor theory. Here, a four-dimensional complex space is regarded as fundamental and space-time emerges as a secondary, derived concept.

While these and other approaches have provided a wealth of insights, they are yet to address the key questions discussed above in a concrete fashion. However, over the past decade, two approaches have been successful in addressing some of these questions and have provided concrete directions to address the remaining ones. I will conclude with a brief summary of this work.

The first approach is STRING THEORY. Here, the basic objects are extended, rather than point-like. Historically, point particles were first replaced by strings. However, recent work has indicated that not only does one have to include higher dimensional objects—membranes—but, in a certain well-defined sense, all these objects are equally important. The fundamental theory is formulated in nine space dimensions. The three-dimensional space of our everyday experience arises because six of the dimensions are tiny and manifest themselves only at extremely small distances or in processes involving very high energies.

At present, string theory is still formulated on a background space-time geometry and the methods used are natural extensions of those developed in quantum field theory. However, because of the use of extended objects, there are fundamental differences from local quantum field theories such as supergravity. In particular, the so-called 'ultraviolet' infinities which arise in local field theories because of the integration over arbitrarily high energies are all absent. Even though the theory is not entirely free of divergences, taming of these ultraviolet infinities is a major triumph. Furthermore, there are situations in which the theory has been able to demonstrate how singularities of general relativity could be cured. More precisely, there exist space-times which are singular in general relativity but non-singular when embedded in string theory. In these situations, none of the physical quantities diverge in the 'fundamental theory' and infinities of general relativity can be seen as artifacts of the approximations in which one ignores the deeper structure.

Perhaps the most exciting contribution of string theory to the basic issues of quantum gravity lies in the domain of black hole thermodynamics. Specifically, for large black holes with electric charge near the maximum allowed value, there is a procedure to count the number of string microstates that can constitute the black hole. The logarithm of this number turns out to give precisely the Hawking–Bekenstein entropy of the black hole. Furthermore, when interactions between string states are included, one obtains the Hawking spectrum of black hole radiation.

The second approach that is addressing the key questions discussed above is based on a QUANTUM THEORY of geometry. Here, one takes the physical role of geometry as fundamental and begins by probing its quantum nature. In contrast to string theory, one works with three-dimensional space and the approach is manifestly background independent. Thus, to begin with, there is no classical space-time whatsoever; everything including geometry is treated quantum mechanically. A systematic mathematical and conceptual framework is introduced to substitute the standard one used in quantum theories of other forces.

Detailed analysis shows that the fundamental excitations of geometry are one-dimensional, rather like a polymer. The fabric of your shirt, for example, is woven by one-dimensional threads. However, for all practical purposes, the shirt appears to be a two-dimensional continuum. Similarly, the three-dimensional continuum of our everyday experience is 'woven' by the 'quantum threads' of geometry. More generally, smooth classical geometries arise from coarse graining of semiclassical, 'weave states'. In extreme circumstances, like those near the Big Bang and black hole singularities, the continuum picture breaks down and one must describe physics directly in terms of the fundamental one-dimensional excitations. Furthermore, in this theory, geometrical quantities such as lengths, areas and volumes are all quantized, i.e. can take on only discrete values. In the case of area, all of these permissible values are known explicitly. As one would expect, the elementary quanta are of the order of $\ell_{\rm P}^2$. But for large areas, the allowed discrete values crowd exponentially so that the continuum limit is reached very rapidly.

The questions raised by black hole thermodynamics have also been addressed in this approach. The microstates underlying a large black hole are now attributed to the quantum excitations of geometry itself. For non-rotating black holes, it is known that these microstates can account for the Hawking–Bekenstein entropy. (The restriction to the non-rotating case is only for technical simplicity and is not regarded as a fundamental limitation.) The Hawking process now corresponds to physical processes in which the quanta of area are converted to quanta of matter; the black hole shrinks as it emits radiation. Furthermore, somewhat surprisingly, the Hawking evaporation of *large* black holes provides a check on the details of predictions of quantum geometry. Specifically, the crowding of the eigenvalues found in the theory is essential for reproducing from first principles the black body spectrum found by Hawking using semiclassical methods.

Because of these successes, research in string theory and quantum geometry has intensified in recent years. (According to a survey by Carlo Rovelli, the number of quantum gravity publications in string theory is approximately three times that in the approach based on quantum geometry.) The strengths of the two approaches are complementary. In the analysis of black hole thermodynamics, for example, detailed calculations in string theory refer to black holes which are not of direct interest to astrophysics. Furthermore, by and large these calculations are performed in flat space and the relation of the microscopic degrees of freedom to the curved geometry of a black hole space-time is yet to become clear. The quantum geometry treatment encompasses black holes which are of interest to astrophysics and the relation to curved geometry is clear. However, in a certain well-defined sense, the quantum geometry treatment provides only an 'effective description' of a large black hole while the stringy description is 'fundamental' within that theory. In particular, string theory is much closer to addressing the issue of the final stages of black hole evaporation and the related 'information loss paradox'.

More generally, string theory has a natural built-in principle to specify the fundamental matter fields and their couplings. Over the last year, an interesting set of conjectures have emerged, pioneered by Juan Maldecena, which have allowed considerable flexibility in the choice of background space-times on which the theory is defined. But to be a satisfactory theory of quantum gravity, it would have to get rid of background dependence altogether. The approach based on quantum geometry is free of this problem. However, like general relativity, it has no principle to determine matter couplings. In the last two years, developments pioneered by Thomas Thiemann have led to considerable progress in formulating a quantum theory based on matter couplings taken from the standard model of particle physics. However, the issue of satisfactory quantum dynamics is yet to be settled. The two approaches seem to be complementary in many ways. Much progress would occur if in the coming years their strengths can be combined to overcome their present limitations.

Quantum Mechanics

A development of quantum theory that was initiated in the 1920s by Werner Heisenberg (1901–76) and Erwin Schrödinger (1887–1961). The theory drew on a proposal made in 1925 Prince Louis de Broglie (1892–1987), that particles have wavelike properties (the wave–particle duality) and that an electron, for example, could in some respects be regarded as a wave with a wavelength that depended on its momentum. In this new formulation, the permitted energy levels in the Bohr theory of the hydrogen atom corresponded to electron orbits into which integral numbers of electron wavelengths could fit. For example, the lowest level (the lowest energy level of the Bohr atom) contains exactly one wavelength, the second level two, and so on. Thus, the discrete orbits and energy states of the atom followed as direct consequences of the wave properties of electrons.

Schrödinger developed a formulation of quantum mechanics, known as wave mechanics, in which an orbiting electron is treated as a standing wave, represented by a 'wavefunction', which is described by the Schrödinger wave equation (an equivalent formulation, based on matrices, was developed by Heisenberg). In accordance with the Heisenberg uncertainty principle, which implies that it is not possible to determine, simultaneously, the position and velocity of an electron, the wavefunction gives only the probability that an electron is in a particular state, or at a particular point at a particular time. Therefore, Bohr's precise orbits are replaced by a set of more fuzzy 'orbitals' within which electrons of a particular energy will lie.

The quantum state of an electron (or other subatomic particle) is defined by a set of numbers (quantum numbers) that specify quantities such as energy, angular momentum and spin and which are associated with solutions to the wave equation. Each energy level within an atom corresponds to a unique set of quantum numbers and various selection rules determine which transitions between levels, and hence which spectral lines, are permitted.

Quantum Theory

A theory based on the premise that, on the microscopic scale, physical quantities have discrete, rather than a continuous range of, values. The theory was devised in the early part of the twentieth century to account for certain phenomena that could not be explained by classical physics. In 1900, the German physicist, Max Planck (1858–1947), was able precisely to describe the previously unexplained distribution of energy radiated by a black body by proposing that light, and other forms of electromagnetic radiation, exist in the form of discrete 'packets' of energy called quanta (singular: 'quantum'). The energy (E) of a quantum of electromagnetic radiation is directly proportional to the frequency (f) of the radiation and inversely proportional to its wavelength (λ); thus, $E = hf = hc/\lambda$, where h is a constant of proportionality, called Planck's constant (or the Planck constant), and c denotes the speed of light. The value of the Planck constant is 6.63×10^{-34} J s.

In 1905, Albert Einstein (1879–1955) used the concept of quanta to explain the photoelectric effect, a phenomenon whereby certain substances will emit electrons when illuminated by light of a sufficiently short wavelength. Einstein showed that, because a certain minimum amount of energy has to be imparted to an electron in order for it to be ejected, the emission of electrons would only take place if the incoming light consisted of quanta (or 'photons') with energies above that minimum and, therefore, wavelengths shorter than a particular value.

In 1913, Danish physicist Neils Bohr (1885–1962) extended the quantum hypothesis to matter as well as radiation by proposing that electrons in atoms could have only certain particular values of energy, values that were simple multiples of the Planck constant. While an electron was in one of the permitted energy states it could remain in orbit around the atomic nucleus without radiating energy (this was in marked contrast to classical theory, according to which an orbiting electron would radiate continuously, lose energy and spiral in towards the nucleus). If an electron were to drop down to a lower level, it would radiate a photon with a particular energy (and hence a particular wavelength) equal to the energy difference between the two permitted levels. Bohr's theory gave very good agreement with the observed wavelengths of the various lines in the spectrum of the element hydrogen. Further development of the theory led to the suggestion that the angular momenta of orbiting electrons were restricted to integer multiples of $h/2\pi$ and to the idea that the electron itself had an intrinsic spin (as if it were a tiny sphere rotating around its axis) of magnitude $h/4\pi$. The precise quantum state of an electron (or other subatomic particle) is defined by a set of numbers (quantum numbers) that specify quantities such as energy, angular momentum and spin.

A more comprehensive, and deeper, version of the theory, called quantum mechanics, was developed during the 1920s. Nowadays, quantum theory embraces practically all aspects of microscopic physics.

Quark

A fundamental particle that joins with others to form hadrons (baryons and mesons).

There are six varieties, or 'flavors', of quark, each of which has an equivalent antiparticle. The six flavors, in order of increasing mass, are called up, down, strange, charm, bottom, and top. Quarks possess fractional charge (i.e. they carry an electrical charge that is a simple fraction of the charge on the electron) and have half-integer values of spin. For example, an up quark (symbol 'u') carries a charge of $+\frac{2}{3}$ and an anti-up ($\bar{u}$), $-\frac{2}{3}$; a down quark (d) carries a charge of $-\frac{1}{3}$ and an anti-down ($\bar{d}$), $+\frac{1}{3}$. Quarks join together in clusters of three to form baryons, such as protons and neutrons, and as quark–antiquark pairs to form mesons. For example, a proton consists of two ups and a down (net charge: $+\frac{2}{3} + \frac{2}{3} - \frac{1}{3} = +1$) and an antiproton of two anti-ups and an anti-down (net charge: $-\frac{2}{3} - \frac{2}{3} + \frac{1}{3} = -1$); a neutron consists of two downs and an up (net charge $-\frac{1}{3} - \frac{1}{3} + \frac{2}{3} = 0$), and so on. A neutral pion (pi-meson) consists of an up and an anti-up ($u\bar{u}$) or a down and an anti-down ($d\bar{d}$), a positive pion of an up and an anti-down ($u\bar{d}$), and so on. Of the six flavors of quark, only the up and down quarks are needed to make the nucleons (the building blocks of atomic nuclei) and pions, the other varieties being required to construct some of the many short-lived particles that are found among cosmic rays and created in high-energy particle accelerators.

Six leptons are associated with the six quarks in three families, or 'generations': the electron and electron-neutrino with the up and down quarks (first generation); the muon and muon-neutrino with the charm and strange quarks (second generation); and the tau and tau-neutrino with the top and bottom quarks (third generation).

In addition to electrical charge, quarks possess another property, called 'color', which in some respects is analogous to electrical charge. There are three types of color (called red, blue, and yellow by analogy with the primary colors), each of which can be positive or negative. As with electrical charge, positive and negative colors attract; but, in addition, different colors attract and like colors repel. In a hadron (a particle that consists of quarks), the net color has to be neutral (or 'white'). This can be achieved either by combining three different colored quarks to make a baryon, or by linking a quark with an antiquark (in which case the opposite color charges neutralize each other) to form a meson. The interaction between the color charges, which is the believed to be the underlying source of the strong nuclear force, is described by a theory called quantum chromodynamics. The strong (color) force is conveyed between bound quarks by force-carrying particles called gluons and is so powerful that, at least to the limits of present-day experiments, individual quarks cannot be ejected from within hadrons.

In the present-day universe, quarks exist only inside hadrons, not as free particles. However, during the very high-energy phase of the very early universe (during the first 10^{-6} s), free quarks would have been abundant.

Quasar

An extragalactic object (one that lies well beyond the confines of our own Galaxy) that has a very small angular size, but which has a high redshift. Because the first objects of this kind to be discovered, in the early 1960s, were radio sources that coincided in appearance with what looked like stars, they were called 'quasi-stellar radio sources', a name that was then abbreviated to quasar. Although it was shown subsequently that only about 10% of objects of this kind were actually strong radio emitters, and the more general term, 'quasi-stellar object' (QSO) was invoked to include the radio-quiet versions, in practice, the term 'quasar' is widely used to describe both kinds of object.

The spectrum of a quasar typically displays emission lines superimposed on a non-thermal (non-stellar) continuous spectrum (continuum). The redshifts of the lines in quasar spectra range from 0.06 to around 5, these values of redshift corresponding to velocities of recession ranging from about 6% to about 95% of the speed of light. If, as is generally accepted, the redshifts imply that quasars are remote objects that are receding because, like conventional galaxies, they are participating in the general expansion of the universe in accordance with the Hubble law, then they must all lie at very great distances. To appear as bright as they do, despite their very great distances, their luminosities must range from about a hundred to about ten thousand times greater than that of a conventional galaxy like the Milky Way (the implied luminosities are in the range 10^{39}–10^{41} watts). Many quasars vary substantially in brightness (by factors of up to 10, or even more in exceptional cases) over periods of time as short as months or even days. This implies that most of their energy is emitted from regions of space that are very small, in some cases less than a light-day in diameter.

Since the 1980s a number of quasars have been shown to be surrounded by faint fuzzy patches of light. The spectra of these 'fuzzy blobs' contain stellar-type absorption lines, consistent with the idea that quasars are embedded within remote galaxies. In addition, studies of quasars that appear to lie within clusters of galaxies have shown that they have the same redshifts as those clusters, consistent with their being located at very great distances. Furthermore, quasars share similar characteristics to active galactic nuclei in general. They radiate strongly over a wide range of wavelengths, have a non-thermal spectrum, display short-term variability, are compact and highly luminous and, in some cases, appear to be emitting jets and blobs of material. In light of this evidence, astronomers (with a few notable exceptions) are convinced that a quasar is an extremely brilliant active galactic nucleus, so remote and so highly luminous compared with the galaxy within which it is embedded that, in most cases, only the compact nucleus can be seen.

As with other active galactic nuclei, the energy source within a quasar is widely believed to be a supermassive black hole that is accreting matter from its surroundings. The broad emission lines in a quasar's spectrum are believed to originate in heated gas clouds revolving around the central black hole at speeds of up to several thousand kilometers per second.

Quasiperiodic Oscillations in X-ray Binaries

The term quasiperiodic oscillation (QPO) is used in high-energy astrophysics for any type of non-periodic variability that is constrained to a relatively narrow range of variability frequencies. X-RAY BINARIES are systems in which a 'compact object', either a BLACK HOLE or a NEUTRON STAR, orbits a normal star and captures matter from it. The matter spirals down to the compact object and heats up to temperatures of 10^7 K, which leads to the emission of x-rays. Such systems therefore provide ways of obtaining information about black holes and neutron stars that cannot be obtained in any other way, as the basic process taking place in them involves matter in close orbit around such a compact object. QPOs are an important diagnostic of these flows of matter in x-ray binaries. They are usually studied by calculating power spectra of a time series of, most commonly, x-ray flux samples by means of the Fourier transform. In such a power spectrum, the QPO shows up as a peak of finite width centered around the oscillation frequency (see figures 1 and 3). If the peak is too narrow, such as in the case of PULSARS, the signal is called periodic instead of quasiperiodic, and if the peak is too broad (conventionally, if its full width at half-maximum is broader than half its centroid frequency) the feature is usally called a 'noise' feature. There is no sharp physical distinction between QPO and noise features, and they are discussed together here. Two important classes of noise are 'power-law noise', which shows up in the power spectrum as a power law and thus has no measured associated time scale, and 'band-limited noise', which steepens towards higher frequency above some break or cut-off frequency $\nu_{\rm break}$.

A variety of processes can produce a similar power-spectral peak. Often the statistical quality of the data is insufficient to see the QPO directly in the time series. Then, it can only be detected by calculating the average power spectrum of a large amount of data. The exact signal causing a given power-spectral QPO peak then remains unknown. Popular examples of signals in the time series that may explain the QPO peaks observed in the power spectra of x-ray binaries are oscillating-shot signals, essentially a superposition of many short-lived oscillations, and frequency-modulated signals, which are oscillations whose frequency varies on a time scale much longer than the oscillation period.

The presence of short-lived 'clumps' of matter orbiting the central object at some preferred radius in the ACCRETION DISK and producing a QPO with a frequency equal to the Keplerian orbital frequency corresponding to that radius may be the most popular explanation for QPOs in x-ray binaries (see the section on models). However, as several different types of QPO are observed, several different models are required. Most QPO phenomena increase in frequency when the accretion rate increases; in Keplerian models this implies the orbits come closer with increasing mass accretion rate. From KEPLER'S LAWS, the closest possible orbits around neutron stars and stellar-mass black holes could have periods as short as 0.5 ms, and from the beginning astronomers have searched for QPOs with frequencies in the corresponding kilohertz domain. Only very recently have such QPOs been found (see the section on the current era). Their exploitation for the study of strong-field general-relativistic effects and the basic properties of neutron stars and black holes has only just begun.

History: the discoveries with EXOSAT and Ginga

Early reports of QPOs in x-ray binaries included observations with the Japanese Hakucho satellite of ∼2 Hz oscillations during bursts of the Rapid Burster and with the European Space Agency's EXOSAT of 0.7–20 mHz QPOs in Cygnus X-3. Both of these objects are unique, very peculiar x-ray binaries. The discoveries of two different QPO phenomena (the 15–60 Hz 'horizontal branch oscillation' and the 6–20 Hz 'normal–flaring branch oscillation', or HBO and NFBO; figure 1) with EXOSAT in the brightest low-mass x-ray binaries (LMXBs) during 1985–1987 were the first which had sufficiently suggestive properties to lead to an appreciable body of interpretative work. In particular, the relatively high frequencies of these oscillations suggested an origin connected in some way with the inner accretion flow, where the characteristic time scales are short.

By the early 1990s, the magnetospheric beat frequency model, in which the oscillations occur as a result of a quasiperiodic modulation of the accretion rate caused by an interaction between the inner accretion disk and the magnetic field of a rapidly spinning neutron star remained as a prominent, although not universally accepted, model for the HBO. The radiative-feedback model, where a radiation-force-driven instability quasiperiodically modulates the optical depth of an approximately radial, near-Eddington accretion flow and thus causes the oscillations by variations in the radiative transfer through this flow, enjoyed a similar status for the NFBO. Studies of correlated changes of the x-ray spectrum and the power spectrum of accreting low-magnetic-field neutron stars in LMXBs led to a subdivision into two groups, named, after the characteristic shapes of the tracks they trace out in x-ray color–color diagrams, the 'Z sources' and the 'atoll sources' (figure 1). In such diagrams, the x-ray 'colors' or spectral hardnesses in two different photon energy bands are plotted versus each other. The tracks in these diagrams are usually quite repeatable in shape (less so in the position in the diagram) and are traced out over and over again on time scales of hours to days. Sources in both groups were found to show several 'source states' characterized by their x-ray spectral and power-spectral properties; the transitions between these states are gradual and occur with intervals of hours to many days. The HBO and the NFBO were observed in the Z sources only; common to both source types were two broad power-spectral components, a power-law noise component called very-low-frequency noise, dominating the power spectra

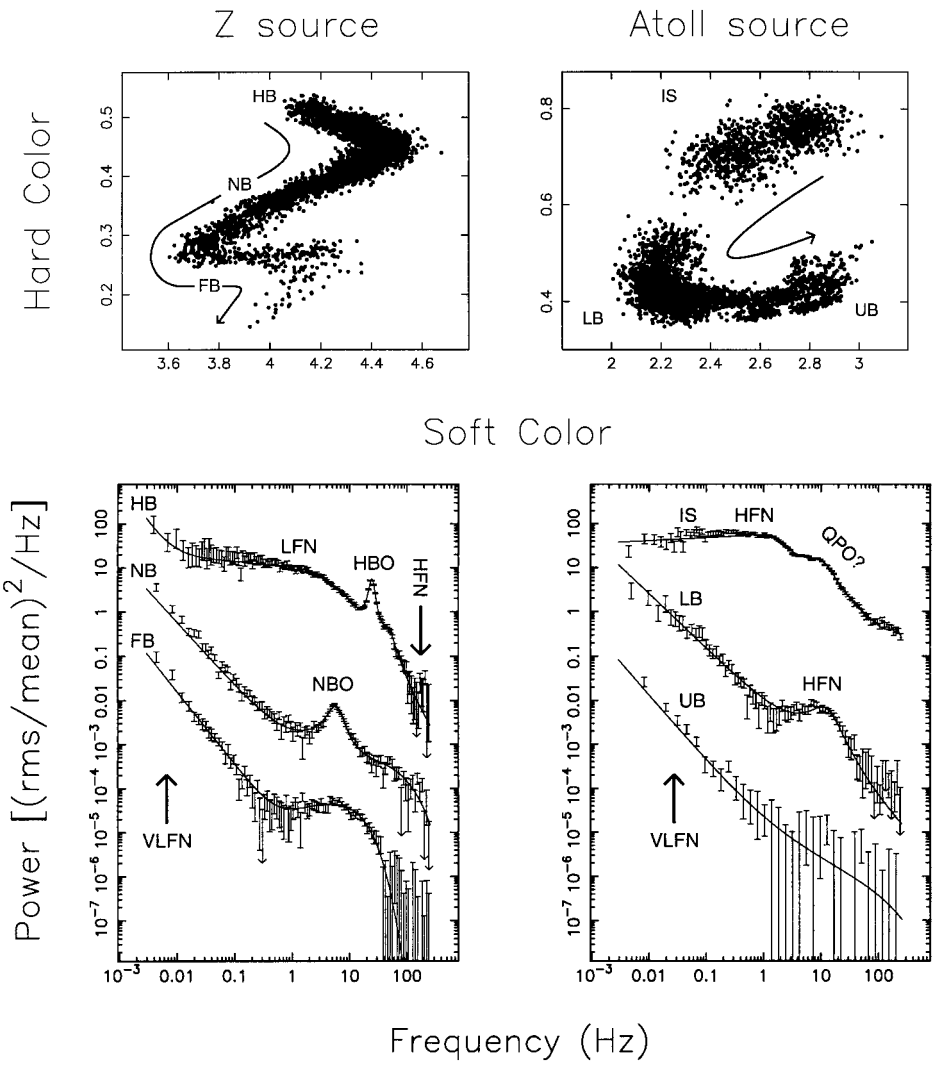

Figure 1. X-ray color–color diagrams (top) and power spectra (bottom) of Z and atoll sources. Top: the soft and hard colors represent the x-ray spectral hardness in the 3–6 and 6–10 keV photon energy bands, respectively. Arrows indicate the sense in which $\dot{M}$ is inferred to increase along each track. The various source states as they appear in the color–color diagram, horizontal branch, normal branch, flaring branch, island, lower banana and upper banana are indicated as HB, NB, FB, IS, LB and UB, respectively. Bottom: typical power spectra are displayed for each of the source states identified in the color–color diagrams. The various power spectral noise (very-low-frequency noise, low-frequency noise and high-frequency noise; VLFN, LFN and HFN) and QPO (horizontal branch oscillation, normal branch oscillation; HBO and NBO) components are indicated. Despite its name, the HFN in the atoll sources is probably similar to the LFN in Z sources.

below ∼1 Hz, and a band-limited noise component called either low- or high- frequency noise, with $\nu_{\rm break}$ typically between 0.1 and several tens of Hz. All these variability phenomena vary in their properties, often monotonically, along the tracks in the color–color diagram. The position of a source in its track was therefore interpreted as a measure of its instantaneous accretion rate, $\dot{M}$; this interpretation implied that x-ray count rates in the usual photon energy bands (e.g. 2–20 keV) are not proportional to $\dot{M}$; it is even possible for the count rate to rise when $\dot{M}$ drops.

Observations with the GINGA satellite in the years 1987–1991 led to a much clearer view of the correlated x-ray spectral and power-spectral properties of the black hole candidates (BHCs), which turned out to be in many ways very reminiscent of those of the (neutron-star) atoll sources. The source states in BHCs were called, in order of increasing inferred $\dot{M}$, the low state, high state and very high state. In the very high state clear 3–10 Hz QPO were seen that are perhaps related to some of the QPOs seen in the Z sources. In the low state the power spectra are dominated by a band-limited noise component similar to that seen in the atoll sources. The break frequency is variable between 0.03 and 1 Hz and correlated with inferred $\dot{M}$. In the high state very little power is observed.

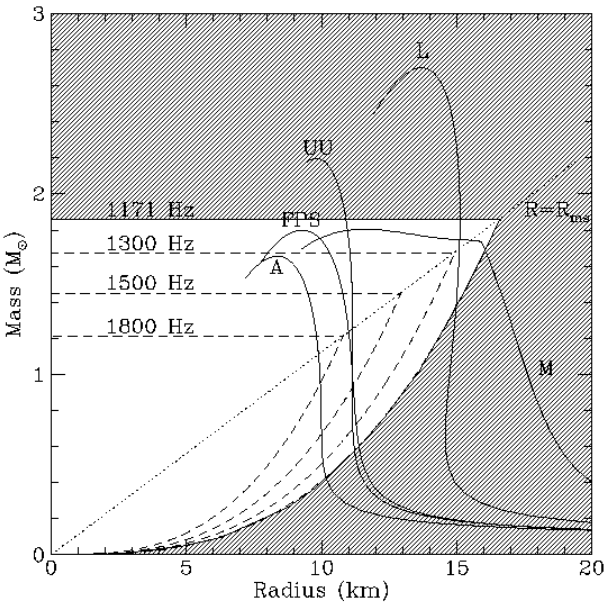

Figure 2. Mass–radius diagram of neutron stars. The curves labeled A, FPS, UU, L and M represent neutron-star mass–radius relations for various different assumed equations of state of high-density matter. The shaded area is the region that can be excluded if orbital motion takes place around the neutron star at a frequency of 1171 Hz, as suggested by observed kHz QPO frequencies. For higher observed frequencies, larger areas can be excluded as indicated. The currently highest measured kHz QPO frequency is 1228 Hz. Adapted from Miller *et al* (1998).

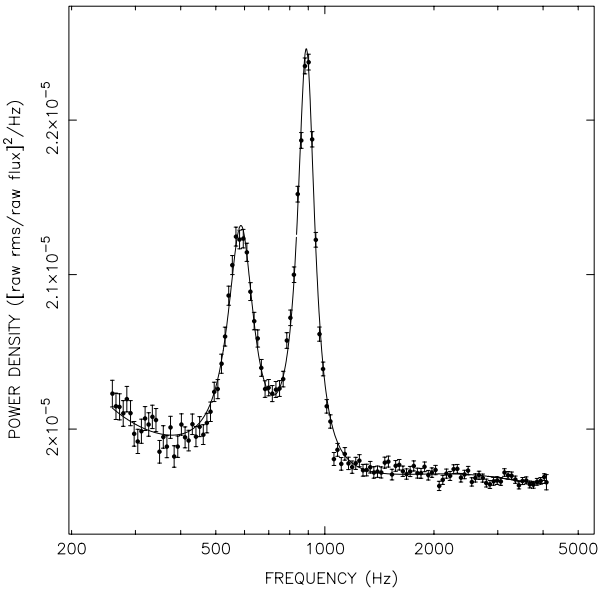

Figure 3. Power spectrum of the Z source Scorpius X-1 showing the twin kHz QPOs.

In the very high state a band-limited noise component reappears with $\nu_{\rm break}$ between 1 and 10 Hz. Later, an intermediate state was identified that fits between the low and high states and has properties similar to those of the very high state.

The current era: RXTE

Launched on 30 December 1995, the ROSSI X-RAY TIMING EXPLORER (RXTE) satellite provided the latest, and largest, upswing in our knowledge of QPO phenomena in x-ray binaries. It seems likely that for the first time we are detecting signals from the bottom of the gravitational potential wells of neutron stars and BHCs related to the orbital motion of matter very close around the compact objects. In these regions, space–time is strongly curved and strong-field general relativity is required to describe the motion of matter. Indeed, interpretations involving strong-field general-relativistic effects are being debated extensively with respect to the newly discovered phenomena. The inferred orbits are so close that they directly constrain the density of the central neutron star, and thus the compressibility (i.e. the equation of state) of the supranuclear-density matter of which they are composed (figure 2).

In both Z and atoll sources, the long-predicted phenomena on millisecond and submillisecond time scales were found at last. Surprisingly, these phenomena are in the form of often quite narrow QPO peaks with frequencies up to about 1200 Hz that come in pairs, the 'twin kHz QPOs' (figure 3). It seems likely that one of these peaks is caused by the orbital motion at the inner edge of the accretion disk. In x-ray bursts of several atoll sources a different type of oscillation was discovered, with a frequency, near constant in each source, between 290 and 590 Hz, that was interpreted as due to the neutron-star spin. RXTE also finally, after a search of nearly 20 yr, found the first accreting millisecond pulsar, which, at a spin frequency of 401 Hz, supports the interpretation of the burst oscillations as being due to the neutron-star spin. More importantly, this discovery provides the first direct confirmation of the evolutionary ideas about the origin of the millisecond radio pulsars.

QPOs at frequencies of a few tens of Hz in atoll sources evident in the RXTE data may be similar to Z source HBOs. QPOs found in two BHCs stand out as perhaps different and possibly related to each other: the 67 Hz QPO in GRS 1915 + 105, which seems to always occur at the same frequency, and the 300 Hz QPO in GRO J1655 − 40, the highest-frequency QPO in a BHC so far. These QPOs may be related to some basic property of accretion onto a black hole of given mass and spin, such as the orbital, Lense–Thirring or apsidal motion frequency near the general-relativistic innermost stable orbit.

Models

Beat-frequency models have played a central part in interpretations of QPO phenomena observed in accreting neutron stars. In such models, there is an interaction between the spin of the neutron star and the orbital

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

motion at some preferred radius in the accretion disk which produces a third phenomenon, the beat, which has a frequency ν_B that is equal to the difference between the neutron-star spin frequency ν_S and the orbital frequency in the disk ν_D according to the relation $\nu_B = \nu_D - \nu_S$. No signal is generated at the sum of these frequencies because the interacting frequencies are those of two angular motions that take place in the same sense (a sum frequency would be observed if the neutron-star spin was in the opposite sense to the orbital motion in the disk, a situation which because of angular-momentum transfer from the disk to the star cannot persist for a long time).

Two mechanisms have been worked out to provide the spin–orbit interaction in a way that would lead to observable QPO phenomena. In the magnetospheric beat-frequency model the accretion of matter from short-lived clumps of plasma in the inner accretion disk is modulated by electromagnetic interactions with the neutron-star magnetic field, which spins with the spin of the neutron star. In this model the preferred disk radius at which we observe the Keplerian orbital frequency is the radius of the magnetosphere. This model has been used to explain the 15–55 Hz HBO in Z sources as due to the beat between the (unobserved) disk orbital and neutron-star spin frequencies, and to explain much slower QPO phenomena that are seen in some accreting x-ray pulsars with periods of $1–10^2$ s, but has also been discussed as a possible explanation of the kHz QPOs. In the sonic-point beat-frequency model the preferred radius in the disk is located at the sonic point, where the disk flow becomes radially supersonic owing to either general-relativistic effects or interaction of the accretion flow with the emerging radiation. This model has been proposed for the twin kHz QPO peaks, where the higher frequency of the twin QPO peaks would be at ν_D and the lower-frequency one at ν_B.

The spin frequency of the neutron stars in some of the twin kHz QPO sources as deduced from the burst oscillations is found to be close to the frequency difference between the two kHz peaks in the same source, in accordance with such a spin–orbit beat-frequency model. However, several discrepancies between the predicted and observed frequencies have emerged since the model was proposed, and it is clear that any spin–orbit beat-frequency model for the twin kHz QPOs cannot be as straightforward as was initially believed. Other models relying on various kinds of hydrodynamic or radiation–hydrodynamic accretion–flow instabilities are also being explored.

Since the discovery of the kHz QPOs, which from their high frequencies probably originate very close to the compact objects, general-relativistic effects have played an increasingly prominent role in the attempts at interpretation of all QPOs. It has been proposed that Z source HBOs and related QPOs in atoll sources are due to Lense–Thirring precession of the inner accretion disk, and evidence has been mounting that the kHz QPO frequencies, which increase in each given source with mass accretion rate, reach a maximum value near ∼1200 Hz. If this is because the orbits corresponding to this frequency are near the general-relativistic innermost stable orbit (at $6GM/c^2$ with small corrections for frame dragging due to the spin of the neutron star), then neutron-star masses near 2 $M_\odot$ are derived for the neutron stars in low-mass x-ray binaries. It so far remains a mystery why 1200 Hz is reached in different sources at luminosities that differ by factors of up to several 100. Lense–Thirring precession of orbits around near-maximally rotating black holes has also been speculated to explain the 67 and 300 Hz QPOs in GRS 1915 + 105 and GRO J1655 − 40. Finally, a model has been proposed where the lower frequency of the twin kHz QPO is due to general-relativistic apsidal motion. In particular, in the case of the neutron stars where HBO, burst QPO and twin kHz QPOs are all seen in a single source, the data can constrain models of this type very well, and a shake-out among these models can be foreseen when data accumulates.

With the discovery of the kHz QPOs, the historical goal of obtaining diagnostic information about the motion of matter at the bottom of the gravitational well of stellar-mass compact objects from high-time-resolution x-ray data appears to have been reached. Future work, requiring much larger-area instruments than even RXTE, will probably concentrate on mapping out space–time in these regions in detail by precisely reconstructing the orbits of matter in these regions.

Quasistellar Objects: Intervening Absorption Lines

Every parcel of gas along the line of sight to a distant QUASAR will selectively absorb certain wavelengths of continuum light of the quasar due to the presence of the various chemical elements in the gas. Through the analysis of these quasar absorption lines we can study the spatial distributions, motions, chemical enrichment and ionization histories of gaseous structures from REDSHIFT five until the present. This includes the GAS IN GALAXIES of all morphological types as well as the diffuse gas in the INTERGALACTIC MEDIUM.

Basics of quasar spectra

Figure 1 illustrates many of the common features of a quasar spectrum. The relatively flat quasar continuum and broad emission features are produced by the quasar itself (near the black hole and its accretion disk). In some cases, gas near the quasar central engine also produces 'intrinsic' absorption lines, most notably Ly α, and relatively high ionization metal transitions such as C IV, N V, and O VI. These intrinsic absorption lines can be broad (thousands or even tens of thousands of km s^{-1} in which case the quasar is called a broad absorption line (BAL) QSO; see QUASISTELLAR OBJECTS: INTRINSIC AGN ABSORPTION LINES), or narrow (tens to hundreds of km s^{-1}). However, the vast majority of absorption lines in a typical quasar spectrum are 'intervening', produced by gas unrelated to the quasar that is located along the line of sight between the quasar and the Earth.

A structure along the line of sight to the quasar can be described by its neutral hydrogen column density, N(H I), the number of atoms per cm^2. N(H I) is given by the product of the density of the material and the pathlength along the line of sight through the gas. Each structure will produce an absorption line in the quasar spectrum at a wavelength of $\lambda_{\rm obs} = \lambda_{\rm rest}(1 + z_{\rm abs})$, where $z_{\rm abs}$ is the redshift of the absorbing gas and $\lambda_{\rm rest} = 1215.67$ Å is the rest wavelength of the Ly α transition. Since $z_{\rm abs} < z_{\rm QSO}$, the redshift of the quasar, these Ly α absorption lines form a 'forest' at wavelengths blueward of the Ly α emission. The region redward of the Ly α emission will be populated only by absorption through other chemical transitions with longer $\lambda_{\rm rest}$. Historically, absorption systems with N(H I) $< 10^{17.2}$ cm^{-2} have been called LYMAN ALPHA FOREST lines, those with $10^{17.2} < N$(H I) $< 10^{20.3}$ cm^{-2} are Lyman limit systems, and those with N(H I) $> 10^{20.3}$ cm^{-2} are damped Ly α systems (see LYMAN ALPHA ABSORPTION: THE DAMPED SYSTEMS).

The number of systems per unit redshift increases dramatically with decreasing column density, as illustrated in the schematic diagram in figure 2. Lyman limit systems are defined by a sharp break in the spectrum due to absorption of photons capable of ionizing H I, i.e. those with energies greater than 13.6 eV. The optical depth, τ, of the break is given by the product N(H I)σ, where the cross section for ionization of hydrogen, $\sigma = 6.3\times10^{-18}(E_\gamma/13.6\,{\rm eV})^{-3}\,{\rm cm}^2$, (and the flux is reduced by the factor $e^{-\tau}$). The energy dependence of σ leads to a recovery of the Lyman limit break at higher energies (shorter wavelengths), unless N(H I) $\gg 10^{17.2}$ cm^{-2} (see figure 1).

The curve of growth describes the relationship between the equivalent width of an absorption line, W (the integral of the normalized profile), and its column density, N. Figure 3 shows that for small N(H I) the number of absorbed photons, and therefore the flux removed, increases in direct proportion to the number of atoms. This is called the linear part of the curve of growth. As N is increased, the line saturates so that photons are only absorbed in the wings of the lines; in this regime the equivalent width is sensitive to the amount of line broadening (characterized by the Doppler parameter b), but does not depend very strongly on N(H I). This is the flat part of the curve of growth. Finally, at N(H I) $> 10^{20.3}$ cm^{-2}, there are enough atoms that the damping wings of the line become populated and the equivalent width increases as the square root of N(H I), and is no longer sensitive to b.

In addition to the Ly α (1s $\rightarrow$ 2p) and higher-order (1s $\rightarrow$ np) Lyman series lines, quasar spectra also show absorption due to different ionization states of the various species of metals. Figure 1 illustrates that the damped Ly α system at $z = 0.86$ that is responsible for the Ly α absorption line at $\lambda_{\rm obs} = 2260$ Å and a Lyman limit break at $\lambda_{\rm obs} = 1700$ Å also produces absorption at $\lambda_{\rm obs} = 2870$ Å due to the presence of C IV in the absorbing gas at that same redshift. Like many of the strongest metal lines seen in quasar spectra, C IV is a resonant doublet transition due to transitions from $^2S_{1/2}$ energy levels to the $^2P_{1/2}$ and to the $^2P_{3/2}$ energy levels. (The left superscript '2' represents the number of orientations of the electron spin, the letter S or P represents the total orbital angular momentum, L, and the right subscript represents the total angular momentum, J.) Doublet transitions are easy to identify. The dichotomy between rest wavelength and redshift is resolved because the observed wavelength separation of the doublet members increases as $1+z$. Table 1 lists some of the metal lines that are commonly detected for intervening absorption systems. Many of these are only strong enough to be observable for quasar lines of sight that pass through the higher N(H I) regions of galaxies.

History, surveys and revolutionary progress in the 1990s

The history of quasar absorption lines began within a couple of years of the identification of the first quasar in 1963. In 1965, Gunn and Peterson considered the detection of flux blueward of the Ly α emission line in the quasar 3C 9, observed by Schmidt, and derived a limit on the amount of neutral hydrogen that could be present in intergalactic space. In that same year, Bahcall and Salpeter predicted that intervening material should produce observable discrete absorption features in quasar spectra. Such features were detected in 1967 in the quasar PKS 0237 $-$ 23 by Greenstein and Schmidt, and in 1968 in

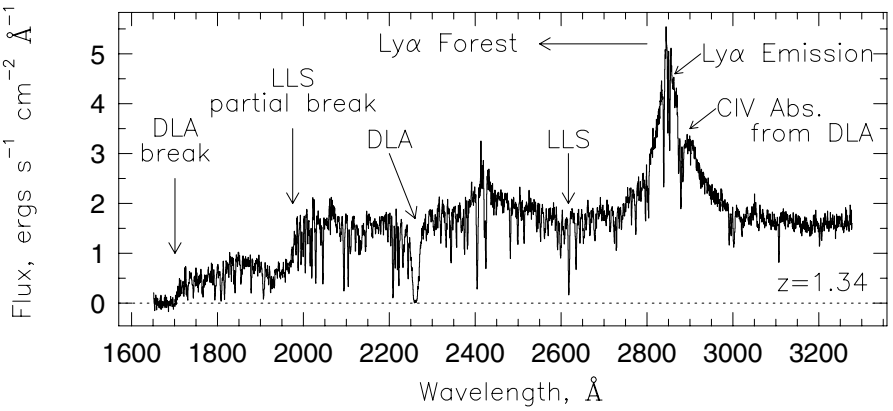

Figure 1. Typical spectrum of a quasar, showing the quasar continuum and emission lines, and the absorption lines produced by galaxies and intergalactic material that lie between the quasar and the observer. This spectrum of the $z = 1.34$ quasar PKS0454 + 039 was obtained with the Faint Object Spectrograph on the Hubble Space Telescope. The emission lines at $\sim$ 2400 Å and $\sim$2850 Å are Ly β and Ly α. The Ly α forest absorption, produced by various intergalactic clouds, is apparent at wavelengths blueward of the Ly α emission line. The two strongest absorbers, due to galaxies, are a damped Ly α absorber at $z = 0.86$ and a Lyman limit system at $z = 1.15$. The former produces a Lyman limit break at $\sim$1700 Å and the latter a partial Lyman limit break at $\sim$1950 Å since the neutral hydrogen column density is not large enough for it to absorb all ionizing photons. Many absorption lines are produced by the damped Ly α system at $z = 0.86$ (C IV $\lambda\lambda$1548, 1550, for example, is redshifted onto the red wing of the quasar's Ly α emission line).

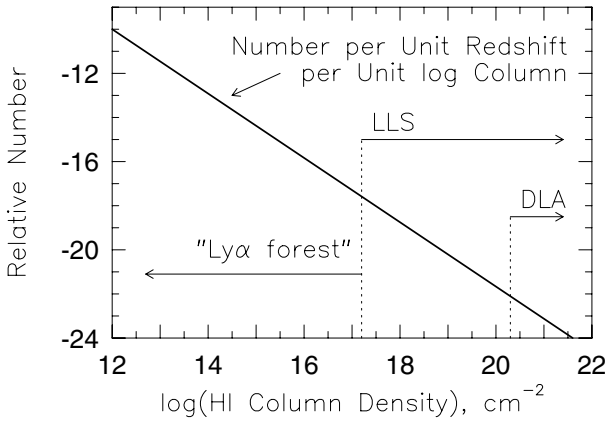

Figure 2. The column density distribution of Ly α clouds, $f(N(\mathrm{H\,I}))$, roughly follows a power law over ten orders of magnitude; there are many more weak lines than strong lines. The column density regions for the three categories of systems are shown: Ly α forest, Lyman limit, and damped Ly α. The term 'Ly α forest' has at times been used to refer to metal-free hydrogen clouds, perhaps those with $N(\mathrm{H\,I}) < 10^{16}$ cm^{-2}, but now metals have been found associated with weaker systems down to the detection limit.

Table 1. Common transitions.

Transition	λ_{rest} (Å)
LL	$\sim$912
Ly γ	972.537
Ly β	1025.722
Ly α	1215.670
Si IV 1393	1393.755
Si IV 1402	1402.770
C IV 1548	1548.195
C IV 1550	1550.770
Fe II 2382	2382.765
Fe II 2600	2600.173
Mg II 2796	2796.352
Mg II 2803	2803.531

PHL 938 by Burbidge, Lynds and Stockton. By 1969 many intervening systems had been discovered, and Bahcall and Spitzer proposed that most with metals were produced by the haloes of normal galaxies. As more data accumulated, the sheer number of Ly α forest lines strongly supported the idea that galactic and intergalactic gas, and not only material intrinsic to the quasar, is the source of most quasar absorption lines.

In the 1980s many more quasar spectra were obtained and many large statistical surveys of the different classes of absorption line systems were published. The emphasis was on characterizing the number of lines per unit redshift, $\mathrm{d}N/\mathrm{d}z$, stronger than some specified equivalent width limit. With 4 m class telescopes (equipped with charge coupled device (CCD) detectors) it was possible to conduct surveys with a spectral resolution of $R \sim 1000$. The spectral resolution is defined as $R = \lambda/\Delta\lambda = c/\Delta v$, so that $R = 1000$ corresponds to 300 km s^{-1} or 5 Å at $\lambda = 5000$ Å. Separate surveys were conducted for Ly α lines, Mg II doublets, C IV doublets, and also for Lyman limit breaks, all as a function of redshift. The Ly α line is observable in the optical part of the spectrum for $z > 2.2$, Mg II for $0.4 < z < 2.2$, C IV for $1.7 < z < 5.0$, and the Lyman limit break for $z > 3$. However, a break is also easily identified in lower-resolution space-based UV spectra, which extended Lyman limit surveys to lower redshift.

In order to consider the cross section of the sky

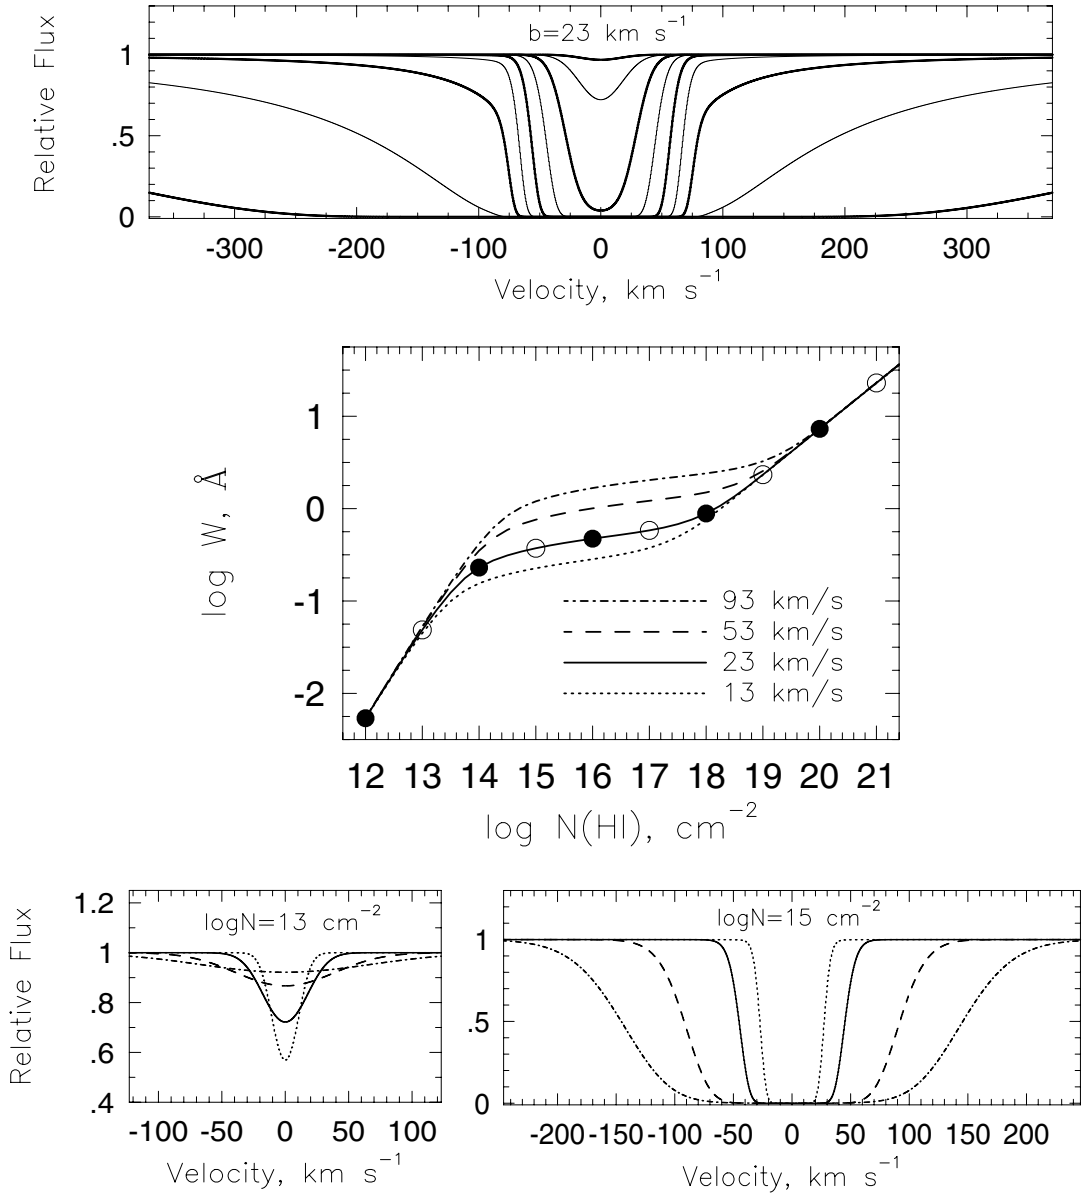

Figure 3. Illustration of the different regimes of the curve of growth. The middle panel shows the curve of growth for the Ly α transition, relating the equivalent width, W, of the absorption profile to the column density, N(H I). The different curves represent four different values of the Doppler parameter: $b = 13$, 23, 53 and 93 km s^{-1}. The upper panel shows absorption profiles with Doppler parameter $b = 23$ km s^{-1} for the series of neutral hydrogen column densities N(H I) = 10^{12}–10^{20} cm^{-2}. The thick (thin) curves correspond to the full (open) points on the $b = 23$ km s^{-1} curve of growth (middle panel), starting at N(H I) = 10^{12} cm^{-2}. For N(H I) < 10^{13} cm^{-2}, known as the linear part of the curve of growth, the equivalent width does not depend on b. The lower left panel shows that, at fixed N(H I), the depth of the profile is smaller for large b, such that the equivalent width remains constant. On the flat part of the curve of growth, profiles are saturated and the equivalent width increases with b for constant N(H I). For N(H I) > 10^{20} cm^{-2}, the profile develops damping wings, which dominate the equivalent width.

covered by the different populations, it can be assumed that absorption will be observed for all lines of sight within some radius of every luminous galaxy (>0.05L_K^*). (L_K^* represents the Schechter luminosity, i.e. the transition between the exponential and the power law forms of the luminosity function, and corresponds to a K-band absolute magnitude of $M_K = -25$.) To explain the observed dN/dz at $z \sim 1.5$, this radius would be 70 kpc for strong C IV (detection sensitivity 0.4 Å), and 40 kpc for strong Mg II (detection sensitivity 0.3 Å) and also for Lyman limit systems, implying that the latter two populations are in fact produced in the same gas. The higher N(H I) damped

Ly α absorbers would be produced within 15 kpc of the center of each galaxy, while the Ly α forest lines would require a considerably larger region, hundreds of kpcs around each galaxy, to produce a cross section consistent with the observed number of weak lines.

Up until the 1990s, the focus of quasar absorption line work was to separately consider the properties of the individual classes of absorbers (e.g. Ly α forest or Mg II absorbers). In the 1990s, however, three different observational advances led to recognition of the direct connections between the different classes of quasar absorption lines, and of direct associations with the population of galaxies:

(a) Deep images of quasar fields could be obtained, and redshifts of the galaxies in the field could be determined from low-resolution spectra. Steidel found that whenever Mg II absorption with $W_r(\text{Mg II}) > 0.3$ Å is observed, a luminous galaxy ($L_K > 0.06L_K^*$) is found within an impact parameter of 38 h^{-1} $(L/L_K^*)^{-0.15}$ kpc with a redshift coincident with that determined from the absorption lines. Also, it is rare to find a galaxy within this impact parameter that does not produce Mg II absorption. There appears to be a one-to-one correspondence between strong Mg II absorption and luminous galaxies. The Mg II absorbing galaxies span a range of morphological types.

(b) The High Resolution Spectrograph on the Keck I 10 m telescope made it possible to obtain quasar spectra at a resolution of $R = 45\,000$, which corresponds to $\sim$6 km s^{-1}. Previous surveys with a resolution of the order of hundreds of km s^{-1} identified absorption due to entire galaxies and their environments. With 6 km s^{-1} resolution it became possible to resolve structure within a galaxy: the clouds in its halo, the interstellar medium of its disk, and the satellites and infalling gas clouds in its environment. Figure 4 is a dramatic illustration of this contrast for the Mg II absorber at $z = 0.93$ toward the quasar PG 1206+459.

(c) The Faint Object Spectrograph (FOS) on the Hubble Space Telescope provided resolution $R \sim 1000$ in the UV, from 1400–3300 Å. Observations of Ly α forest clouds could be extended from $z = 2.2$ down to the present epoch. Furthermore, absorption from a given galaxy could be observed in numerous transitions; if Mg II was observed in the optical, the Lyman series and C IV could be studied in the UV (see figure 4). With information on transitions with a range of ionization states, consideration of the degree of ionization (related to the gas density and the intensity and shape of the ionizing radiation field) and the multiple phase structure of galactic gas became possible.

No longer is analysis of absorption lines in quasar spectra an esoteric subject. It has developed into a powerful tool to be used in the study of GALAXY EVOLUTION (e.g. similar to imaging the stellar components of the galaxies). At least in principle, quasar spectra can be used for an unbiased study of the gaseous environments of galaxies from the present back to the highest redshifts at which quasars are observed. Gas structures smaller than $1M_\odot$ can be detected if they are intercepted by the quasar line of sight, irrespective of whether they emit light. Through the tool of quasar absorption lines, protogalactic structures and low surface brightness galaxies can be studied as well as high-luminosity galaxies.

Developing physical intuition

With high-resolution spectra of quasars, it is possible to consider the physical conditions of the gaseous structures that produce absorption. However, it is challenging to separate the various effects that 'shape' the spectral features in the different chemical transitions. The absorption profiles observed for the different chemical transitions are determined by a combination of the spatial distribution of material along the line of sight, its bulk kinematics, temperature, metallicity and abundance pattern. The ionization structure is influenced by gas densities and by the UV radiation field, which is a combination of the extragalactic background radiation due to the accumulated effect of quasars and stellar photons escaped from galaxies (and corrected for absorption by the intergalactic medium).

The shape of an absorption line can be modeled with a Voigt profile, which is a combination of the natural, quantum mechanical Lorentzian broadening and the Gaussian broadening caused by the thermal and turbulent motions in the gas. Several Voigt profiles can be blended together to form an overall complex absorption feature (see figure 4). The 'width' of a single Voigt profile is characterized by the Doppler parameter, b (expressed in velocity units and related to the Gaussian σ by $b = 2^{1/2}\sigma$). Physically, the Doppler parameter is the sum of thermal and turbulent components, $b_{\text{tot}}^2 = 2kT/m + b_{\text{turb}}^2$, where T is the temperature of the gas, and m is the mass of an atom.

Kinematic models

Two of the simplest types of organized kinematics in galaxies are illustrated in figure 5: clouds distributed in a rotating disk, and radial infall of clouds in a spherical distribution. Here, Mg II absorbers are used as an example, but the same kinematic arguments would apply to other transitions. For radial infall, clouds can be distributed over the range of velocities, with a tendency for a 'double peak' from material that is redshifted and blueshifted but with a considerable amount of variation if there are typically several discrete clouds along the line of sight. A rotating disk with a vertical velocity dispersion characteristic of a spiral galaxy disk (10–20 km s^{-1}) will have clouds superimposed in velocity space, and an overall kinematic spread of tens of km s^{-1}. Strong Mg II absorption has been found to arise along nearly all lines of within $\sim$40 kpc of normal galaxies (i.e. the covering factor is nearly unity within that radius). The large variety of kinematics evident in Mg II absorption profiles is, in fact, consistent with a superposition of disk and radial infall (halo) motions, and not with just one or the other. In addition to these simple, toy models, insights can be gleaned by passing lines of sight through the structures in cosmological N-body/hydrodynamic simulations. In a few studies, metals

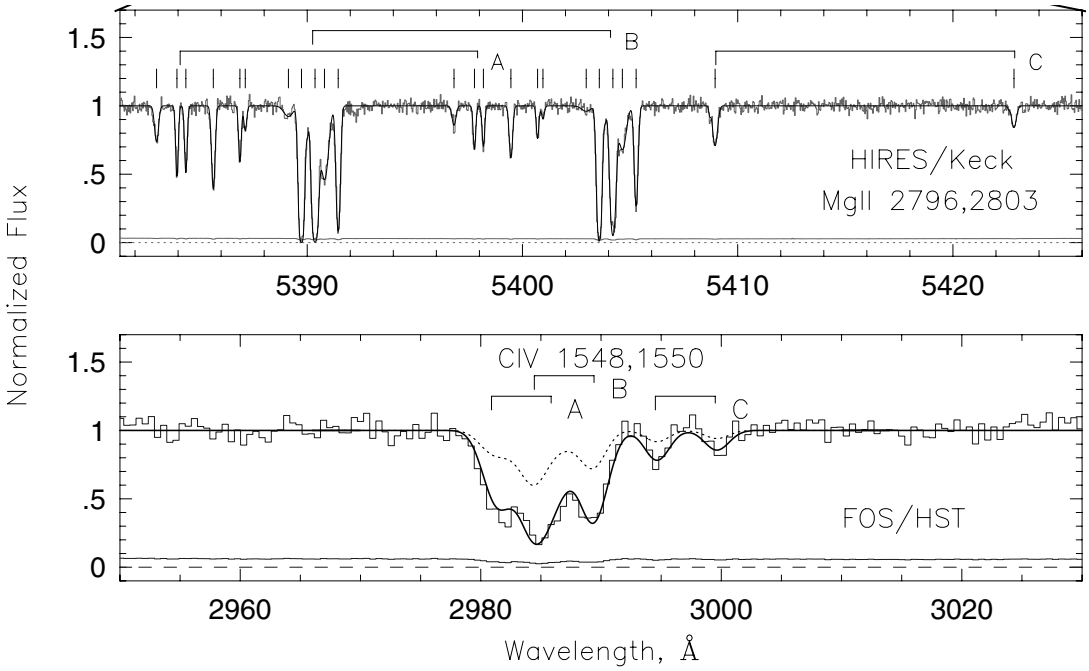

Figure 4. Dramatic demonstration of gains due to high-resolution spectroscopy of the Mg II doublet. The top panel is an $R = 3000$ spectrum of PG1206 + 459. The doublet that is apparent at an observed wavelength of ∼5400 Å is due to Mg II absorption from a system at $z = 0.927$. The middle panel shows the remarkable kinematic structure that is revealed at the resolution ($R = 45\,000$) of the Keck/HIRES spectrograph of the same quasar. The 2796 Å transition is resolved into multiple components (5583–5592 Å), which also appear in the 2803 Å transition (5396–5406 Å). This system can be separated in two 'clusters' of clouds, labeled 'A' and 'B'. Another weaker Mg II doublet is observed at 5409 and 5423 Å, from a system at $z = 0.934$ Å, labeled with a 'C'. The solid line through these complex Mg II profiles is the result of multiple Voigt profile fitting, with a cloud centered on each of the ticks drawn above the spectrum. The lower panel shows the C IV doublets associated with the same three systems, observed with the Faint Object Spectrograph on HST, but at much lower resolution ($R = 1300$). The C IV is in three different concentrations around the three systems 'A', 'B' and 'C'. The C IVλ1550 transition from system A is blended with the C IVλ1548 transition from system B. The C IV equivalent width is too large for this absorption to be produced by the same phase of gas that produces the Mg II cloud absorption. The maximum absorption that can arise in the Mg II phase is given by the dotted line; a plausible model with a kinematically broader C IV phase yields the solid curve.

have been added uniformly throughout the simulation box and photoionization models used to predict the absorption expected from different structures. This is especially important for establishing the kinematics that would be observed from the process of structure formation at high redshifts.

Photoionization models

Consider a cloud of material, modeled by a plane parallel slab with a certain total column density of hydrogen, $N(\mathrm{H}) = N(\mathrm{H\,I}) + N(\mathrm{H\,II})$, and with a constant total number density $n_{\mathrm{H}} = n(\mathrm{H\,I}) + n(\mathrm{H\,II})$ along the line of sight. The cloud is also characterized by its metallicity, Z, which is the ratio of Fe/H expressed relative to the solar value, $Z_{\odot}$, and by an abundance pattern (the abundance ratios of all other elements to Fe). The degree of ionization in the gas depends upon the intensity and shape of the spectrum of ionizing radiation. The intensity is characterized by the ionization parameter, $U = n_{\gamma}/n_{\mathrm{H}}$, which is the ratio of the number density of photons at the Lyman edge to the number density of hydrogen ($n_{\mathrm{H}} = n_e$, where n_e is the total number density of electrons). The larger the value of U, the more ionized the gas. Collisional ionization can also be an important process for some absorption systems with gas at high temperatures (hundreds of thousands of degrees). Photoionization equilibrium models typically yield temperatures of tens of thousands of degrees.

Once the metallicity, abundance pattern, ionization parameter and spectral shape are specified the equations of RADIATIVE TRANSFER can be solved to find the column densities of all the different ionization states of various chemical elements. Figure 6 illustrates, for $N(\mathrm{H\,I}) = 10^{16}$ and 10^{19} cm^{-2}, the dependence of column densities of various transitions on the ionization parameter, U. For optically thin gas ($N(\mathrm{H\,I}) < 10^{17.2}$ cm^{-2}), the column density ratios of the various metal transitions are not dependent on the overall metallicity, i.e. the curves shift vertically in proportion to Z. For optically thick gas, ionization structure develops, with an outer ionized layer around a neutral core, and there is no simple scaling relation with metallicity.

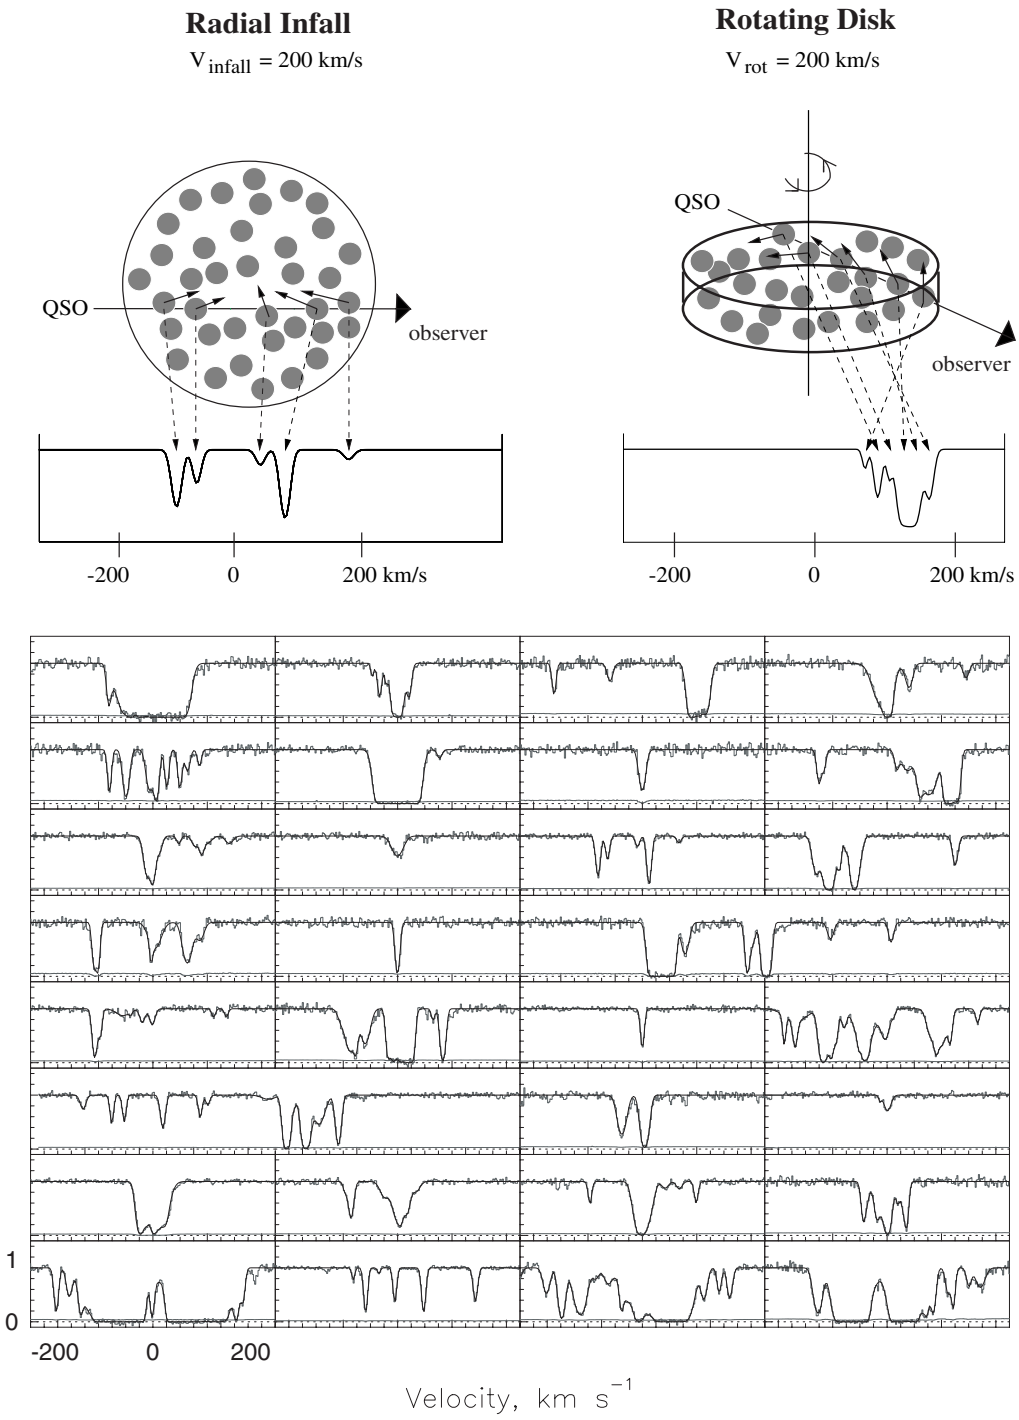

Figure 5. Illustrations of two simple kinematic models are shown in the top panel. To the left, the model is radial infall of clouds to the center of a sphere, with constant velocity. The line of sight passes through five clouds, which leads to five different absorption features (for a single transition) in the quasar spectrum. Two of the features are blueshifted relative to the standard of rest of the absorbing galaxy, and the other three are redshifted. The absorption features from a radial infall model can be spread over a velocity of 100–200 km s^{-1}, typical of the velocity dispersion of a galaxy halo. To the right, a rotating disk model is illustrated. In this case all the 'clouds' along the line of sight have a component of motion that is redshifted, and they tend to be clustered together in velocity space, with a typical spread of 20–60 km s^{-1}. The lower panel shows a sample of $0.4 < z < 1.4$ Mg II absorption profiles observed with the Keck/HIRES spectrograph at $R = 45\,000$, corresponding to a resolution of ∼6 km s^{-1}. The solid lines through these data are Voigt profile fits and the ticks drawn above the spectrum represent the cloud velocities. Some of these profiles are consistent with the kinematics of a rotating disk, and others with radial infall kinematics. However, to explain the full ensemble of profiles a model combining these two basic types of kinematics is needed.

In practice, if we assume that a cloud has a simple, single phase structure, the ratios of the column densities can be used to infer the ionization parameter, which relates to the density of the gas. However, the abundance pattern can differ from the solar abundance pattern because of differing degrees of depletion onto dust, or because of different processing histories. Most of the so-called α particle nuclei (such as Mg and Si) are synthesized primarily by Type II SUPERNOVAE during the early history of a galaxy when most massive stars form and quickly evolve to reach their end states. On the other hand, the Fe group elements are primarily produced by Type Ia supernovae, and therefore build up over a longer timescale. In the basic picture of galactic evolution, the halo stars are formed early, have been enriched only by Type II supernova, and therefore are α-element enhanced. Younger disk stars have also incorporated the Type Ia processed material and therefore have relatively larger Fe group abundances. Ideally, several different ionization states of the same chemical element are observed so that there is no ambiguity between the ionization parameter and the abundance pattern, but this has generally not yet been possible because of limited wavelength coverage at high resolution.

Examples of the variation of column density ratios with velocity in two absorption systems are shown in figures 7 and 8. In figure 7, N(Fe II)/N(Mg II) varies by an order of magnitude over the four components in the $z = 1.325$ system toward the quasar Q0117 + 213. This represents a variation of an order of magnitude in the ionization parameter ($10^{-4} < U < 10^{-3}$), or an order of magnitude variation in the abundance pattern. Figure 8 is a very unusual system with two clouds separated by only 20 km s^{-1} in velocity, one of which has a silicon to aluminum ratio similar to the Milky Way ISM, and the other which requires a significant enhancement of aluminum.

Multiphase conditions

The gaseous component of the the Milky Way and nearby galaxies has a phase structure (i.e. spatial locations with different densities and/or temperatures). Examples are the disk/halo interface (galactic coronas) and the cold, warm and hot phases of the interstellar medium. From photoionization models, it is not usually possible to generate absorption that is simultaneously consistent with all observed chemical transitions for a given system. For example, in single cloud Mg II systems, figure 6 (with N(H I) = 10^{16} cm^{-2}) shows that if Fe II is detected at a similar column density to Mg II, the ionization parameter must be small, and W_r(C IV) cannot be large. Many systems have C IV absorption which exceeds this limit and requires a higher ionization (lower density) phase; generally, this phase must have structure over a large velocity range (a large 'effective' Doppler parameter). The $z = 0.93$ system toward the quasar PG 1206+459 is another case that requires multiphase structure. The observed C IV profile in figure 4 is much too strong for this absorption to arise in the same clouds that produce the Mg II, even if their ionization parameters are pushed to the largest values consistent with the data.

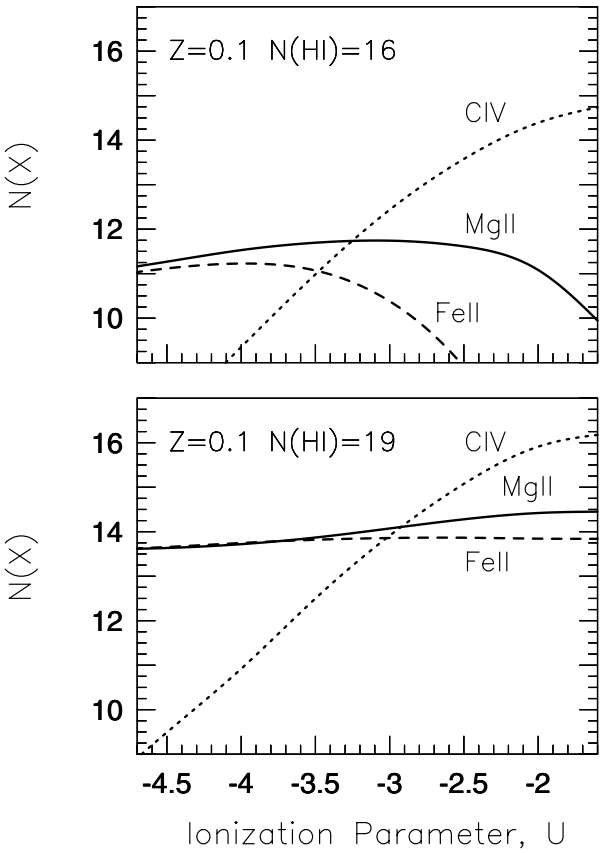

Figure 6. Photoionization model predictions of the column densities of Mg II, Fe II and C IV as a function of the ionization parameter (the ratio of ionizing photons to the electron number density in the gas). The spectrum incident on the cloud, represented by a constant density slab, is the 'Haardt–Madau' spectrum (attenuated spectrum due to the integrated effect of quasars and young galaxies). The predicted column densities are presented in two series of models with N(H I) = 10^{16} cm^{-2} and with N(H I) = 10^{19} cm^{-2}, the optically thin and optically thick cases. For both, the metallicity is fixed at 10% of the solar value. For the optically thin case, the column densities scale with metallicity, i.e. the ratios remain constant, but for the optically thick case the situation is more complex.

Statistics, evolution and interpretation

Future quasar absorption line studies will combine insights gained from detailed analyses of individual systems with conclusions drawn from the large statistical samples assembled over cosmic time. Evolution of the ensemble of absorption profiles generated by the universal collective of intervening structures is a result of the combined effects of numerous processes. These include growth of structure, star formation, morphological evolution of galaxies, galaxy mergers and changes in the extragalactic background radiation. Here, we summarize

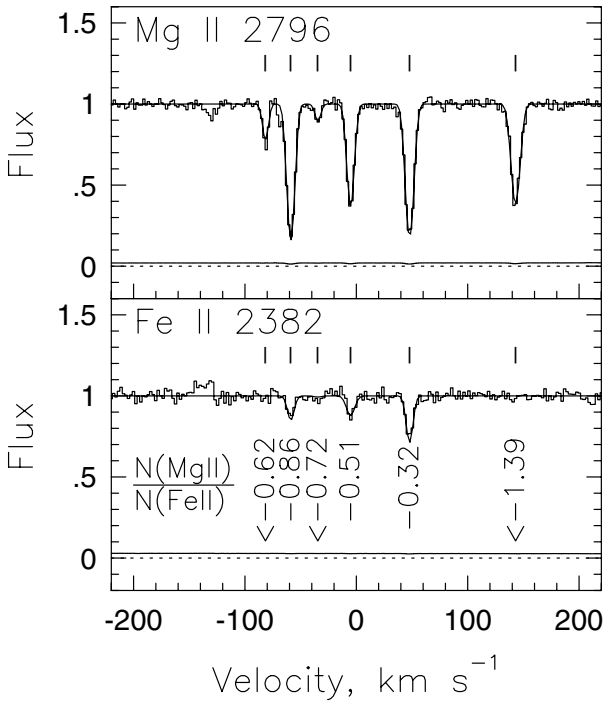

Figure 7. HIRES/Keck Fe II and Mg II absorption profiles for the $z = 1.325$ system in the spectrum of the quasar Q0117 + 213. The six clouds in this system show a range of more than an order of magnitude in N(Fe II)/N(Mg II), given below each cloud in the lower panel. These variations could be due to cloud to cloud variations of ionization parameter (density) or of abundance pattern within the system.

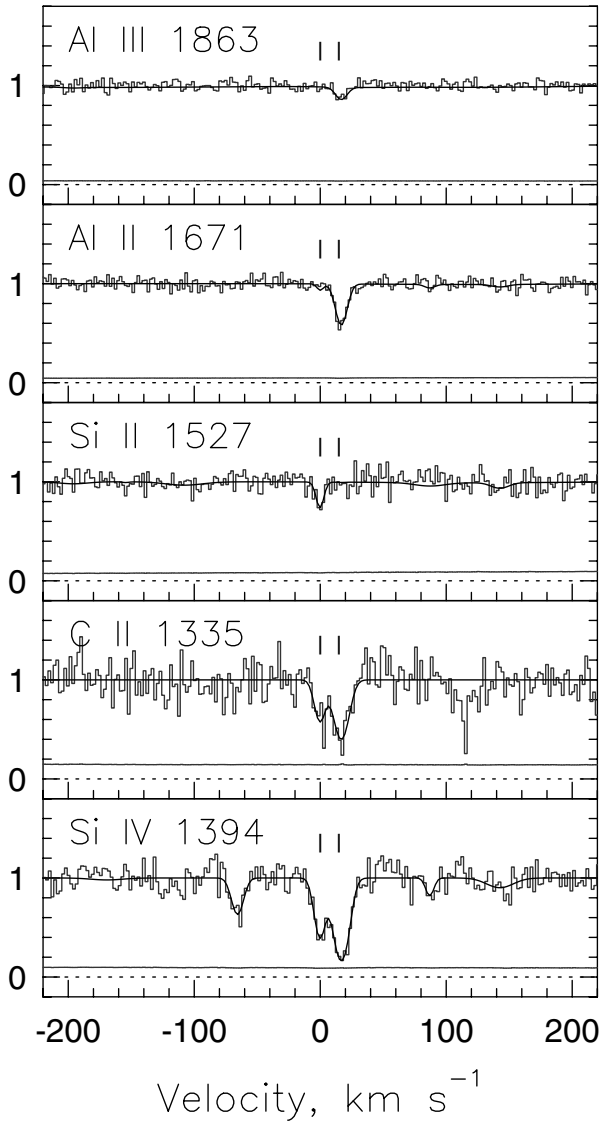

Figure 8. An unusual aluminum-rich cloud is apparent in the $z = 1.93$ system toward the quasar Q1222 + 228, and it is close in velocity space to a normal (relative to galactic clouds) cloud which has detected Si II. Note the different kinematic structure in the higher ionization transitions. The excess of Al II and Al III in the cloud at $v = 9$ km s^{-1} is best explained by an abundance pattern variation, since Si II and Al II are transitions with very similar ionization states.

the best present statistical data and likely interpretations for the different classes of absorbers. The number of lines per unit redshift for various populations of absorbers is represented by a power law $\mathrm{d}N/\mathrm{d}z \propto (1+z)^{\gamma}$. For a universe with only the cosmological evolution due to expansion, $\gamma = 1.0$ for deceleration parameter $q_0 = 0$ and $\gamma = 0.5$ for $q_0 = 0.5$.

Ly α *forest*

The Ly α forest evolves away dramatically from high to low redshift, as is strikingly clear from the spectra of $z \sim 3$ and $z \sim 1$ quasars in figure 9. The evolution of the Ly α lines with W_r(Ly α) > 0.3 Å can be characterized by a double power law with $\gamma \sim 2$ for $1.8 < z < 4.5$ and $\gamma \sim 0.2$ for $z < 1.8$. Help in understanding the physical picture has come from sophisticated N-body/hydrodynamic simulations that incorporate the gas physics and consider cosmological expansion of the simulation box. The dynamical evolution of the H I gas can be described as outflow from the centers of voids to their surrounding shells, and flows along these sheets toward their intersections where the densest structures form. This picture is consistent with observational determinations of the 'sizes' of Ly α structures. It is difficult to obtain direct measurements of sizes except in some special cases to use 'double lines of sight', close quasar pairs, either physical or apparent due to gravitational lensing. If the spectra of the two quasars both have a Ly α absorption line at the same wavelength that implies a 'structure' which covers both lines of sight. From these studies, it is found that 'structures' are at least hundreds of kpc in extent.

At redshifts $z = 5$ to $z = 2$ $\mathrm{d}N/\mathrm{d}z$ for Ly α forest absorption is quite large, but it is declining very rapidly over that range. This dramatic evolution in the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

number of forest clouds is mostly due to the expansion of the universe, with a modest contribution from structure growth. At $z < 2$, the extragalactic background radiation field is falling, and Ly α structures are becoming more neutral. Therefore, the more numerous, smaller N(H) structures are observed at a larger N(H I) and this will counteract the effect of expansion, thus slowing the decline of the forest.

The high-redshift Ly α forest was once thought to be primordial material, but in fact it is observed to have a metallicity of 0.1% solar, even at $z = 3$. For $N(\text{H I}) < 10^{14}$ cm^{-2}, the expected N(C IV) would be below the detection thresholds of current observations, so truly pristine material still eludes us. Perhaps it does not exist. To spread metals all through the intergalactic medium may have required a 'pre-galactic' population of stars at $z > 10$ that polluted all of intergalactic space.

Lyman limit and metal line systems

The dN/dz of Lyman limit systems is consistent with that of strong Mg II absorbers (with $W_r(\text{Mg II}) > 0.3$ Å) over the redshift range for which both have been observed, $0.4 < z < 2.2$. For $W_r(\text{Mg II}) > 0.3$ Å, $\gamma = 1.0 \pm 0.1$, consistent with no evolution. For even stronger Mg II systems ($W_r(\text{Mg II}) > 1$ Å), dN/dz increases more dramatically with z, with $\gamma = 2.3 \pm 1.0$.

The number of Mg II systems (equivalent width distribution) continues to increase down to the sensitivity of the best surveys, $W_r(\text{Mg II}) > 0.02$ Å, such that $dN/dz = 2.7 \pm 0.15$ at $z \sim 1$. The 'weak' Mg II absorbers are therefore more common than the strong systems ($W_r(\text{Mg II}) > 0.3$ Å) known to be associated with luminous galaxies. Unlike the strong Mg II absorbers, the weak Mg II absorbers are sub-Lyman limit systems (they do not have Lyman limit breaks), and no galaxies have been identified at the redshift of absorption. Yet, photoionization models indicate that the metallicities of these weak absorbers are at least 10% of the solar value, and in some cases comparable to solar. They are a varied population: some have relatively strong Fe II while others have no Fe II detected, and some have strong C IV that requires a separate phase while others have no C IV detected. Those with strong Fe II are constrained to be smaller than 10 pc (the ionization parameter must be small and n_e large, as can be seen in figure 6). Also, since Fe is produced primarily by Type Ia supernovae they must be enriched by a relatively old STELLAR POPULATION. Those with weaker or undetected Fe II could be larger (kpcs or tens of kpcs) and possibly enriched by Type II supernovae. Candidate environments that could be traced by weak Mg II absorption are: remnants of pre-galactic star clusters formed in mini-haloes at $z > 10$, super star clusters formed in interactions, tidally stripped material, low surface brightness galaxies and ejected or infalling clouds (analogous to the Milky Way high-velocity clouds).

The evolution of dN/dz for C IV absorbers can be studied in the optical for high redshifts. For $W(\text{C IV}) > 0.4$ Å and $z > 1.2$, the number decreases with increasing z, as $\gamma = -2.4 \pm 0.8$. In this same interval, the number of Lyman limit systems is still increasing with redshift, with $\gamma = 1.5 \pm 0.4$. This implies that the dramatic evolution in the number of C IV systems is either due to a change in metallicity or a change in ionization state. The dN/dz for C IV systems peaks at intermediate z and declines, consistent with no evolution, until the present. Combining optical and UV data, C IV and Mg II have been compared at $0.4 < z < 2.2$. The fraction of systems with large $W_r(\text{C IV})/W_r(\text{Mg II})$ decreases rapidly with decreasing redshift; there is a shift toward 'lower ionization systems'.

It is important to consider that the H I, Mg II and C IV absorptions do not always arise in the same phase. It is possible that the C IV in many $z \sim 1$ Mg II absorption systems arises in a phase similar to the galactic coronas. If the origin of this phase is related to star-forming processes in the disk, then it might be expected to diminish below $z = 1.2$ since peak star formation rate is passed.

Another important trend is the fact that the very strongest Mg II absorbers evolve away from $z = 2$ until the present. If we study the kinematic structure of these objects, we find that they commonly have a 'double' structure, with two separate kinematic regions in the Mg II profile. These objects also have strong C IV which also has separate components around the two Mg II regions in the 'double' structure. The C IV does not arise primarily in the individual Mg II clouds, nor is it in a smooth, 'common halo' structure that extends in velocity space around the entire Mg II profile. As more data are collected on the kinematic structure of various transitions in these 'double' systems, it will be interesting to consider the hypothesis that galaxy pairs in the process of merger are responsible. The number of these is thought to have been dramatically larger in the past.

Damped Ly α systems (DLAs)

The $N(\text{H I}) > 10^{20.3}$ cm^{-2} systems are of particular interest because it is possible to observe many different chemical elements (such as Zn, Cr, Fe, Mn and Ni) in these objects back to high redshift. Metallicities and abundance patterns can be studied and compared with those of old stellar populations in the Milky Way. Back to $z = 3$, the metallicity in DLAs, as measured by the undepleted element zinc, is about 10% of the solar value, but it may decline at $z > 3$. The identity of sites responsible for DLAs at high z remains controversial, but they do contain most of the neutral hydrogen in the universe, from which most of its stars form. The kinematic structure of the absorption profiles of neutral and low ionization species is consistent with the rotation of a thick disk, so that it is possible that these are the $z = 3$ progenitors of normal spiral galaxies. However, this signature is not unique. It could also be the consequence of directed infall in an hierarchical structure formation scenario. The higher-ionization species show complex kinematics which vary in relation to those of the lower-ionization gas; in some systems they appear to trace

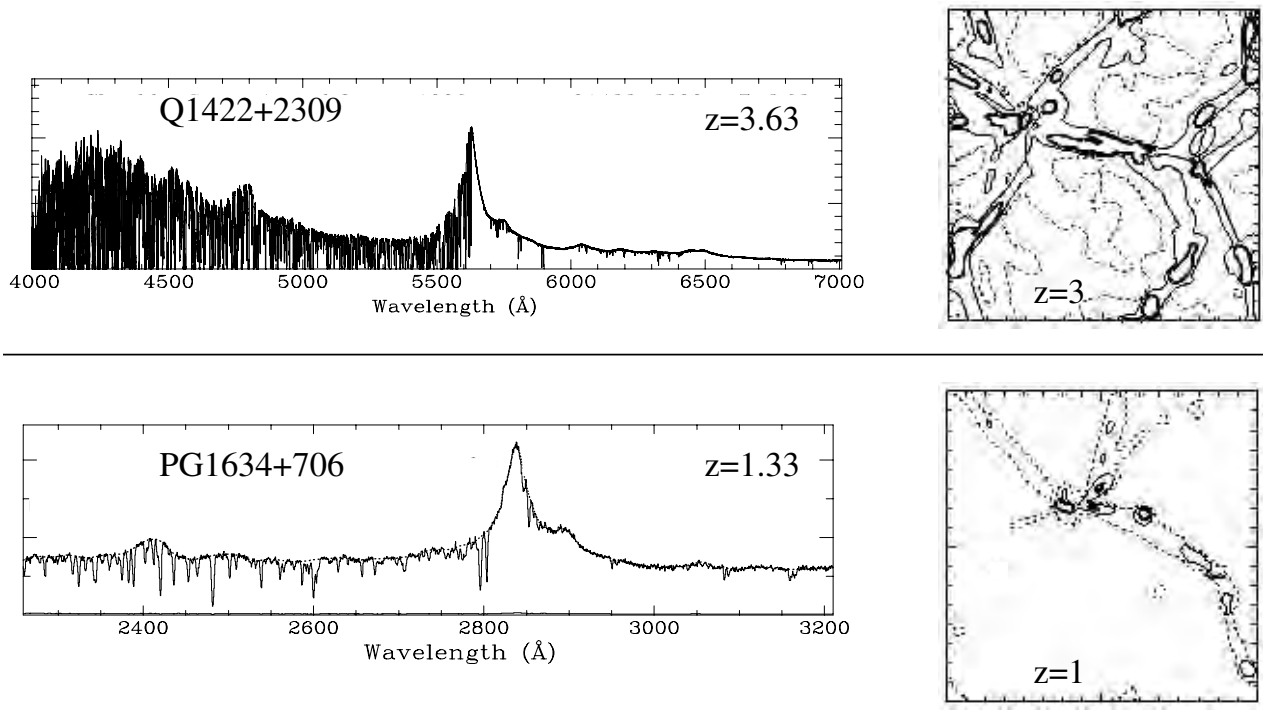

Figure 9. Illustration of structure evolution of intergalactic gas from high to low redshift. The upper spectrum of a $z = 3.6$ quasar is a Keck/HIRES observation, while the lower spectrum is a FOS/HST observation of a $z = 1.3$ quasar. Higher-redshift quasars show a much thicker forest of Ly α lines. Slices through N-body/hydrodynamic simulation results at the two epochs $z = 3$ and $z = 1$ are shown in the right-hand panels. Three contour levels are shown: 10^{11} cm^{-2} (dotted lines), 10^{12} cm^{-2} (solid lines) and 10^{13} cm^{-2} (thick solid lines). Evolution proceeds so that the voids become more empty so that even the low column density material is found in filamentary structures at low redshifts.

relatively similar structure, and in others there are clearly several different phases.

At low redshift, many of the galaxies that are responsible for the DLA absorption can be directly identified. These galaxies are a heterogeneous population. They are not just the most luminous galaxies, but include dwarf and low surface brightness galaxies, and even cases where no galaxy has been identified to sensitive limits. Damped Ly α absorption does not trace the most luminous objects, but rather it traces the largest neutral gas reservoirs. An additional selection effect may be important. The most dust-rich galaxies that have the potential to produce DLA absorption could produce enough extinction so that their background quasars will not be included in quasar surveys. In this way, the population of DLAs that are actually observed could be significantly biased against dusty galaxy hosts.

Future prospects

The next decade will see the synthesis of the various techniques for the study of galactic evolution, through their stars and through their gas. Higher-resolution quasar spectra will be obtained in the ultraviolet (with the Space Telescope Imaging Spectrograph (STIS) and with the Cosmic Origins Spectrograph (COS) on the HST, and later, hopefully, with a larger UV space telescope). It will then be possible to conduct a systematic analysis of the relationships between the different ionization species that trace the different phases of gas in $0.4 < z < 1.5$ galaxies. In this redshift regime, comparisons with the detailed morphological structure and orientations of the absorbing galaxies is possible from HST images.

Invaluable insights into the origin of quasar absorption lines have been gleaned from absorption studies of nearby galaxies, for which it is possible to directly observe the processes that are involved. Making more observations of this type will be possible by discoveries of bright quasars that fall behind nearby galaxies. The discoveries of quasars in large surveys will also include multiple lines of sight behind distant absorption line systems which can be used to produce 3D maps of the structures.

The interstellar medium of the Milky Way shows structure on sub-pc scales, and absorption features can only be resolved with resolution <1 km s^{-1}. Such a resolution will soon be available on 8 m class telescopes. This is important for separating blends and for looking for metallicity, ionization and abundance pattern gradients along the line of sight.

The key low-ionization transitions of Mg II and Fe II are shifted into the near-IR region of the spectrum for $z >$

2.5. Very soon, near-IR quasar spectra will be obtained at relatively high resolution ($\sim$20 km s^{-1}). Also, IR-imaging, narrow-band techniques and multi-object spectroscopy in the near-IR should provide much more information about absorbing galaxies at higher redshifts. This will extend evolutionary studies back to an epoch at which formation processes may be contributing significantly to evolution.

Quasistellar Objects: Intrinsic AGN Absorption Lines

Any gaseous material along our line of sight to distant QUASARS or, more generally, ACTIVE GALACTIC NUCLEI (AGNs) will absorb light according to the amounts and range of ions present. Strong absorption lines are common in rest-frame ultraviolet (UV) spectra of AGNs due to a variety of resonant transitions, for example the Lyman series lines of neutral hydrogen (H I, most notably Lyα λ1216; see also LYMAN ALPHA ABSORPTION: THE DAMPED SYSTEMS) and high-ionization doublets like CIV $\lambda\lambda$1549, 1551 (of triply ionized carbon).

The lines are called *intrinsic* if the absorbing gas is physically related to the AGN, e.g. if the absorber resides broadly within the radius of the AGN's surrounding 'host' galaxy. Intrinsic absorption lines are thus valuable probes of the kinematics, physical conditions and elemental abundances in the gas near AGNs.

Studies of intrinsic absorbers have historically emphasized quasar broad absorption lines (BALs), which clearly identify energetic outflows from the central engines. Today we recognize a wider variety of intrinsic lines in a wider range of objects. For example, we now know that SEYFERT 1 GALAXIES (the less luminous cousins of quasars) have intrinsic absorption. We also realize that intrinsic lines can form in a range of AGN environments—from the dynamic inner regions like the BALs, to the more quiescent outer host galaxies $>$ 10 kpc away. One complicating factor is that most AGNs also have absorption lines due to unrelated gas or galaxies far from the AGN (see QUASISTELLAR OBJECTS: INTERVENING ABSORPTION LINES). Part of the effort, therefore, is to identify the intrinsic lines and locate their absorbing regions relative to the AGNs. Empirical line classifications are a good starting point for this work.

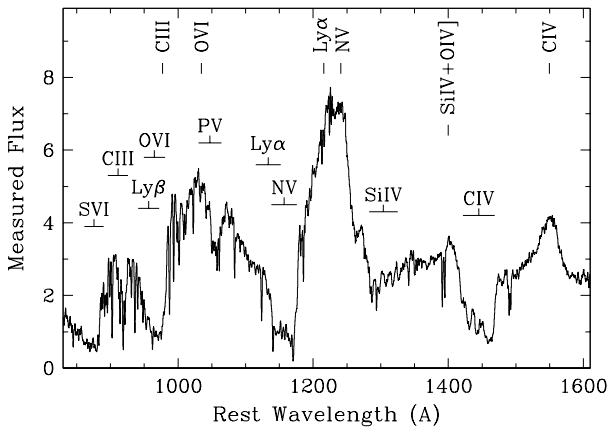

Figure 1. Detached BALs in the quasar PG 1254 + 047. The BALs are labelled just above the spectrum. The wavelengths of prominent broad emission lines are marked across the top. The flux has units 10^{-15} erg s^{-1} cm^{-2} Å^{-1}.

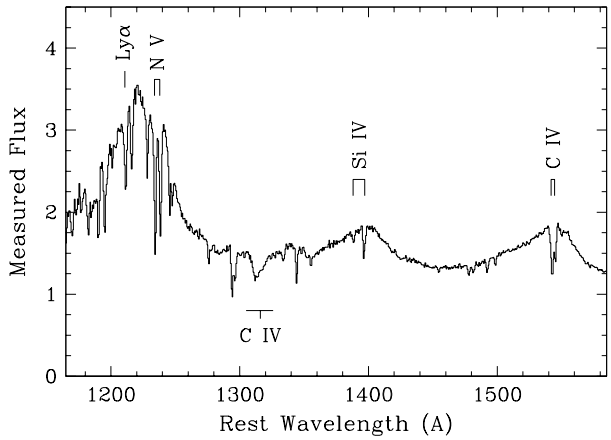

Figure 2. Intrinsic absorption in the quasar PG 0935 + 417. A system of associated NALs is labelled above the spectrum, with open brackets showing the doublet separations. A mini-BAL due to CIV blueshifted by $\sim$ 51 000 km s^{-1} is labelled below. The flux has units 10^{-15} erg s^{-1} cm^{-2} Å^{-1}.

Empirical line types

AGN absorption lines are usually classified according to the widths of their profiles. These classes separate the clearly intrinsic broad lines from the many others of uncertain origin. The main empirical classes are (1) the BALs, (2) the narrow absorption lines (NALs), and (3) the intermediate 'mini-BALs.'

Broad absorption lines (figure 1) are blueshifted relative to the AGN emission lines, implying outflow velocities from near 0 km s^{-1} to as much as $\sim$ 60 000 km s^{-1} ($\sim$ 20% of the speed of light). A representative line width is $\sim$ 10 000 km s^{-1}, although there is considerable diversity among BAL profiles. Velocity widths $\gtrsim$ 3000 km s^{-1} and blueshifted velocity extrema $\gtrsim$ 5000 km s^{-1} are usually considered minimum requirements for classification as a BAL. Some BALs have several distinct absorption troughs, while others are strictly 'detached' from the emission lines—such that the absorption appears only at blueshifts exceeding several thousand km s^{-1} .

Narrow absorption lines (figure 2) have widths less than a few hundred km s^{-1}. NALs with absorption redshifts, z_a, within $\pm$5000 km s^{-1} of the emission redshift, z_e, are called 'associated' (or $z_a \approx z_e$) lines because of their likely physical connection to the AGN. In general, NALs can appear at redshifts from $z_a \approx z_e$ to $z_a \approx 0$. Many of these systems are not related to the AGNs.

Absorption lines with intermediate widths between the BALs and NALs are increasingly called mini-BALs (figure 2). Their strictly blueshifted profiles appear smooth and BAL-like in high resolution spectra, and their centroid velocities span the same range as the BAL troughs (from near 0 km s^{-1} to almost 0.2c). Mini-BALs evidently form in outflows similar to the BALs.

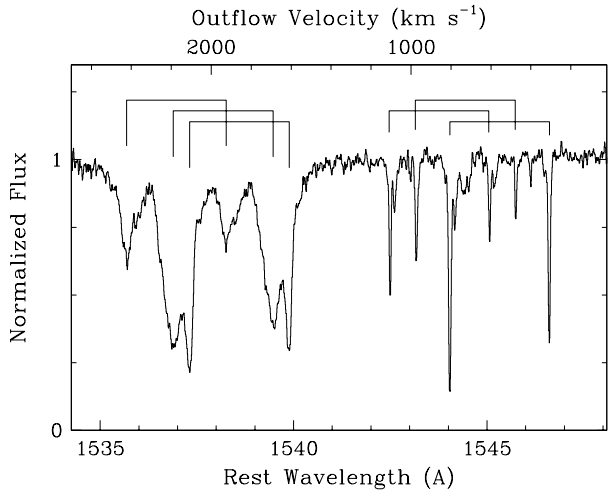

Figure 3. High-resolution blow-up of the CIV NALs in PG 0935 + 417, revealing multiple components (cf figure 2). The open brackets mark the strongest doublet pairs. The outflow velocities are appropriate for the short-wavelength doublet members. The absorption complex at 1535–1540 Å is intrinsic based on the broad line profiles and doublet ratios that imply partial line-of-sight coverage.

Identifying intrinsic NALs

The first evidence that some NALs are intrinsic came from statistical tendencies, namely, (1) quasar NALs appear with greater frequency near the emission-line redshift, and (2) the strengths of these $z_a \approx z_e$ systems correlate with the quasars' radio properties. The first tendency might be explained by external galaxies clustering around quasars, but the second clearly demonstrates a physical relationship to the quasars themselves.

Direct evidence for the intrinsic origin of specific NALs has come from spectroscopic indicators, such as (1) time-variable line strengths, (2) well-resolved line profiles that are smooth and broad compared to the thermal velocity, (3) multiplet ratios that imply partial coverage of the background light source(s), and (4) high space densities ($\gtrsim$100 cm s^{-3}) inferred from the presence of excited-state absorption lines. These properties signal intrinsic absorption because they are most easily understood in terms of the dense and dynamic environments near AGNs. Unrelated intervening absorbers—typically inter-galactic gas clouds or extended galactic halos—should generally be larger, more quiescent, and less ionized for a given gas density. The link between the first three properties and the near-quasar environment is further strengthened by the fact that they are common in BALs and mini-BALs. NALs with these characteristics probably also form in outflows; they have been measured at blueshifted (ejection) velocities from ~ 0 to $\sim$ 24 000 km s^{-1} (e.g. figure 3).

Global covering factors and the ubiquity of intrinsic absorbers

All varieties of quasars and Seyfert 1 galaxies show some type of intrinsic absorption, but different objects favor different types of absorbers. For example, BALs and other high-velocity ($\gtrsim$ 3000 km s^{-1}) intrinsic lines appear only in quasars and never in the Seyfert galaxies. BALs also tend to avoid quasars with strong radio emission, while associated NALs seem to favor them. Preferences like these are probably tied to the unique physical conditions, whereby different AGNs drive different types of outflows.

Intrinsic lines also do not appear in every individual spectrum. For example, BALs are detected in only $\sim$ 12% of quasars. The detection rate of associated (and so probably intrinsic) NALs in quasars is not well known, but it appears to be roughly similar to the BALs. Mini-BALs may be somewhat rarer than both BALs and associated NALs in quasars, but they can appear in either 'radio-loud' or 'radio-quiet' objects. Mini-BALs and intrinsic NALs are both common in Seyfert 1 galaxies, with at least one of these features appearing in 50–70% of the low-luminosity sources.

These detection rates (for any given object class) depend on viewing angle effects and on the global covering factors of the absorbing gas. If the objects are randomly oriented, the absorption-line detection frequencies should approximately equal the average value of the global covering factor, $Q \equiv \Omega/4\pi$, where Ω is the solid angle subtended by the absorber as seen from the central light source. In practice, the situation can be more complicated. For example, attenuation by BAL gas might bias quasar samples against the inclusion of sources with BALs. Thus the true global covering factor of BAL regions could be 20–30%, instead of the $\sim$ 12% implied by the detection rate. Nonetheless, the overall conclusion is that intrinsic absorbers are present in all AGNs, with global covering factors *similar* to the line detection frequencies in each type of object.

Absorber geometry

A consistent picture of the geometry has emerged in which the absorbing gas resides primarily near the equatorial plane of the AGN ACCRETION DISK (figure 4). In particular, spectropolarimetric observations show that the continuum light from BAL quasars is more polarized than non-BAL quasars. Also, the percentage polarization is typically much greater inside BAL troughs compared to the adjacent continuum. These results are understood in terms of light scattering in the disk geometry. Quasars viewed close to edge-on exhibit BALs because our sight-line intersects the the absorbing gas. These objects are also more polarized because the direct (unpolarized) light through the BAL region is slightly attenuated; thus the scattered (polarized) light makes a relatively larger contribution to their measured flux. BAL troughs have higher percentage polarizations because the direct (unpolarized) light in the troughs is more attenuated than the continuum. Quasars without BALs, viewed from

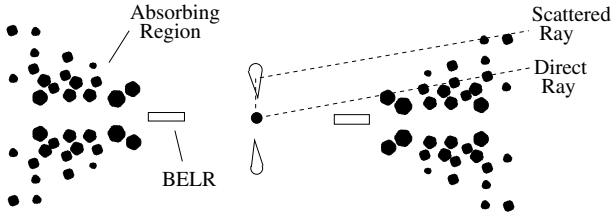

Figure 4. Schematic absorber geometry. The dotted lines are representative light rays from the continuum source (central dot). The open rectangles mark the broad emission line region (BELR) near the accretion disk plane. The teardrop lobes above and below are putative scattering regions near the disk axis. Extended radio jets, when present, would lie along this axis. The radius of the BELR (equation (3) below) sets the scale.

above or below the disk plane, have low polarizations because their direct (unpolarized) light dominates the measured flux.

This picture is also supported by observations showing that quasars with reddened spectra, presumably caused by dust near the disk plane, are more likely to have BALs and high polarizations. Similarly, studies of radio-loud quasars show that associated NALs are stronger and more common in sources with their radio jets aligned perpendicular to our line of sight (such that their unresolved inner disks are viewed nearly edge-on).

Basic physical properties

Kinematics

One surprising property of intrinsic absorbers is that none of them have changed velocity between observations that now span 10–20 years. In one well-studied case, distinct features in a quasar BAL show < 30 km s^{-1} of movement over 5 years in the quasar rest frame, implying an acceleration of < 0.02 cm s^{-2}. The outflow speeds of 10 000–20 000 km s^{-1} are therefore stable to $\lesssim 0.2\%$ on this time scale.

Another general property is the kinematic complexity (e.g. figures 1–3). Many intrinsic absorbers have multiple distinct absorption troughs. Sometimes BALs, mini-BALs and/or NALs appear together in the same spectrum, either blended together or at different (non-overlapping) outflow velocities. The narrower lines, i.e. the NALs and mini-BALs, generally have small velocity dispersions compared to the outflow speeds. Evidently, the outflows producing these lines are not continuously accelerated from rest along our line of sight. These properties all present challenges for the physical models discussed below.

Column densities and partial coverage

Estimates of the column densities in each absorbing ion are complicated by the fact that many (most?) intrinsic absorbers only partially cover the background light source(s) along our line(s) of sight. Partial coverage might occur if the absorbing regions are porous or they are smaller than the emission sources in overall projected area (see figure 4). In any case, partial coverage leads to unabsorbed flux filling in the bottoms of the measured troughs. The observed line intensities thus depend on both the line-of-sight coverage fraction, $C_{\rm f}$, and the line optical depths as

$$I_v \;=\; (1 - C_{\rm f})\, I_o \;+\; C_{\rm f}\, I_o\, {\rm e}^{-\tau_v} \qquad (1)$$

where $0 \leqslant C_{\rm f} \leqslant 1$, I_v and I_o are the observed and emitted (unabsorbed) intensities, and τ_v is the line optical depth, at each line velocity v. The first term on the right-hand side represents the unabsorbed light that fills in the troughs. In the limit $\tau_v \gg 1$ we have simply,

$$C_{\rm f} = 1 - \frac{I_v}{I_o}$$

Outside of that limit, we can compare lines whose true optical depth ratios are fixed by atomic constants, such as the HI Lyman lines or doublets like CIV $\lambda\lambda$1548, 1550, to determine uniquely both the coverage fractions and the true optical depths across the line profiles. For the commonly measured doublets (like CIV), where the true optical depth ratios are ~ 2, the coverage fraction at each velocity follows from equation (1) such that,

$$C_{\rm f} \;=\; \frac{I_1^2 - 2I_1 + 1}{I_2 - 2I_1 + 1} \qquad (2)$$

where I_1 and I_2 are the observed line intensities, normalized by I_o, at the same velocity in the weaker and stronger line troughs, respectively. The column densities, N, follow from the line optical depths via,

$$N = \frac{m_e c}{\pi e^2 f \lambda_o} \int \tau_v {\rm d}v$$

where f and λ_o are the line's oscillator strength and laboratory wavelength. The integral is performed over all or part of the line profile.

This analysis has been applied to well-resolved multiplets in NALs and mini-BALs. The derived coverage fractions range from $\sim 10\%$ to 100%. The column densities in commonly measured ions (e.g. H I, C IV, N V, Si IV, etc) are usually in the range $10^{13} \lesssim N \lesssim 10^{16}$ cm s^{-2}, consistent with the usual absence of Lyman edge absorption at 912 Å. Most BALs are too broad and blended for this analysis. They probably have $C{\rm f} < 1$ in general, but the exact values are rarely known. Crude estimates suggest that the range of BAL column densities is perhaps an order of magnitude larger than the well-measured NALs.

Ionization and total column densities

Intrinsic absorbers are in general highly ionized. Their lowest levels of ionization are usually characterized by ions such as C III, N III, Si IV or C IV. Lower ionization species like Si II, Fe II, Mg II or C II are rarely present. The upper limits of ionization are generally not known because higher ions have their resonance lines at shorter (and more difficult-to-measure) wavelengths. Existing data suggest that ionizations up to at least Ne VIII are common.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

The strong radiative flux of the AGN provides a natural ionization source. Theoretical simulations of photoionized plasmas in equilibrium with the AGN radiation field are used to match the measured column densities, and thus derive the overall ionization state(s) and total column densities (in H I + H II). The ionization state is described by an ionization parameter, U, which is the dimensionless ratio of hydrogen-ionizing photon to hydrogen particle densities in the absorber:

$$U \equiv \frac{1}{4\pi R^2 c n_{\rm H}} \int_{\nu_{\rm LL}}^{\infty} \frac{L_\nu}{h\nu} {\rm d}\nu$$

where $n_{\rm H}$ is the absorber's hydrogen density, R is its radial distance from the central quasar, L_ν is the quasar luminosity distribution and $\nu_{\rm LL}$ is the frequency at the H I Lyman limit. For a 'typical' AGN spectral shape (with $L_\nu \propto \nu^{-1.5}$ in the Lyman continuum) we have

$$U \approx 0.3\, n_{10}^{-1}\, R_{0.1}^{-2}\, L_{46} \qquad (3)$$

where n_{10} is the density in units of 10^{10} cm s^{-3}, $R_{0.1}$ is the radial distance in units of 0.1 pc, and L_{46} is the AGN luminosity relative to 10^{46} erg s^{-1}. Typical U values are between ~ 0.01 and ~ 1. Absorbers at the same velocity, or at different velocities in the same spectrum, often have a range of U values implying a range of densities or radii in the overall absorbing region. Derived total column densities are usually $N_{\rm H} \approx 10^{19}$ to 10^{21} cm s^{-2} for NAL regions and $\gtrsim 10^{22}$ cm s^{-2} for the BAL gas.

Correlated x-ray absorption

Recent studies have shown that the presence of intrinsic lines in the UV correlates with continuous (bound-free) absorption in soft x-rays. Evidently, the UV lines are just one aspect of the intrinsic absorber phenomenon. The x-ray results are important because they reveal generally higher ionizations, $U > 1$, and much higher total column densities, by 1–2 orders of magnitude, compared to the UV lines. A critical issue, therefore, is the physical relationship between the UV and x-ray absorbers.

The data clearly show that different absorbers (of either type) can have a wide range of physical conditions. Some well-measured UV absorbers, in particular, have ionizations and total column densities that should produce only minimal x-ray absorption. Moreover, the best ensemble data are often inconsistent with a 1-zone medium producing all of the measured features. Spatially distinct zones with different ionizations and column densities are at least sometimes present. It is therefore likely that the UV and x-ray absorbers are physically related but not, in general, identically the same.

Space densities and radial distances

Most constraints on the radial distance come indirectly from estimates of the space density and ionization parameter (via equation (2)). The densities are derived in several ways. For example, the absence of broad or blueshifted forbidden emission lines, e.g. [O III] λ5007, suggests (for BAL regions only) that this emission is suppressed by collisional de-excitation at high densities. Some AGNs have absorption lines from excited energy states, implying significant densities to support the upper level populations. In other cases, time-variable absorption lines require minimum densities to allow the gas to adjust its ionization structure within the variability time. This last method assumes that the variability time exceeds the recombination time, $t_{\rm recomb} \approx (n_{\rm e}\alpha)^{-1}$, where $n_{\rm e}$ is the electron density and α is the recombination rate coefficient. Even if the line variability is not caused by changes in the ionization, it turns out that dynamical limits on clouds moving across our line of sight lead to similar R constraints.

The overall results imply densities from $\lesssim 7$ cm s^{-3} to $> 10^6$ cm s^{-3} and corresponding distances from $\gtrsim 300$ kpc to $\lesssim 10$ pc in different sources. The largest confirmed distances apply only to narrow and non-variable NALs. Lines with clear dynamic signatures, e.g. the BALs, mini-BALs and some NALs, probably form closer to the AGN than even the smallest of these upper limits. The minimum radial distance, $R_{\rm min}$, is set by the fact that many intrinsic absorbers, e.g. most BALs, suppress both the continuum and broad line emissions. The absorber distances therefore cannot be much less than the broad emission line region radius, $R_{\rm BELR}$, which is known independently to scale with AGN luminosity, such that

$$R_{\rm min} \approx R_{\rm BELR} \approx 0.1\ (L_{46})^{1/2}\ \ {\rm pc} \qquad (4)$$

where $L_{46} \approx 1$ is 'typical' for quasars. (Values of L_{46} can actually range from $\lesssim 0.001$ in Seyfert nuclei to > 100 in the most luminous quasars.) If there is absorbing gas near this minimum radius, the densities could reach $\sim 10^{10}$ cm s^{-3} (see equation (2)).

Physical models

Most physical models of intrinsic absorbers feature a wind-disk geometry similar to figure 4. The outflowing gas stays close to the accretion-disk plane, and we observe it (via blueshifted absorption lines) only if our sight line(s) to the emission source(s) intersect wind material. The disk provides a likely source for the wind material, and its acceleration to high speeds probably occurs via radiation pressure from the central emission source. The outward transfer of angular momentum in these winds might facilitate the *inward* flow of matter in the accretion disk, thus promoting the growth and fueling of the central black hole.

The measured line velocities suggest that the outflows often originate near the minimum radius implied by equation (3). In particular, the radial acceleration of a wind driven by radiation pressure from a central point source with luminosity L and mass M is

$$\frac{v\,{\rm d}v}{{\rm d}R} = \frac{f_L L}{4\pi R^2 c m_{\rm H} N_{\rm H}} - \frac{GM}{R^2}$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

where f_L is the fraction of the luminosity absorbed or scattered in the wind. Integrating this equation from R to infinity yields the terminal velocity,

$$v_\infty \approx 10\,000\, R_{0.1}^{-1/2} \left(\frac{f_{0.1} L_{46}}{N_{22}} - 0.8 M_9 \right)^{1/2} \quad \mathrm{km\ s^{-1}} \quad (5)$$

where N_{22} is the total column density in 10^{22} cm s^{-2}, M_9 is the central black hole mass relative to 10^9 $M_\odot$, and $f_{0.1}$ is the absorbed fraction compared to 10%. These expressions hold strictly for open geometries, where the photons escaping one location in the wind are not scattered or absorbed in another location. Estimates of the total absorption indicate that $f_{0.1}$ could be as large as a few for BAL flows, and proportionately less for the narrower mini-BALs and NALs. Estimates of N_{22} range from $\lesssim 0.01$ for some intrinsic NALs to $\gtrsim 1$ for typical BALs. Radiative acceleration therefore requires small radii—very roughly similar to the radius of the broad emission line region.

The radial scale is important for defining the mass and kinetic energy of outflowing gas. The total wind mass at any instant is,

$$M_w \approx 1.1\, Q_{0.1}\, N_{22}\, R_{0.1}^2 \quad M_\odot$$

where $Q_{0.1}$ is the global covering factor relative to 10%. The mass loss rate, $\dot{M}_w$, depends further on the characteristic flow time, $v/\Delta R$, such that,

$$\dot{M}_w \approx 0.11\, Q_{0.1}\, N_{22}\, \frac{R_{0.1}^2}{\Delta R_{0.1}}\, v_4 \quad M_\odot\ \mathrm{yr^{-1}}$$

where v_4 is the flow velocity in units of 10^4 km s^{-1} and $\Delta R_{0.1}$ is its radial thickness in units of 0.1 pc. The kinetic energy luminosity is $L_\mathrm{K} \approx \frac{1}{2}\dot{M}_w v^2$, or,

$$L_K \approx 4 \times 10^{42}\, Q_{0.1}\, N_{22}\, \frac{R_{0.1}^2}{\Delta R_{0.1}}\, v_4^3 \quad \mathrm{ergs\ s^{-1}}$$

During a quasar's lifetime, perhaps $\sim 10^8$ years, outflows with these parameter values will eject a total of $\sim 10^7$ $M_\odot$ of gas with kinetic energy $\sim 10^{58}$ ergs. BAL winds might often have total masses, kinetic energies, etc, that are an order of magnitude larger, based on our best estimates of $Q_{0.1} = 1$–3 and $N_{22} \gtrsim 1$ for these outflows.

One unresolved issue is whether the outflowing gas is smoothly distributed or residing in discrete clouds. This seemingly simple question goes to the heart of the wind physics. It was long believed that the flows consist of many discrete clouds because, for example, a flow with $N_{22} \approx 1$ and $\Delta R_{0.1} \approx R_{0.1} \approx 1$ would have a mean density of only $n \approx 3 \times 10^4$ cm s^{-3} . This density would lead to U values several orders of magnitude larger than expected from the data (equation (2)). Moreover, a gas with this high ionization cannot be radiatively accelerated because the ions would be too stripped of electrons to absorb enough incident flux. The flows must therefore be distributed in much denser clouds that fill only part of the wind volume. If these clouds individually have velocity dispersions close to the sound/thermal speed (roughly 15 km s^{-1} for a nominal 15 000 K gas), then a smooth BAL profile of width 10^4 km s^{-1} requires $\gtrsim 1000$ clouds along the line of sight. The main objection to this scenario is that the clouds must be very small, $\lesssim 10^9$ cm across, and they cannot survive as discrete entities without some *ad hoc* external pressure.

An alternative model has emerged in which the flows are, in fact, smoothly distributed with high ionization parameters. The high U values, $\gtrsim 100$, are reconciled with the data (and with radiative acceleration) by invoking a large column density ($N_\mathrm{H} \gtrsim 10^{23}$ cm s^{-2} for BAL winds) of highly ionized gas at the base of the flow. This gas is not radiatively accelerated because it is too ionized. But its bound–free absorption (in soft x-rays and the extreme UV) greatly 'softens' the spectrum seen by the wind material downstream, thereby lowering the wind's ionization level and facilitating its acceleration. The most compelling aspect of this model is that it provides a physical basis for the observed correlation between UV and x-ray absorption: the winds revealed by the UV lines cannot exist without the shielding x-ray absorber. The leading alternative explanation, which simply equates the two absorbing regions, presents a serious problem because the high column densities implied by the x-ray absorption might be impossible to radiatively accelerate (equation (4)).

A serious challenge to all models is the kinematic complexity. It is surprising, for example, that no intrinsic absorbers have shown line-of-sight acceleration. The crossing time for a flow with $v_4 = 2$ and $\Delta R_{0.1} = 1$ is only ~ 5 years, yet repeated observations over this time frame reveal no velocity changes. Just as challenging are the multi-component line troughs and the frequent lack of absorption near zero velocity. These characteristics might be caused by the episodic ejection of discrete 'blobs,' or by well-collimated flows that cross our line of sight and thus reveal only part of their full velocity extent. The latter hypothesis seems more likely for at least the broader lines, because their supersonic velocity dispersions (> 1000 km s^{-1}) should quickly dissipate discrete blobs. Collimated accretion disk winds might cross our line of sight if they are driven at first vertically off the disk, before being bent into fully radial motion by the AGN's radiative force. The collimation and vertical ejection might both be facilitated by magnetic fields running perpendicular through the disk plane. However, multiple line troughs would require multiple collimated outflows. A major problem with this picture is that these intricate flow structures, which are tied to the accretion disk, must remain stable while the disk rotates.

A more general problem is determining how much, and what aspects, of the diversity among intrinsic absorbers results simply from orientation effects. Do the various outflows identified by BALs, mini-BALs and intrinsic NALs coexist generally in AGNs? Orientation is clearly not the only factor. For example, the complete lack of high-velocity lines in Seyfert galaxies suggests a luminosity dependence, probably related to

the requirements for radiative acceleration. Similarly, the relationships to AGN radio emissions suggest that there is some (unknown) physical connection between the disk-wind properties and the formation of radio jets.

Element abundances and host galaxy evolution

Our understanding of the element abundances near AGNs is based on general principles of stellar NUCLEOSYNTHESIS and galactic chemical evolution. All of the heavy elements from carbon on up are synthesized from primordial H and He in stars. The amounts of these elements are thus revealing of both the amount of local STAR FORMATION and the evolutionary status of the galactic environment. The elements near AGNs specifically probe these properties in the centers of big galaxies. For distant quasars, the local abundance evolution might involve some of the first stars forming in collapsed structures after the Big Bang.

Abundance measurements from absorption lines are, in principle, quite simple; one has only to apply appropriate correction factors for the ionization to convert the ionic column densities into relative abundances. For example, the abundance ratio of any two elements a and b can be written simply as

$$\frac{a}{b} = \frac{N(a_i)}{N(b_j)} \frac{F(b_j)}{F(a_i)}$$

where N and F are respectively the column densities and number fractions of element a in ion state i, etc, in the absorbing gas. The F values are generally adopted from photoionization calculations.

The results from intrinsic NALs, and independently from the broad emission lines, indicate that quasar environments have roughly solar or higher heavy-element abundances out to redshifts > 4. (Results based on the BALs are so far unreliable because of the problems with partial line-of-sight coverage mentioned earlier.) The local star formation must be both rapid and extensive to achieve these high abundances at early cosmic times. In particular, much of the gas must have already collapsed into stars by the time the quasars 'turned on' or became observable—just a few billion years after the Big Bang. These findings support prior expectations for the rapid, early-epoch evolution of massive galactic nuclei.

Bibliography

Studies of intrinsic AGN absorption lines began in the 1960s with measurements of BALs and associated NALs in quasars. The status of this evolving field circa 1997 is summarized by numerous articles and reviews in the conference proceedings:

Quasistellar Objects: Overview

Quasistellar objects, or quasars, were defined originally as star-like objects of large redshift. Quasars are believed to be powered by the accretion of matter onto massive black holes at the centers of galaxies, a process that emits more energy than thermonuclear reactions. Today, quasars are considered to be the most luminous members of the general class of objects called active galactic nuclei, or AGNs. Quasars are the most luminous objects in the universe.

This article begins with a brief history of the discovery of quasars. Next it describes their main properties and the concepts that have been developed to explain them. It continues with a description of their nature and theoretical models. Then additional properties and topics are considered: absorption lines, host galaxies, and luminosity functions and evolution.

History

In 1960 Mathews and Sandage identified the radio source 3C 48 (the 48th object in the 3rd Cambridge catalog of radio sources) with a star-like object of 16th magnitude. Its optical spectrum showed unusual emission lines that could not be identified, and the object was considered to be a radio star, more of which were identified in the course of their work. In 1962, Hazard, Mackey and Shimmins established an accurate radio position for another source, the BRIGHT QUASAR 3C 273, by observing the object as it was being occulted by the Moon. Schmidt used this position to identify 3C 273 with a 13th magnitude star-like object (figure 1), whose spectrum also displayed unusual emission lines. Schmidt subsequently realized that the emission lines could be identified with lines from hydrogen and oxygen redshifted by 15.8% of their rest wavelength. A redshift of 0.158 was unprecedented for such a bright object. If the redshift arose from the expansion of the universe, it meant that 3C 273 was about two billion light-years distant, according to the Hubble law, in which the redshift of objects increases in proportion to their distance. Furthermore, the combination of the observed brightness of 3C 273 with the inferred distance meant that it had an intrinsic luminosity 100 times that of an entire galaxy like the Milky Way.

Following Schmidt's work, it was immediately realized that the redshift of 3C 48 was 0.37. By 1965, 3C 9 was found to have a redshift of 2.01, well in excess of the 0.46 value for 3C 295, the most distant galaxy known at the time. It had taken more than 30 yr of work on galaxies with the largest telescopes in the world for astronomers to push the limit of the observable universe to the distance of 3C 295. Only 2 yr after the discovery of quasars, the maximum observed redshift had increased by more than a factor of 4. The light from 3C 9 had taken 80% of the age of the universe, or more than 10 billion years, to reach Earth. The ability to observe objects at redshifts greater than 2 meant that astronomers could probe back in time to within a few billion years of the big bang.

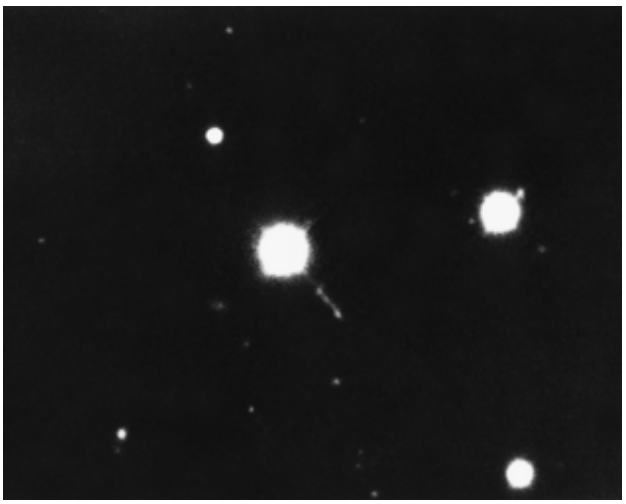

Figure 1. Optical image of 3C273. The object looks stellar in this image except that it is accompanied by a jet of radiation extending to the lower right. (Credit National Optical Astronomy Observatories/National Science Foundation. Copyright Association of Universities for Research in Astronomy Inc (AURA), all rights reserved.)

The unusual nature of quasars was compounded by the work of Smith and Hoffleit, who showed that 3C 273 varied significantly in brightness on timescales of months. This variability indicated that the characteristic size of the emission region was light-months and led immediately to the question, how could such a small object produce more light than an entire galaxy, with a typical size of 100 000 light-years?

To summarize, quasars revolutionized astronomy in the 1960s for two reasons: (1) they pushed back the limits of the observable universe significantly in both distance and lookback time and (2) their compact size and great luminosities could not be explained in terms of the stars and galaxies known at the time. Quasars opened new frontiers in cosmology and stimulated the development of a new subject—relativistic astrophysics.

Main properties and concepts

The main observed properties of quasars are the following.

1. Nuclei that appear starlike in optical images. Extended emission can now often be detected around the nucleus, and jets extending away from the nucleus are occasionally seen.
2. Spectra showing broad emission lines with widths greater than observed in normal galaxies and a range

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of ionization broader than seen in typical nebulae ionized by stars.
3. Structures in quasars with observable radio emission that range in angular extent from m arcsec to tens of arcsec. The most compact structures are often observed to expand on timescales of years.
4. Radiation of similar power at energies ranging from γ-rays to the far-infrared (100 μm) region of the spectrum, with a decrease in energy at radio frequencies.
5. Redshifts, z, of spectral features ranging from 0.1 to 5.
6. Variability in brightness at different wavelengths on timescales as short as days to weeks.
7. Luminosities as high as 10^{14} Suns.
8. Total energy in high-energy electrons in the region of radio emission that can exceed 10^{60} erg.

Additional information about these properties and the concepts they imply about the nature of quasars follows below.

Redshifts

The large redshifts of quasars are one of their distinctive features, and the value of the greatest known redshift, z, continued to increase after 1965, surpassing $z = 3$ in 1973 and $z = 4$ in 1987. The maximum value reached $z = 4.9$ in 1991, and an object at $z = 5$ was discovered in the first stages of the Sloan Digital Sky Survey in 1998 (see QUASISTELLAR OBJECTS: SURVEYS). The great majority of quasars, however, have redshifts less than 2.5. This occurs for two reasons: (1) such quasars are easier to find because they are brighter in the ultraviolet than most stars and (2) they are intrinsically more numerous than quasars with $z > 2.5$. The low-redshift limit of quasars is normally set at 0.1 because objects at lower redshift are usually resolvable as galaxies and are cataloged as ACTIVE GALACTIC NUCLEI.

In addition to providing our first view of the universe at $z > 0.5$, quasars also proved to be valuable cosmological probes because they were luminous enough to yield clues on the properties of matter along the line of sight back to the Earth (see discussion on absorption lines below and in more detail in QUASISTELLAR OBJECTS: INTERVENING ABSORPTION LINES).

Variability

Observations indicate that variability is a common feature of quasars and most quasars are believed to show variations in light at the 10–40% level over timescales of months to years. Furthermore, variations are observed in the strength and shape of emission lines and in continuum emission at x-ray, ultraviolet and radio wavelengths. The variations are irregular in nature, with periods of flaring and relative quiescence being intermixed. Some objects, which are called BLAZARS, show variations in light on timescales as short as 1 day (see BL LACERTAE, BL LACERTAE OBJECTS and AGN: VARIABILITY).

Variability provides powerful tools for determining the inner structure and nature of quasars. When the central source itself varies in brightness, the effects of the variation propagate outward with time and produce changes in, for example, the emission line spectra and continuum radiation from the material surrounding the central source. In the case of blazars, we are seeing almost directly down the axis of the jets of material that are being ejected from the central regions. By following how the radiation from the jets varies at different wavelengths with time, we are able to infer the physical conditions and processes that are occurring in the jets.

Observations of the variability of quasars carried out at different wavelengths in intensive campaigns and also in programs extending for years have provided some of the most direct information on the nature of the inner regions in quasars and AGNs. These programs have shown that the emission line regions are considerably smaller and closer to the central source than was originally thought.

Continuum emission and multi-wavelength observations

Quasars emit radiation strongly in bands ranging from γ-rays and x-rays to the far infrared (100 μm). The amount of energy emitted in each band by most objects is remarkably similar, in contrast to normal thermal radiation from stars, which is much more peaked and restricted in wavelength. For example, most stars are cool and are faint at ultraviolet wavelengths. In contrast, most quasars with redshifts less than 2.5 are bright at ultraviolet wavelengths, a property that is very helpful in distinguishing them from the more numerous stars that are found in sky surveys.

Although quasars were discovered through their radio emission, about 90% of quasars do not emit strongly at radio wavelengths and are classified as radio quiet. Radio-loud quasars are typically 100 times brighter at radio wavelengths than radio-quiet quasars.

The continuum emission in quasars appears to arise from a combination of thermal and non-thermal processes. For the latter, synchrotron emission from relativistic electrons produces the lower-energy radiation. The x-ray and γ-ray emission may come from the inverse Compton scattering of lower-energy photons by high-energy electrons, although thermal mechanisms may also play a part in x-ray emission. In any event, the continuum radiation from quasars demonstrates that some very energetic processes are involved. Furthermore, the continuum radiation at the highest energies tends to show the most dramatic variability and the shortest timescales, which is another indication of the extreme conditions that exist near quasars.

Emission lines

The emission line spectra of quasars (figure 2) are characterized by the large widths of the lines and wide range of ionization. The full widths at half-maximum of the emission lines are typically 5000 km s^{-1} and range from about 500 km s^{-1} to greater than 10 000 km s^{-1}. Full widths at the base of the lines can exceed a tenth the speed of light.

The widths are produced by motions of gas in the emitting region, where a mixture of infall, rotation and ejection probably occurs. The widths are consistent with the emission region being at a distance of light-months to a few light-years from a central black hole.

One of the most striking observational properties of the spectra of quasars and AGNs is the anticorrelation of the strength of the C IV emission line at 1550 Å and the continuum luminosity, that is the emission line is observed to be weaker relative to the continuum in more luminous objects. This relation, which is called the Baldwin effect, is perhaps the most prominent observed correlation that has been found for quasar and AGN spectra. It is important for two main reasons: (1) the clues it provides about the nature of the emission line region and central source and (2) the potential it offers for using quasars as cosmological probes at high redshifts.

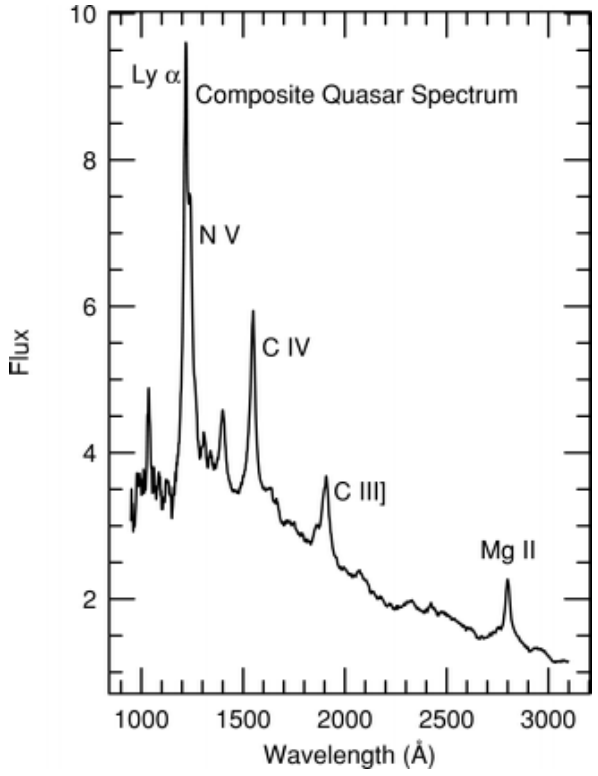

Figure 2. A composite quasar spectrum covering the ultraviolet region of the spectrum. It shows strong emission lines from hydrogen, carbon, nitrogen and magnesium. (Credit Francis P *et al* 1991 *Astrophys. J.* **373** 465.)

The strongest emission lines in quasar spectra come from hydrogen, carbon and magnesium, with lines of nitrogen, oxygen, iron and other elements also being visible. The observed levels of ionization range from neutral for hydrogen and oxygen up to five-times ionized oxygen and even more highly ionized iron. The range of ionization is another indicator of the strength of the non-thermal continuum radiation in quasars and its extent to high energies.

Although it is difficult to make a reliable determination of the chemical abundances in quasar emission line regions, results to date indicate that the abundances are similar to those observed in present-day stars and nebulae, even in quasars at the highest redshifts. This is a striking result when one considers that the most distant quasars correspond to cosmic times of 1 or 2 billion years after the big bang. Except for hydrogen, all the elements mentioned above originate in the thermonuclear reactions that occur in stars. The abundances of these elements increase with cosmic time as successive generations of stars complete their evolution. When stars die, they return part of their newly produced elements to interstellar space, and the next generation of stars forms from the enriched material.

Thus, the apparently normal abundances of the elements in high-redshift quasars implies that they were preceded by substantial stellar activity in the early universe.

Nature

The prodigious luminosities of quasars in combination with their small size led theorists to consider gravity as their energy source immediately on their discovery. It was realized that normal stars and thermonuclear reactions were entirely insufficient to produce the observed properties of quasars. However, the required gravitational potential energy could only be extracted if quasars contained compact objects with masses of a hundred million Suns and sizes about that of the solar system. In addition the gravitational field of such objects was so strong that the effects of general relativity would be dominant in their vicinity. Since that time, gravity has remained as the consensus source of energy for quasars, although the concepts of the nature of the central source have changed considerably. For example, supermassive 'stars', were originally postulated as the central objects in quasars, but enough difficulties were found with such ideas that they were soon abandoned.

Subsequently, it was realized that BLACK HOLES were the most likely central engines of quasars. A black hole was an object with gravity so strong that not even light could escape from its surface. The widths of the emission lines in quasars and estimates of the size of the emission line region suggested that the central mass was about 10^8 Suns. Such objects would not be able to support themselves against the pull of their of their own gravity,

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

and they would collapse to form a black hole. The collapse could liberate 10% or more of the rest energy, mc^2, of the object, that is, more than 10 times the energy of the thermonuclear reactions that occur in stars. Similarly, any material later captured by the black hole would liberate the same fraction of rest energy. This of course provided an explanation for the energies found in quasars. As a result, quasars stimulated much work on the origin and nature of black holes and the detailed processes of how the observed energy could be obtained from them.

Today, the working hypothesis for quasars and AGNs is that massive (10^6–10^9 solar masses) black holes exist at their centers. The radiated energy we detect from them comes from matter being accreted onto the black hole. According to general relativity, the radius of a black hole is 3 km per solar mass, and the radii of black holes in AGNs and quasars range from a few solar radii to 20 times the distance of the Earth from the Sun.

It is most likely that much of the matter surrounding the black hole is in the shape of a disk. The matter in the disk orbits the black hole and moves inward as it loses angular momentum from some source of viscosity in the disk. The inner edge of the disk may extend to within a few radii of the central black hole. The gas in the inner regions of the disk is expected to be hot enough, about $10^{4–6}$ K, to account for the thermal component of the continuum radiation at ultraviolet wavelengths.

The x-ray observations of quasars provide evidence of the existence of a corona of energetic particles above the accretion disk. The x-rays may be produced by upscattering of the ultraviolet photons from the disk on the energetic particles via the inverse Compton process. Some x-rays may also be produced in shocks located farther from the central source.

Jets of beamed radiation are also an important feature. They are frequently observed in radio-loud quasars and, as in the case of 3C 273, sometimes are seen at optical wavelengths. The jets are thought to be accelerated electromagnetically and ejected along the rotational axis of the black hole. They can be moving at relativistic speeds and contain high-energy particles, such as the relativistic electrons that produce the radio emission through the synchrotron process. The radio emission in the 3C 273 jet is located several light-years distant from the central source.

A striking feature of jets in some radio sources is that repeated observations on the smallest angular scales with radio interferometers show them to be moving outwards at speeds that appear to be several times greater than the speed of light. This of course would violate a basic limit of relativity. The most satisfactory explanation for this paradox is that the jets are moving at speeds near that of light in the direction of the Earth. In this case the apparent time interval in the expansion motion of the jet appears smaller than it really is because of the motion toward the Earth. See the article on SUPERLUMINAL MOTION for more information.

The emission line spectra of quasars indicate that there are also gas clouds surrounding the black hole. The clouds occupy about 10% of the volume of the region where the broad emission lines are produced. The broad emission line region in quasars can extend to several light-years from the black hole.

Understanding the nature of the inner regions of quasars and the central black holes continues to be an important subject of research both observationally and theoretically. Specific topics include the formation of black holes and their relation to the formation of galaxies, the role that galaxy interactions play in providing the fuel supply of gas for accretion onto the black hole and how quasars evolve in time and what is their relation to the inactive black holes now being observed in the centers of nearby galaxies.

Alternative theories

One of the first alternative explanations for the large redshifts of quasars to be investigated was gravitational. If the emission arose near a compact massive object with a sufficiently strong gravitational field, then the emission lines could exhibit large redshifts. However, it was realized almost immediately that such a hypothesis was inconsistent with the widths and other properties of the emission lines, and the hypothesis was ruled out.

Another hypothesis was that quasars were being gravitationally lensed and thus appeared much brighter than they really were. Interestingly, many years after this idea was proposed, some quasars were discovered to be lensed, but they are only a small fraction of the total.

From observations of the apparent associations of quasars with galaxies of much lower redshift, Arp has challenged the concept that quasar redshift arise from the cosmological expansion of the universe. In this picture, the redshifts arise from some other, non-cosmological effect whose nature has yet to be determined.

Subsequent observations, however, have shown that quasars do reside in galaxies. In the cases where it has been possible to measure the redshifts of the host galaxies, they agree with the redshifts of the quasars. Furthermore, low-luminosity quasars and luminous Seyfert galaxies overlap in luminosity and show a general continuity of properties.

Today, it is generally accepted that the large redshifts of quasars do arise from the expansion of the universe and that they are at the distances indicated by the redshifts.

A different approach has been taken by Terlevich and collaborators, who have proposed that starbursts, intense episodes of star formation, can account for quasars. In this case energy from hot, young stars and the supernova explosions that occur at the end of their evolution provides the radiation and spectral properties

observed in quasars and AGNs. While there are abundant observations showing that starbursts are common in regions around AGNs and may well be related to the processes that fuel the central object, the starburst model has great difficulty in accounting for the most luminous quasars and for the rapid variability in x-rays that is observed in AGNs. Furthermore, the observational evidence for black holes in nearby galaxies has become increasingly strong.

Additional topics

Absorption lines

Absorption lines were detected in quasars within a few years of their discovery and were initially believed to be rare. However, with improved sensitivity and spectral resolution, it became clear that absorption lines were present in all quasars with redshifts 2 and greater. A contributing factor to their presence was that ultraviolet, ground-state lines were being redshifted to wavelengths where they could be observed with ground-based telescopes. Today, the study of quasar absorption lines is a major topic and the article on this subject should be consulted for more details.

Absorption lines may be placed in three categories according to the distance of the absorbing gas from the central emission source of the quasar: (1) intrinsic systems, (2) associated systems and (3) intervening systems.

Intrinsic systems arise close to the quasar itself. The most conspicuous members of this class are the broad absorption line (BAL) quasars, whose spectra show broad troughs of absorption on the short-wavelength side of the Lyman α line of hydrogen and such high-ionization lines as C IV λ1549 and N V λ1240, for example. The troughs indicate outflow velocities that can exceed 30 000 km s^{-1}. BAL features are seen in about 10% of high-redshift quasars, a value that gives an indication of the average covering factor of the outflowing gas.

Associated systems show absorption features from elements such as hydrogen, carbon and magnesium. They have redshifts close to that of the emission lines in quasars but are much narrower. They are believed to arise in gas associated with the host galaxy of the quasar or the environment in which the host galaxy resides, which might be a group or cluster of galaxies.

Intervening systems have redshifts smaller than the emission lines in quasars and arise in clouds of gas unrelated to the quasar that lie along the line of sight to the Earth. In this case, the quasar serves as a background beacon that enables the study of otherwise invisible gas. The sight lines to quasars probe representative samples of intergalactic space, and absorption line spectra provide an unbiased way to determine the nature and distribution of the gas. Studies of absorption lines in quasars have provided crucial information about gas in the high-redshift universe. Intervening systems may themselves be classified in three groups according to the column density of the absorbing gas: (a) damped Lyman α systems, (b) intermediate (metal line and/or Lyman limit) systems and (c) the Lyman α forest.

Damped Lyman α systems represent the highest column densities, typically in excess of 10^{20} neutral hydrogen atoms cm^{-2}, and are so called because absorption is so strong that the damping wings of the line are seen. Such systems are thought to occur when the line of sight passes through a disk galaxy. Some may also arise in dense clouds or filaments of intergalactic gas at high redshift.

Damped Lyman α systems, because of their high column densities, also exhibit absorption lines from heavier elements such as carbon, silicon, magnesium and iron, with additional elements being detected in the most favorable cases. Analyses of these lines indicate that the abundance of metals in the systems is about one-tenth of the solar value. This is consistent with our understanding of the chemical evolution of galaxies, in which the abundance of metals increases with cosmic time owing to the continuing enrichment of the interstellar medium by supernovae and red giant stars as they complete their life cycle. Damped Lyman α systems can only be observed from the ground for redshifts greater than 1.8, which corresponds to a lookback time of approximately 80% of the age the universe.

Intermediate systems, with a characteristic column density of 10^{17} neutral hydrogen atoms cm^{-2}, also show absorption lines from elements such as carbon, magnesium and other metals plus a discontinuity at the Lyman limit of hydrogen. They are commonly attributed to the halos of galaxies. Their metal abundances range down to 1% of the solar value, indicating that they have had less chemical enrichment than the gas in damped Lyman α systems.

The Lyman α forest lines are the most numerous and ubiquitous absorption features and are attributed to clouds of gas in the intergalactic medium. They are seen in a range of column densities beginning at the limit of detectability around $10^{12–13}$ neutral hydrogen atoms cm^{-2} and extending up into the range of the intermediate systems. Their number density increases with redshift; by redshift 4, the integrated effect of absorption from the Lyman α forest produces a significant depression of the flux shortward of the Lyman α emission in quasar spectra. Observations of the Lyman α forest are used to deduce the state of ionization of the intergalactic medium. Much of the ionizing flux at high redshift is produced by quasars. The data are also important for understanding the formation of structure in the universe.

Host galaxies

The regions immediately around quasars are difficult to observe because of the glare from the central source, which is why quasars were originally called star-like objects. However, with improved observations, extended emission began to be detected around quasars. In the meantime the realization was developing that quasars, Seyfert galaxies and other active galactic nuclei were members of the same family. One of the main differences among the different classes of objects was the luminosity of the central source, and the host galaxies with low-luminosity nuclei were much easier to study.

The excellent image quality and spatial resolution of the Hubble Space Telescope have enabled a significant advance of our knowledge of quasar host galaxies (figure 3). Results to date for low-redshift objects show that quasars occur in elliptical, spiral and interacting galaxies, with some of the latter appearing very disturbed by the interaction. On average, the host galaxies are brighter than normal field galaxies. The radio-loud quasars tend to occur in elliptical or interacting galaxies. The radio-quiet quasars can occur in elliptical or spiral galaxies. These results are in contrast to the situation for lower-luminosity AGNs, where there are stronger tendencies for radio-quiet objects to occur in disk galaxies and radio-loud objects in ellipticals.

The study of host galaxies is important to improving our understanding of how both galaxies and quasars form and evolve. The quasar is in the nucleus of the galaxy and represents the endpoint of the process that produced the central concentration of matter in the galaxy. How a massive black hole formed and grew from the central concentration remains an important research question. At the same time, for the black hole to be visible and attain the luminosity observed for bright quasars, it must accrete several solar masses of material per year. What causes this inflow of matter from the outer parts of the galaxy to the nucleus is also an important topic. It is thought that the interaction of two galaxies, that is their collision or near collision, can produce enough disruption to the orbit and angular momentum of stars and gas to produce the inflow, but the details of the process are not yet fully understood.

Luminosity functions and evolution

The luminosity function of quasars is the distribution of their volume density as a function of luminosity and redshift. As with galaxies, the number density decreases steeply at the highest luminosities. At low luminosities the slope of the function is smaller than at high luminosities, so the rate of increase of objects slows with decreasing luminosity.

Luminosity functions are among the most basic parameters in astronomy and provide a basis for determining the amounts of matter in different forms in the universe.

One of the most striking properties of quasars is the evolution of their luminosity function with redshift. This was first noticed by Schmidt, who realized there were too many quasars at high redshift in early surveys if the space density of objects were constant. Interpreted as density evolution, the space density of luminous quasars is more than a thousand times greater at $z = 2$ than in the local universe. An alternative explanation is that quasars were brighter at high redshift than at present.

At redshifts greater than 3, there is considerable observational evidence that the space density of quasars declines steeply. A logical interpretation of the results (figure 4) is that we are seeing back to the epoch of peak quasar activity. Alternatively, clouds of dust at high redshift could be blocking our view of more distant quasars. For example, such clouds could be associated with star formation regions in the host galaxy of the quasar. However, the best information currently available indicates that dust is an important factor for some types of quasars but does not account by itself for the decline in space density at high redshift. In any event, the most distant objects now known in the universe are galaxies, the first time this has happened since 1965. Although this may be a coincidental result, it is another indication that quasars at redshifts greater than 5 are genuinely very rare objects.

Current observations of quasars and distant galaxies are consistent with bursts of star formation occurring in galaxies before the quasar activity builds up to its peak around redshift 2–3. As was mentioned earlier, the gas in the emission line regions of distant quasars appears to have relatively normal abundances of elements heavier than hydrogen, which implies that the gas has been enriched by massive stars before reaching the quasar. Furthermore, it takes time for a supermassive black hole to attain the masses needed for quasars, time that allows for a few generations of massive stars to complete their evolution. For reference, the age of the universe is only about a billion years at redshift 5.

Subsequently, the overall rate of star formation in the universe reaches a peak as galaxies continue to form and assemble. After that, both quasar activity and star formation rates decline until they reach the values observed today in the local universe. Both declines are probably related to galaxies completing their formation and assembly. In addition, the rate of interactions and mergers of galaxies decreases as the universe continues to expand. As a result less material is available (1) to fall to the central regions of galaxies and fuel the massive black holes and (2) to form stars.

In this picture, the quiescent black holes that today are found to be ubiquitous in nearby galaxies are the products of the spectacular galaxy formation process and quasar activity that occurred in the first third of the history of the universe.

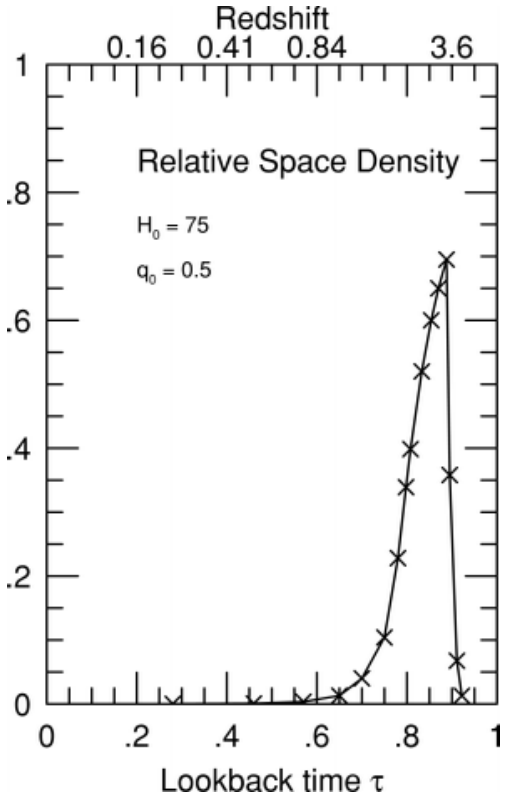

Figure 4. The evolution of the space density of luminous quasars as a function of cosmic lookback time, expressed as a fraction of the age of the universe. The space density shows a strong peak at 0.85, when the universe was 15% of its present age. (Credit Warren S, Hewett P and Osmer P 1994 *Astrophys. J.* **421** 412.)

However, the picture is but a sketch and is in need of both development and confirmation. We may expect significant progress in the near future on several fronts.

- Large new surveys for quasars that are being carried out at optical and radio wavelengths, such as the Sloan Digital Sky Survey, the Australian 2dF Survey and the FIRST radio survey, will increase the number of known quasars by a factor of ten. (In June 2001, two quasars with redshifts of 6.0 and 6.2, the most distant objects ever observed in the universe were identified in the Sloan Digital Sky Survey.)
- The new generation of large telescopes with 8–10 m apertures that has come into operation and space observatories such as Chandra and XMM that will soon be launched provide powerful tools for observing quasars with significantly more sensitivity and resolution at optical, infrared and x-ray wavelengths than has been available previously.
- Advances in theoretical modeling and the continuing increase in computing power will enable significant progress in interpreting the new observations and in modeling the inner regions of quasars and key processes such as accretion.

Thus, the prospects for improving our understanding of how quasars form and evolve and for determining their relation to galaxies are very bright.

Quasistellar Objects: Surveys

Since the discovery of QUASARS in 1963, surveys have been a prerequisite both for investigating models of the central regions of quasars themselves and to provide samples of quasars for use as cosmological probes. The early history of surveys for quasars was determined by our incomplete knowledge of their nature and of their relationship to galaxies. Discovered initially through the campaign to identify the strong RADIO SOURCES in the Third Cambridge Radio Catalogue (3CR), the optical counterparts were found to be stellar, i.e. unresolved point sources, and to possess blue optical colors. Following the initial spectroscopic identification of 3CR273 as an object with the then unprecedented REDSHIFT of $z = 0.16$ (see BRIGHT QUASAR 3C 273), by Maarten Schmidt, a significant number of quasars were soon found by obtaining optical spectra of unresolved blue objects within the positional error boxes of radio sources. A further major advance was made in 1965 when Allan Sandage showed that there existed a much larger population of unresolved blue sources with very similar properties to 'quasars' except that the objects were not detectable as radio sources. Some researchers continue to draw a distinction between quasi-stellar radio sources (quasars) and quasi-stellar objects (QSOs). However, many workers regard the distinction as primarily historical and both 'quasar' and 'QSO' may be used to refer to objects irrespective of whether they possess significant radio emission.

An enormous observational effort at radio, infrared, optical and x-ray wavelengths in the three decades following the discovery of quasars has resulted in the identification of some 12 000 quasars. Most recently, the ability to undertake sensitive surveys over very large areas of sky has marked the beginning of projects that will produce catalogs of hundreds of thousands of quasars, allowing entirely new scientific investigations to be undertaken.

Identifying quasars

Quasars are rare objects that exhibit a very broad range of intrinsic properties. Normal stars and the majority of galaxies, whose spectral energy distributions are dominated by the radiation from their constituent stars, possess blackbody-like spectral energy distributions that are strongly peaked. The characteristic temperature of the stellar photospheres determines the wavelength at which the bulk of the radiation is emitted. By contrast, the extreme physical conditions in the central regions of quasars lead to the emission of radiation over many decades of wavelength and quasars emit significantly in the x-ray, ultraviolet, optical, infrared and radio portions of the spectrum. With only a few exceptions, surveys for quasars rely on identifying objects whose spectral energy distributions differ from the blackbody-like spectra of normal stars and galaxies.

The majority of known quasars have been identified using data from the optical region of the electromagnetic spectrum. At redshifts $z \leq 2.2$ quasars exhibit an excess of near-ultraviolet light compared with common Galactic stars. The 'ultraviolet-excess' technique, involving the selection of objects with unusually blue broad-band colors derived from B and U band magnitudes, has produced several thousand quasars—figure 1. The technique can be made both more efficient, by reducing the number of contaminating hot stars included, and more complete, by increasing the sensitivity to a larger fraction of the quasar population, by extending the wavelength interval through the use of additional broad-band magnitudes (e.g. one or more of V, R, I). The so-called 'multicolor' technique has proved very effective, allowing the identification of quasars over the redshift range $0 < z < 5$.

The second primary methodology employed in the optical regime relies on the identification of the prominent emission lines, present in most quasars, visible in low-resolution spectra. Slitless spectroscopy, a technique that employs a thin prism (objective prism) or a combination of prism and transmission grating (grism) enables spectra of thousands of objects over large fields to be obtained. Prior to the development of the multi-color selection techniques virtually all quasars with redshifts $z > 2.2$ were located through the identification

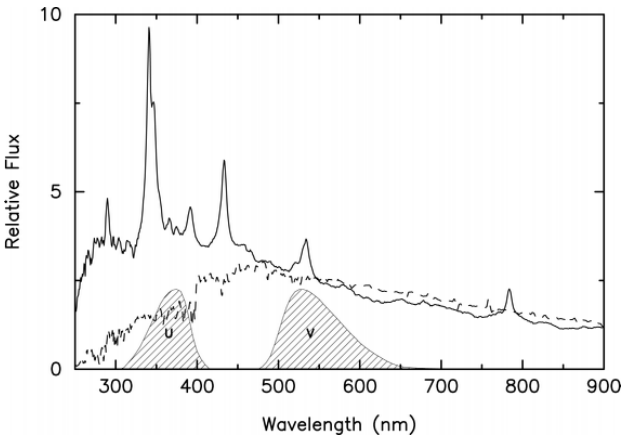

Figure 1. Spectra of a solar-like star (dashed curve) and a typical quasar of redshift $z = 1.8$ (solid curve). The measured fluxes of both objects in an optical passband, such as the V band represented by the hatched region to the right, are very similar. However, the flux of the quasar measured using a passband in the near-ultraviolet, such as the U band represented by the hatched region to the left, is relatively much greater than for the star. Employing this characteristic excess of ultraviolet flux is one of the simplest and most effective techniques for identifying quasars with redshifts $z \leq 2.2$. Another class of discovery techniques focus on the detection of the strong emission lines which are visible in the quasar spectrum but absent in the spectra of normal stars.

and Institute of Physics Publishing 2001

of the strong hydrogen Lyman-α 121.6 nm and carbon C IV 154.9 nm emission lines which, for redshifts $1.5 < z < 3.5$, appear in the optical portion of the spectrum.

While the basic methodologies of the color, slitless-spectroscopic and other discovery techniques have been established for several decades, there has been a longstanding debate over the relative effectiveness of quasar survey techniques. Advocates of particular methodologies have often claimed to detect a greater fraction of the quasar population compared with other approaches. Originally, the selection of candidate quasars was performed by individual researchers visually inspecting photographic plates through a binocular microscope. In recent years a significant improvement in the agreement between the results of different surveys has come about through the use of digital data and the implementation of automated, computer-based selection procedures. The computer-based selection ensures homogeneity in the candidate selection and, most importantly, allows a precise quantification of the effectiveness of a particular survey (see e.g. SOFTWARE: DIGITAL SKY SURVEYS). A now well-established technique is to simulate the appearance of quasars of given properties—redshift, magnitude and spectral energy distribution—in the data set under examination. The survey selection procedure can then be applied to the simulated objects to establish what fraction of quasars with particular properties can be successfully identified—figure 2. An example of the success of such methodology was the remarkable agreement in the derived space density of HIGH-REDSHIFT QUASARS, $z = 3$–4.5, from two groups, one employing multicolor selection and the other using slitless-spectroscopic techniques.

The extreme luminosities and very extended spectral energy distributions of quasars mean that many of the apparently brightest sources of radiation at x-ray, infrared and radio wavelengths are quasars. Employing the very-large-wavelength baseline between, for example, the optical and x-ray portions of the electromagnetic spectrum should provide a highly efficient technique for identifying quasars; given a sample of quasars and stars of similar optical brightness, the quasars will appear unusually 'x-ray bright'. Relatively small numbers of quasars have been identified through investigation of radio, infrared and x-ray catalogs and these samples have proved particularly important for studies of the physics of the central energy source of quasars. However, the sensitivity of telescopes and their associated detectors at wavelengths away from the optical is, in a relative sense, poor. Thus, only a small fraction of the quasars detectable via optical techniques have been accessible to observations made at the extremes of the electromagnetic spectrum.

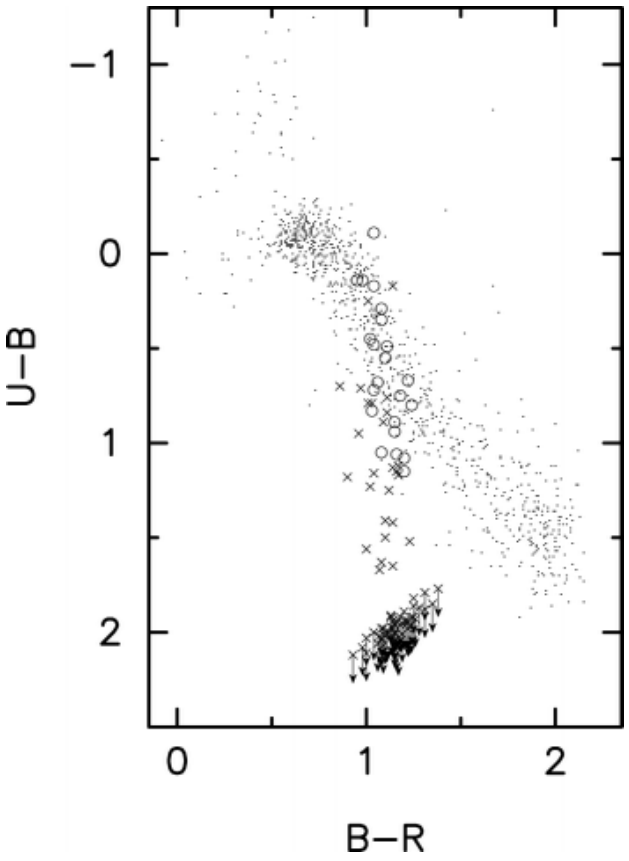

Figure 2. Many modern surveys aim to detect quasars with a variety of spectral energy distributions over a large range in redshift. Simulations of the appearance of a quasar in a particular survey, incorporating a detailed model of the effects of intervening absorption and the properties of the survey itself, allow the probability that a quasar of given brightness, redshift and spectrum will be detected to be calculated. The figure shows a two-color diagram with the colors of 980 of the total of ~30 000 objects in the survey area (•). The larger symbols show the predicted colors of a quasar with redshift $z = 3.33$ derived from such a simulation. ○s indicate occasions when the quasar would not have been identified, while ×s represent occasions when the quasar was successfully picked out. The simulation shows that the probability of detecting a quasar of the specified type is $P = 0.78$. Symbols with downward pointing arrows correspond to occasions when the simulated U magnitude was below the survey detection limit and the quasar lies somewhere below the plotted symbol, with a larger $U - B$ color.

Notwithstanding a general convergence in the results from, and understanding of the differences between, various survey techniques, some researchers continue to believe that a significant fraction of the quasar population remains to be identified. Two alternative techniques, based on lack of proper motion and the presence of photometric variability, have been proposed to address this question. Over timescales of decades essentially every star in our own Galaxy exhibits a small, but detectable, motion on the sky and surveys for quasars employing so-called PROPER MOTIONS focus on objects

Dirac House, Temple Back, Bristol, BS1 6BE, UK

that do not appear to move. Photometric variability, with a wide range of amplitudes, was recognized soon after the discovery of quasars as a distinctive feature of many objects. The cause in the majority of quasars is believed to be variations in the rate at which material is accreted by the central massive object. The statistical properties of photometric variability are not well determined but, if monitored at approximately monthly intervals over a period of one or two decades, virtually all quasars exhibit brightness changes of at least 10%. Variability surveys thus treat any object showing evidence of variability, not explicable as a variable or binary star, as a quasar candidate. Recent results from both techniques agree well with those derived from other surveys.

Present status

Impressive progress has been made over the last 15 years in compiling samples of quasars from x-ray to radio wavelengths. As a result, the general behavior of the quasar luminosity function over the redshift range $0 < z < 5$ is fairly well established. Significant constraints on models of the central regions of quasars have been derived from the spectroscopic and other properties of quasars in existing surveys. However, the popular unified scheme models for quasars and ACTIVE GALACTIC NUCLEI predict that the population should exhibit a very large spread in luminosity and spectral energy distribution. Similarly, quasars viewed along a line of sight that passes through an intervening galaxy containing dust may be dimmed by very large factors. Virtually all current surveys, independent of wavelength, are sensitive to objects with only a narrow range in luminosity at fixed redshift (see also GALAXY REDSHIFT SURVEYS). As a consequence, existing surveys do not in general provide strong tests of a number of different theoretical models. While the total number of quasars known, ~12 000, may seem large, for many investigations, including those that exploit quasars as cosmological probes, very large numbers of objects are required. Progress in areas where the signal sought is weak, such as defining the clustering behavior of quasars as a function of redshift, are still limited by the lack of surveys containing many thousands or tens of thousands of quasars.

Future surveys

Undertaking surveys for many thousands of quasars has in practice been impossible because of the lack of an instrument capable of obtaining spectroscopic observations of hundreds of faint candidate objects over areas of at least a square degree on the sky. Recent developments in instrumentation have overcome this practical restriction and two major surveys now in progress will produce samples of tens of thousands of quasars within the next five years.

In Australia, at the 3.9 m Anglo-Australian Telescope, a multiobject fiber spectrograph with 400 fibers and a 2º diameter field of view, the so-called '2 degree field' (2dF), has been commissioned (see also SPECTROGRAPHS: FIBER-FED SPECTROGRAPHS). Simultaneous spectroscopy of quasar candidates to $B = 21$ over an area of three square degrees is relatively straightforward and the '2dF Quasar Survey', with a target of 25 000 quasars, is a key program. The survey area consists of two long strips on the sky, 75º × 5º in extent, with the selection of the targets based on a three-color (*UBR*) technique that is sensitive to quasars over the redshift range $0.2 < z < 3.0$. The magnitude limit of the survey and the geometry of the survey regions have been chosen to optimize the quasar sample for investigation of spatial clustering properties as a function of redshift. The quasars act as probes of large-scale structure and the extended redshift range over which quasars are detected will provide an order of magnitude improvement in the determination of the development of large-scale clustering with redshift, providing an important new constraint on theories of structure formation.

A still more ambitious program involves the SLOAN DIGITAL SKY SURVEY (SDSS) which has recently begun to acquire imaging in five broad optical passbands (*u*,*g*,*r*,*i*,*z*) with the aim of covering 10 000 square degrees of the sky at high Galactic latitude. The second element of the project is to obtain spectra of the brighter galaxies and quasar candidates identified from the broad-band imaging data. Although the study of some 1 000 000 galaxies is the principal motivation for the SDSS some 150 000 quasar candidates will be observed using the dedicated multifiber spectrograph mounted on a 2.5 m telescope at Apache Point in New Mexico. The broad-band filters employed in the SDSS extend from the near-ultraviolet through to a '*z*'-band at the far-red extreme of the optical atmospheric window. The *u* and *g* colors allow the detection of low-redshift quasars via the ultraviolet-excess technique with additional information from the redder filters, while sensitivity to radiation with wavelengths as red as 1000 nm means the SDSS is sensitive to quasars with redshifts as high as $z = 6$ (see below). The primary, 10 000 square degree, survey will identify relatively bright quasars, $B \leq 20$, and the number of very-high-redshift objects is not expected to be large. However, a smaller area of 100 square degrees will be surveyed to much fainter limits. It will also be possible to select subsets of potentially rare quasar candidates to rather fainter limits that may be followed up using telescopes of larger aperture. The first results from such a strategy are already encouraging, with a number of high-redshift quasar candidates observed in late 1998 producing the first quasar to be found with a redshift $z = 5$. More recently, a group of astronomers in California discovered a quasar with $z = 5.50$, and in April 2000 a group from Chicago reported a quasar with $z = 5.8$. In June 2001, two quasars with redshifts of 6.0 and 6.2, the

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

most distant objects ever observed in the universe, were identified in the Sloan Digital Sky Survey.

The use of the FIRST (FAR-INFRARED AND SUBMILLIMETRE TELESCOPE) radio source catalog to identify optically bright quasars has proved highly successful, with an initial catalog of more than 650 objects. The origin of the very large range in radio luminosity at fixed optical luminosity among the quasar population has been an outstanding question for several decades. The FIRST sample and future extensions to fainter optical magnitudes will make a significant contribution in this and a number of other areas. Similarly, the quasar samples to be defined from the CHANDRA and XMM x-ray satellites will be well suited to addressing key questions such as the contribution of quasars to the x-ray background and testing the predictions of unified schemes for quasars and active galactic nuclei.

The capabilities of optical telescopes with apertures of 8–10 m will allow fainter quasars at redshifts $z \sim 2$–3 to be investigated, helping to extend the dynamic range of the surveys. Probably of even greater significance will be the ability to conduct surveys for quasars at near-infrared wavelengths to relatively faint magnitudes over many hundreds of square degrees of sky. Extinction of radiation by dust is greatly reduced at wavelengths of ~2000 nm compared with optical wavelengths and quasars at very high redshifts, with very faint optical colors owing to the presence of intervening hydrogen clouds, should also be detectable in the near-infrared. Such infrared surveys will be possible early in the millennium and a resolution to the ongoing debate concerning whether a significant proportion of the quasar population has eluded detection owing to extinction by dust and gas, either associated with the quasars themselves or present in intervening systems, should result.

Quetelet, Lambert Adolphe (1796–1874)

Statistician, born in Ghent, Flanders, Belgium, founder (1833) and director of the Brussels Observatory. Studied astronomy at the Paris Observatory under FRANÇOIS ARAGO, and probability under Joseph Fourier and PIERRE LAPLACE. Apart from social statistics (crime, mortality, census taking), he worked on statistical, geophysical and meteorological data, and established statistical methods. Following a suggestion of Arago, he studied the statistics of the visibility of meteors and showed that there was a greater frequency of meteors in the month of August. He found archival records of earlier exceptional meteor displays in August, and predicted the shower (the Perseids) of 10 August 1837 (see EDWARD CLAUDIUS HERRICK). He published the *Catalogue des Principales Apparitions d'Étoiles Filantes* (1839) listing 315 meteor displays recorded until then.

R Coronae Borealis Stars

The R Coronae Borealis stars (RCB) stars fade dramatically and unpredictably by factors of up to 1000 within a few weeks. Over succeeding months, they gradually recover their original brightness. This spectacular fading is caused by the formation of sooty dust clouds above the surface of the star. The surfaces of RCB stars are unusually poor in hydrogen, and rich in carbon and nitrogen, which implies that they are the remnants of evolved stars. Practically all RCB stars pulsate, which may help to explain the dust formation episodes.

R Coronae Borealis, or RCB, stars are an important class of VARIABLE STAR. Stars vary in many different ways, often by changing the amount and color of the light they emit. They can change regularly or irregularly. RCB stars, remarkably, do both.

RCB stars are best known because of their irregular 'fades'. Unpredictably and every few years or so, their brightness suddenly drops by a huge amount. Then they get slowly brighter until they look the same as before the fade. The fades are caused by enormous clouds of dust which cover a large part of the star's surface. The dust is thought to be made of small particles of carbon—rather like ground-up pencil sharpenings.

Why the dust clouds form is harder to understand. As well as irregular fades, the light output from RCBs goes up and down by a few per cent every 40 days or so. This is due to the star swelling and shrinking—known as pulsation. It seems that these pulsations may cause dust to form which is then thrown out from the star. Thus, indirectly, they may be responsible for the irregular fades.

Another remarkable thing about RCB stars is that their surfaces contain almost no hydrogen, the most common element in space. In fact, they are mostly made of helium and carbon. These elements are made by nuclear reactions deep inside stars. Since they are now seen on the surface, RCB stars must be very old.

This article introduces the history and basic properties of RCBs, before exploring them in more detail. Three brief sections address the origin of RCBs, the occurrence of RCB activity in other stars, and recent progress towards solving some of the outstanding problems.

Historical background

RCB stars are named after a star just visible to the naked eye in the constellation of Corona Borealis. R CrB was discovered by Edward Pigott, an English amateur astronomer who had been observing a star in the 'Northern Crown' for over a decade. In the spring of 1795 he noticed that it had disappeared, but over succeeding months it gradually reappeared and recovered its original brightness. Pigott estimated a period of 10.5 months for this phenomenon, but he was puzzled that the changes did not repeat themselves precisely.

In fact, unlike δ CEPHEI and other variable stars known at the time, R CrB's changes in brightness are irregular and unpredictable. This irregularity has prompted numerous astronomers to observe R CrB so regularly that its light curve has now been monitored continuously for almost 200 years.

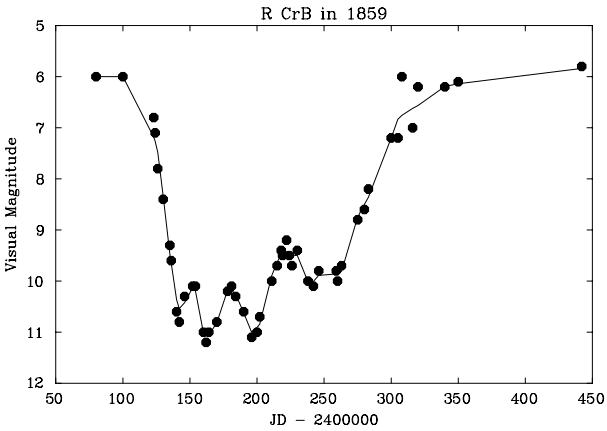

Figure 1. The light curve of R Coronae Borealis during a fading event in 1859.

Since 1795, other RCB stars have been discovered and their properties have been carefully observed. The defining property is their characteristic light curve, marked by the irregular fadings first seen by Pigott. In addition, nearly all RCB stars pulsate with periods between 40 and 100 days. Their surfaces contain very little hydrogen, unlike the vast majority of stars which have about 90% hydrogen. Instead their surfaces are rich in helium and carbon, which must have been produced by nuclear reactions deep within the star.

It is established that the sudden fadings of RCBs are caused by clouds of carbon-rich dust passing in front of the star, but it is unclear what causes carbon gas in the stellar atmosphere to condense into dust. Other questions remain about the precise composition and origin of RCB surfaces.

Remarkable as their properties are and extensive as two centuries of observations have been, RCB stars continue to pose many problems. The irony is that the original question posed by Pigott's observations in 1795 remains essentially unsolved—'what causes the sudden fadings of R CrB ?'

Basic properties

RCB stars were first identified by their characteristic light curves. A part of the light curve of R CrB itself is shown in figure 1.

Spectrum

Many light-curve identifications were made retrospectively from photographic plates originally obtained to patrol the sky for asteroids, supernovas and other variable phenomena. As a consequence the light curves were often incomplete so that symbiotic, cataclysmic and semiregular variables were sometimes identified as RCBs.

RCB stars have a spectrum which resembles that of an F or G supergiant. Balmer lines are weak or absent, there are many lines of neutral atomic carbon and strong bands of molecular carbon (C_2 and CN). In one of the earliest analyses of stellar surface composition, it was shown that R CrB itself was extremely hydrogen deficient. A handful of hot RCB stars have B-type spectra. These characteristics have enabled the identification of 34 RCB stars in the Galaxy to be confirmed.

Galactic distribution and absolute magnitudes

The distribution of galactic RCB stars is controversial. Several authors have argued that they belong to a thick galactic disk, and are thus old Population I stars. However, they may alternatively belong to the even older galactic bulge (Population II). The controversy may simply be a result of the different ways in which surveys for RCB stars and related objects have been carried out. In either case, the populations are sufficiently old that RCB stars must have relatively low masses ($\leq 1 M_{\odot}$).

A growing number of RCBs have been discovered in the LARGE MAGELLANIC CLOUD (LMC), most recently as a result of wide field surveys. These are the only RCB stars for which a distance is known and hence for which an absolute magnitude can be deduced. With $M_V \sim -4$ to -5, the LMC RCBs are 3000–10 000 times more luminous than the Sun.

Numbers and distances

The absolute magnitude of the RCBs in the LMC and the small number of galactic RCBs implies that they are very rare stars. Together with statistics for related stars, the total number of hydrogen-deficient stars in the Galaxy is estimated to be about 1000. Whilst the luminosity of RCBs is similar to that of other low-mass stars as they evolve rapidly from the asymptotic RED GIANT branch to become WHITE DWARFS, their frequency is much lower. They do not, it seems, represent a stage in the evolution of all normal low-mass stars.

From the preceding estimates of mass and luminosity, it is seen that RCBs have very high luminosity-to-mass ratios ($L/M \sim 10\,000$) and lie close to the Eddington limit for radiative stability. If they were any more luminous, their atmospheres would be expelled by radiation pressure.

Physical characteristics

Atmospheres

The fundamental properties of RCBs may be deduced from their spectra at maximum light. A typical spectrum looks like that of an F or G supergiant. RCB effective temperatures fall mostly around 7000 K, although a small number are as cool as 5500 K. The spectra of most RCBs have now been analysed in detail. They show that hydrogen makes up less than one part per thousand down to less than one part per million of the STELLAR ATMOSPHERE. Most of the atmosphere is neutral helium. Although carbon is enriched, it is not possible to establish its abundance reliably. All RCB atmospheres show products of hydrogen- and helium-burning NUCLEOSYNTHESIS in several different episodes, as well as mild enhancements of s-process elements.

Pulsations

Most RCB stars are small-amplitude variables at maximum light. Light variations are typically a few tenths of a magnitude with periods between 40 and 100 days. In well-studied cases, radial-velocity variations have been found with amplitudes proportional to the light variations. The visual light curve of RY Sgr (period ~38 days, amplitude 0.2–0.3 mag) correlates well with the radial velocity curve (amplitude 40 km s^{-1}) and indicates that RCBs are radially pulsating stars.

The light curves of RCB stars are not strictly periodic. Some authors suggest that this is due to interference between a number of radial modes with different periods. It is more likely due to extreme non-adiabacity in the stellar envelope which can lead to chaotic behavior in the pulsation cycle length. Since pulsation periods are directly related to the mean density of a star, evidence for period changes was thought to imply secular changes in RCB radii. It now seems likely that the observed period changes are due to chaotic behavior.

The driving mechanism for pulsations in RCB stars is not the classical κ mechanism found in δ Cepheid variables; RCB stars do not lie in any of the classical instability strips. Their pulsations are due to 'strange-mode' oscillations whereby waves trapped in parts of the acoustic cavity of the stellar envelope are amplified. Such pulsation modes are also seen in other HIGH-LUMINOSITY STARS, such as luminous blue variables and α Cyg variables.

A consequence of the high L/M ratios of RCB stars is that densities in their atmospheres are low. The action of the pulsations on the photosphere resembles that of a piston imparting an outward impulse at regular intervals. In between these impulses the photosphere is virtually in free-fall. During the impulse, highly nonlinear processes can generate shock waves within the photosphere. Evidence for such nonlinearity has been observed in RY Sgr where, at minimum radius, absorption lines are seen to double. A redshifted component is due to infalling material and a blueshifted component is due to lower-lying plasma that has already being accelerated outwards.

Frequency of fading events

The most obvious and spectacular properties of RCB stars are their dramatic fading events. They spend the majority of their time at maximum light. Initial decline is sudden and steep, the star can fade by up to eight magnitudes in a few weeks. The decline may show a series of standstills, partial recoveries and subsequent declines. The final recovery to maximum light may take several months to a year.

The first outline of a mechanism for the fading events was proposed in the 1930s when it was 'shown that the shape of the light curve of R CrB and its spectral variations

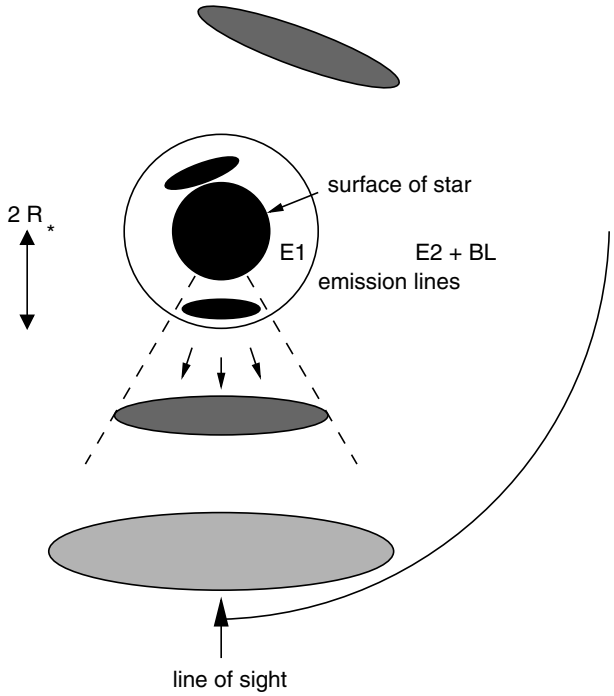

Figure 2. RCB dust-cloud ejection and evolution. (Based on a figure in Clayton (1996) and reproduced by permission.)

at minimum can be accounted for by supposing it to eject matter which condenses at a considerable distance and forms obscuring clouds. The solid matter is believed to be principally carbon.'

From nearly two centuries of observations of R CrB, a characteristic interval of 1100 days between fading events has been deduced. Several searches have consistently failed to find any regular patterns in RCB declines which might help to identify a causal factor such as rotation or binarity. For two cases only, RY Sgr and V854 Cen, it has been shown that the onset of the decline episodes may be closely correlated with a particular phase of the pulsation cycle. It is attractive to relate the onset of a dust formation episode to the pulsation of the stellar envelope, but the evidence for such a connection is not yet compelling.

The ratio between the characteristic interval between fades and the typical pulsation period of RCBs implies that a decline occurs about once every 20 pulsation cycles.

Anatomy of a decline

Infrared observations of RCBs show that, even at maximum light, there are copious amounts of dust surrounding the star. A very interesting result is that during a decline, when the V-band brightness is plummeting, the infrared L-band brightness shows no significant change and continues to show pulsational variations. It seems that the V-band brightness is dominated by the obscured atmosphere, but the L-band brightness is dominated by dust surrounding the star at some distance. Evidently the dust continues to be illuminated by light from the photosphere, including its pulsations, whilst light coming directly from the photosphere to the observer is obstructed. Therefore the obscuring dust can only cover a fraction of the stellar surface.

The picture that emerges (figure 2) is that at a particular phase in the pulsation cycle, conditions in the photosphere can compel the carbon-rich gas to be expelled from a part of the stellar surface to cool, condense and form dust grains. Roughly once every 20 cycles, this 'puff of soot' is directed into our line of sight, and obscures the photosphere from view.

Another important observation associated with RCB declines is that, during the early part of the decline, a rich emission spectrum appears, consisting of many narrow lines of neutral and singly ionized metals. These lines (known as E1 lines) appear to be short-lived so that within two or three weeks, they are replaced by a simpler broad-line spectrum (BL), although a few narrow lines (E2) persist for an extended period. The E1 spectrum is probably due to hot gas close to the stellar surface which is visible only when the photosphere alone is obscured. As the dust cloud moves away from the stellar surface it expands, obscuring the E1 region. Since the E2 and BL regions remain visible, they must arise from cooler gas spread over a much larger volume around the star.

This picture of clouds of dust ejected by the pulsating stellar surface has been successful in explaining many properties of RCBs. There remain a number of difficult questions, the hardest being 'What is the origin of RCB stars?'

The evolutionary status of RCBs

Nuclear processes within stars first convert hydrogen to helium, then helium to carbon, and eventually to heavier elements. RCB surfaces consist primarily of a mixture of helium and carbon-rich layers, with a trace of hydrogen. Single-star evolution does not normally succeed in mixing such different layers of a star, so special models have been proposed to explain their origin.

In one model, a low-mass star which has finished its evolution as a red giant contracts to become a white dwarf, passing through a phase when it illuminates a PLANETARY NEBULA. It may happen that sufficient unprocessed helium remains on the surface of the white dwarf that nuclear reactions can be reignited. The star then expands suddenly to become a helium-burning red giant for a second time. Convection will thoroughly mix the outer layers of this star to give the mixture of helium and carbon seen in RCBs.

In another model, it is supposed that two white dwarfs are in orbit around one another. Over a long time scale ($\sim 10^{10}$ years), GRAVITATIONAL RADIATION will make the orbit decay and the stars will spiral in towards one another. If one star is a helium white dwarf (HeWD), and the other a carbon/oxygen white dwarf (COWD), the HeWD will be cannibalized by the more massive COWD. This helium will be capable of initiating new nuclear reactions and,

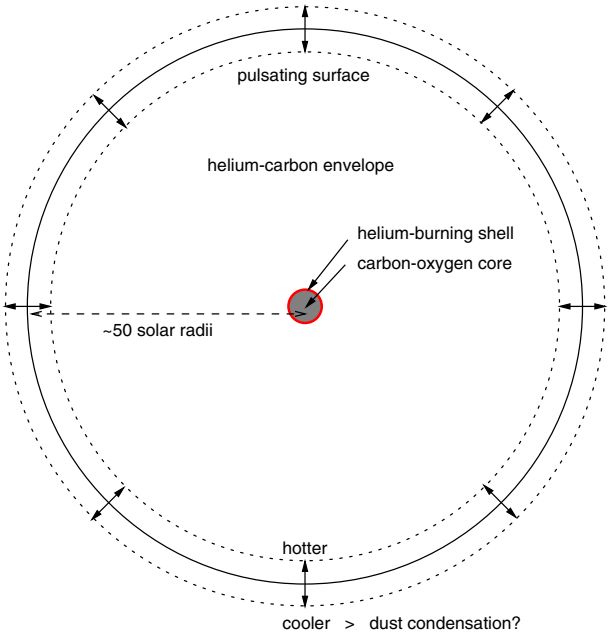

Figure 3. Internal structure of an RCB star.

like the previous model, the star will expand to become a helium-burning giant, with a helium- and carbon-rich surface.

It is difficult to resolve which model is correct, if either, because RCBs show a range of surface compositions, and the crucial carbon abundance is not well known. However, it is agreed that RCBs probably have a degenerate carbon-oxygen core, and their energy comes from a nuclear-burning shell at the bottom of the helium-carbon envelope (figure 3).

Other hydrogen-deficient stars

The Galaxy hosts a variety of other extraordinary stars with little or no surface hydrogen. Most are rare, but nevertheless intriguing. Massive WOLF–RAYET STARS are young (Population I) hydrogen-deficient stars, as are binary systems such as υ Sgr. Low-mass stars like the RCBs belong to an old population. A group of hydrogen-deficient giants with spectra similar to RCBs show no RCB fading events. These have probably failed to become RCB stars because their luminosities are too low.

As well as RCB stars with F- and G-type spectra, several other stars show RCB-type light curves. Two, MV Sgr and DY Cen, are B-type helium-rich giants and are very similar to a group of about 20 'extreme helium stars', A- and B-type stars with weak or no Balmer lines, strong neutral helium and ionized carbon lines. If they are indeed RCB stars, they are not very active. Their surface carbon abundance is ~1% by number, the remainder being helium. A more active B-type helium star, V348 Sgr shows strong emission lines at all times, and has a surface carbon abundance of ~10% by numbers. This star may be related to about 20 hydrogen-deficient central stars of planetary nebulae which have similar carbon abundances and strong emission line spectra. These stars are all overluminous and have strong stellar winds. Carbon-rich knots may form in the winds and give rise to RCB behavior. Of importance to understanding the RCB fading events, the discovery in 1997 of weak RCB-like fading events in CARBON STARS suggests that the process of carbon condensation in stellar atmospheres is not confined to classical RCB stars.

During the past century three stars have been observed as being both hot subdwarfs and RCB stars at different times. V605 Aql is now the hydrogen-deficient central star of a planetary nebula (Abell 58). In 1919 it brightened as a slow nova, and there is a report that its spectrum at one time resembled an RCB star. FG Sge was a faint blue star in 1900. Since then, it has become progressively redder and brighter so that now it has the spectrum of a K-type giant. In 1960 it started to pulsate and in 1992 it started to show RCB-type fading events. Its surface composition contains the products of many nuclear reaction processes, and is thought to be hydrogen poor. FG Sge may be a new-born RCB star. Most recently, in 1996, an unremarkable faint blue star suddenly brightened and within three years had become a very cool and luminous carbon star, now known as SAKURAI'S OBJECT or V4334 Sgr. The spectacular evolution of these three stars and their similarities with RCB stars may eventually help to explain the origin of RCB stars.

Unsolved problems

Since the discovery of R CrB itself, the mechanism that produces fadings has been elusive. Primary data connecting pulsation phase and the trigger for fadings exist for only two RCBs (V854 Cen and RY Sgr), and protracted photometry of several RCBs will be necessary to establish any connection firmly.

A second difficulty is encountered by the physical conditions necessary for dust to condense above the surface of the star. The frequency and duration of fading events implies a geometry in which the dust clouds form within two stellar radii ($2R_\star$). Under normal conditions, the local temperature would be too high for dust to condense at this distance, and a condensation distance of $20R_\star$ would be expected. Recent models treat the chemistry, energy balance and dust nucleation in pulsating star atmospheres in considerable detail. They show that excess cooling can occur during adiabatic expansion after the passage of a shock wave, reducing the local temperature to about 1500 K within 1.5–3$R_\star$. It remains to be shown that pulsations in all RCB stars provide the necessary conditions for dust nucleation to occur at this distance.

The RCB carbon abundance remains an enigma. Whether it is ~1% or ~10% determines if RCBs are related to the C-rich remnants like the extreme helium stars or to C-strong remnants like the H-deficient central stars of planetary nebulae.

The problem is a natural consequence of stellar atmosphere physics. The strength of a stellar absorption

line represents the ratio of line opacity to continuous opacity in the atmosphere; both are related to the number density of the absorbing atoms and so provide the number ratio of line absorbers to continuum absorbers. When the line and continuum absorbers are the same, it becomes impossible to measure the abundance of the absorbing species. In hydrogen-rich stars, hydrogen is normally the main continuum absorber and, since it is also assumed to be the most abundant species, the problem does not arise. Since the predominant continuum absorber in RCB atmospheres is neutral carbon, it has not yet proved possible to measure the carbon abundance from carbon absorption lines.

Finally, the emission line spectrum seen during fading events is difficult to explain, especially the sodium D lines which indicate an expansion (or wind) velocity of several hundred km s^{-1}. Superimposed are a number of narrow absorption components, possibly representing cooling gas from previous ejections. The presence of heavily blueshifted absorption from infalling material remains a puzzle.

RCB stars offer the astronomer a wealth of information, from their spectacular fadings, through their pulsations and dust shells, to the nuclear waste on their surfaces that traces previous evolution. Even with all of these data, RCBs retain much of their original mystery.

Bibliography

Most general astronomy texts and books on stellar variability refer to RCB stars, but only briefly. For example:

Hoffmeister C, Richter G and Wenzel W 1985 *Variable Stars* (Berlin: Springer)

In contrast, the academic literature is extensive and this article can only provide a few pointers. A recent and comprehensive review provides many important references:

Clayton G C 1996 The R Coronae Borealis stars *Publ. Astron. Soc. Pacific* **108** 225–41

A conference held in 1995 was devoted to hydrogen-deficient stars in general. Its proceedings contain many excellent reviews covering recent work on RCBs and related objects:

Jeffery C S and Heber U (eds) 1996 *Hydrogen-deficient Stars (Astr. Soc. Pac. Conf. Ser. 96.)*

Simon Jeffery

Rømer [Römer, Roemer], Ole [Olaf] Christensen (1644–1710)

Born in Aarhus, Denmark, studied at the University of Copenhagen under Thomas and Erasmus Bartholin, who gave him TYCHO BRAHE's manuscripts to edit and his own daughter to wed. Rømer accompanied Bartholin and JEAN PICARD to Hven to measure the position of Tycho's observatory, the better to reduce Tycho's observations. He went on to the Paris Observatory where he made and used instruments for the measurement of star positions. While in Paris, he timed the eclipses of Io, the innermost of Jupiter's moons. He discovered that the period between eclipses was changing. The change of period was due to a Doppler shift, caused by the changing velocity of Earth relative to Jupiter, and led Rømer to a value of 11 minutes for the value of the light travel time from the Sun to Earth (the 'light equation'). The modern value is 499 s. Rømer's explanation of the eclipses of Io was criticized by CASSINI, who could not repeat it with the other Galilean satellites, and by an incredulous ROBERT HOOKE. Hooke maintained that light travels instantaneously, and ''tis so exceeding swift that 'tis beyond Imagination; for so far he thinks indubitable, that it moves a Space equal to the Diameter of the Earth, or near 8000 miles, in less than one single Second of the time, which is in as short time as one can well pronounce 1, 2, 3, 4: And if so, why not be as well instantaneous I know no reason. . .'. Rømer was supported by HUYGENS and NEWTON. Rømer became professor of astronomy and of mathematics in Copenhagen, astronomer royal to Kings Christian V and Frederick IV of Denmark, and director of the Copenhagen Observatory. He carried out a succession of state tasks, including development of a reformed measurement system for Denmark.

Radar Astronomy

The branch of astronomy that is concerned with the investigation of solar system bodies by radar methods. The technique involves transmitting a beam of microwave radiation from an Earth-based radio telescope or an orbiting spacecraft towards a target and analyzing the faint 'echo' that returns from the target's surface. Radar techniques can yield information on the precise distance between the Earth and the target body, the rate at which the target body is rotating, the altitude of a spacecraft above a body's surface, the vertical relief and topography on the surface of a planet or satellite, and the nature and roughness of that surface.

The transmitted beam may be continuous (continuous wave) or pulsed. Typical pulses transmitted by Earth-based astronomical radar systems have lengths (durations) of between 10 μs and 10 ms (10^{-5} to 10^{-2} seconds) and peak powers of tens of megawatts. Pulsed radar is used to measure planetary distances. During the time interval (Δt) between the transmission of a pulse and the arrival back at Earth of the reflected pulse, the signal has traveled, at the speed of light (c) a distance equal to twice the distance between Earth and the target planet. Therefore the distance (d) between Earth and the target planet is given by: $d = c\Delta t/2$. The distance to a planet (Venus) was measured for the first time in 1962 and, from this result, the value of the astronomical unit (the mean distance between Earth and the Sun) was calculated to a much higher precision than had previously been possible. The altitude of a spacecraft above any particular point on a planet's surface (and hence the heights of features on the planet's surface above or below the mean surface level) can be measured in a similar way.

If the target body is rotating, part of the reflected radar pulse will be reflected from the side of the planet that is approaching the observer and part from the side that is receding. Compared with the transmitted signal, the part that has been reflected from the 'approaching' side will be Doppler shifted to a higher frequency and the part from the 'receding' side Doppler-shifted to a lower frequency. The spread of frequencies in the returning signal, therefore, provides information on the rotation rate of the target body. This technique enabled the retrograde rotation period of cloud-covered Venus to be determined in 1962 and the 59-day rotation period of Mercury to be determined in 1965.

Detailed mapping of the surface topography of Venus has been carried out using ground-based radar and radar instrumentation carried on a succession of spacecraft that have been placed in orbit round that planet, including Pioneer Venus (1978), Veneras 15 and 16 (1983) and Magellan (1990–4). The key to achieving high-resolution radar mapping is synthetic aperture radar (SAR), a technique that uses the movement of the spacecraft in the time interval between the transmission of the signal and the return of its 'echo' to simulate the performance of a 'dish' much larger than the onboard radar dish. By this means, the Magellan mission achieved best resolutions of about 120 m on the surface of Venus. Radar techniques have been used to study meteors, planets, satellites, comets and asteroids.

Radial Velocities

The radial velocity of a star is the component of its motion along the line of sight to the observer. A typical value for the radial velocity of a star in the solar neighborhood is 10–20 km s^{-1}. The early work with radial velocities, dating back more than 100 yr, is reviewed in the first section of this article. Then the efforts over the past 25 yr to survey many thousands of stars with correlation techniques are described, together with examples of applications to Galactic structure and to studies of the frequency and characteristics of spectroscopic binaries. Recent efforts to achieve velocity precisions better than 10 m s^{-1} are outlined next, along with their successful use for the discovery of extrasolar planets. The final section speculates about the future of radial velocity research, especially in conjunction with space astrometric missions.

Early radial-velocity work

The measurement of stellar radial velocities has a long and rich history. KIRCHHOFF and Bunsen electrified the scientific and intellectual world in 1862 with their wonderful demonstration that spectral analysis could be used to unlock the chemistry of the Sun and stars. Doppler and Fizeau had already proposed, independently in 1842 and 1848, that the motion of a star along the line of sight would introduce a shift in its spectral features, such as the dark Fraunhofer absorption lines, according to the formula[1]

$$\frac{\lambda - \lambda_0}{\lambda_0} = \frac{v}{c} \qquad (1)$$

and Kirchhoff and Bunsen's discoveries inspired several stellar spectroscopists to look for Doppler shifts in the spectra of stars.

For example, at his private observatory in England, the great spectroscopist SIR WILLIAM HUGGINS compared the position of a prominent hydrogen emission line from a Geissler tube with the position of the corresponding hydrogen absorption line in the spectrum of Sirius. Huggins reported the detection of a Doppler shift for Sirius in 1868, but his result was off by more than 50 km s^{-1} and did not even have the correct sign; Sirius is moving towards the solar system, not away from it. Except in the hands of JAMES KEELER with the great 36 in refractor at the Lick Observatory on Mt Hamilton in California, visual spectroscopy was unable to achieve the precision needed to make sense out of the radial velocities of nearby stars.

A breakthrough in this field came with the application of photography to stellar spectroscopy, which led to an order-of-magnitude improvement in the precision of the measurements. HERMANN CARL VOGEL at Potsdam pioneered the use of dry plates for radial-velocity work and was able to achieve a precision of 2 or 3 km s^{-1} for bright stars.

Leadership in this field soon moved to the Lick Observatory, where WILLIAM WALLACE CAMPBELL had taken over the reins from Keeler. With generous long-term financial support from D O Mills, Campbell and his staff were able to undertake an ambitious survey of all the stars brighter than visual magnitude 5.5, first with the 36 in refractor in the north, and subsequently with a 36 in reflector at a southern station near Santiago in Chile. For solar-type stars the precision of their measurements was about 1 km s^{-1}, more than good enough for studies of Galactic structure, and well suited for solving the orbits of SPECTROSCOPIC BINARY STARS. The great catalog reporting the results of this work was published by Campbell and Moore in 1928, with center-of-mass velocities listed for 57 spectroscopic binaries among the 2771 stars in the catalog.

Photographing stellar spectra for the purpose of measuring radial velocities continued to be a major enterprise at several observatories on the North American continent up through the time of the Second World War, especially with the telescopes at the Mt Wilson Observatory, built by GEORGE ELLERY HALE. The fruits of these labors were summarized in 1953 by Ralph E Wilson in a catalog of mean radial velocities for more than 20 000 stars, with the Mt Wilson and Lick Observatories contributing more than half of the total between them.

Radial-velocity measurements using correlation techniques

In that same year, 1953, a revolutionary new approach to measuring stellar radial velocities was proposed by Peter Felgett. One of the main goals of the new scheme was to take advantage of the much higher quantum efficiency of photoemissive cathodes, which offered a gain of at least a factor of 10 compared with photography. The best photographic emulsions were barely able to register 1% of the incident light, even when hypersensitized for the low light levels encountered in ASTRONOMICAL SPECTROSCOPY. Felgett's second idea was to measure many FRAUNHOFER LINES simultaneously, thus gaining a major advantage over the traditional procedure of measuring the positions of only a small number of lines carefully selected to be unblended.

Correlations using a physical mask

Felgett's ideas were implemented by Roger F Griffin with a new instrument at the Cambridge Observatory. A physical mask containing 240 fine slots, chosen to match selected absorption lines in the spectrum of the K2 giant ARCTURUS, was placed at the focus of the spectrometer, and the light passing through the slots was gathered onto the cathode of a photomultiplier tube. By driving the mask back and forth in the dispersion direction with a micrometer, it was possible to determine the shift of the mask that gave the best match to the stellar spectrum being observed. The shift of the mask could then be converted into a Doppler shift using a calibration curve. Griffin used this

[1] Where c is the speed of light, v is the velocity of the star along the line of sight to the observer, λ_0 is the wavelength measured in the laboratory for a chosen spectral feature and λ is the wavelength observed for the same feature in the spectrum of the star. A negative velocity, or blueshift, indicates that the star is approaching the observer.

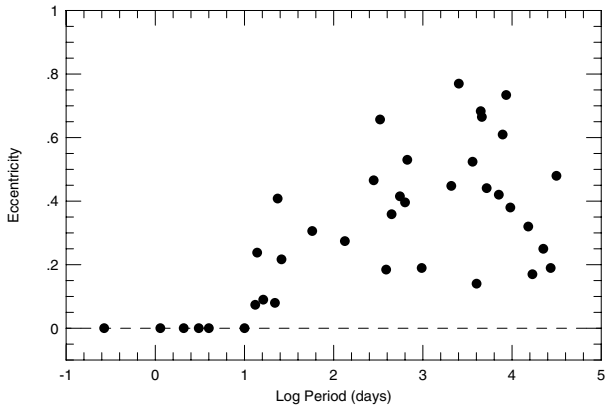

Figure 1. Eccentricity versus log(period) for the stellar companions orbiting nearby solar-type stars.

instrument for nearly 30 yr to monitor the radial velocities of thousands of stars. One of the main achievements of this work was a series of more than 150 papers on the orbits of spectroscopic binaries.

Similar instruments with physical masks were put into operation at several other observatories, including the Dominion Astrophysical Observatory near Victoria, British Columbia, and the 200 in Hale Telescope on Palomar Mountain. Especially noteworthy were the CORAVELs, operated for many years by a team led by Michel Mayor at the Geneva Observatory, both on the 1 m Swiss telescope at the Observatoire de Haute Provence in France and on the 1.5 m Danish telescope at the European Southern Observatory (ESO) on La Silla in Chile. These two, nearly identical, instruments also used physical masks, but were based on a spectrometer design that employed a cross-dispersed echelle grating. This provided significantly larger spectral coverage than Griffin's spectrometer, with the result that the CORAVELs could go fainter, easily reaching to visual magnitude 13. Altogether the two CORAVELs accumulated 286 181 measurements of 60 811 stars, with velocity precisions mostly in the range 0.3–1.0 km s^{-1}.

The CORAVELs were used to study pulsating stars, the memberships and kinematics of stars in clusters, and especially the frequency and orbital characteristics of spectroscopic binaries in a variety of stellar populations, including open clusters and globular clusters. Perhaps the most famous result from the CORAVELs was a comprehensive summary of the stellar companions found in a volume-limited sample of 164 solar-type dwarfs within 22 pc of the Sun. Figure 1 shows the distribution of eccentricity versus period for the binaries in this sample with orbital solutions. Notice that there is a transition at about 10 days. For longer periods the orbital eccentricity shows a wide distribution with a median value of about 0.3, but for periods shorter than 10 days the orbits all have very small eccentricities, presumably because they have been circularized by tidal mechanisms.

In addition to measuring radial velocities, it was possible to calibrate the shape and area of the cross-correlation dips produced by the CORAVELs, in order to derive rotational velocities up to about $v \sin i = 50$ km s^{-1}, and even metallicities.

Correlations with digital template spectra

Physical-mask instruments suffer from the disadvantage that the detector provides just a single channel. Only one wavelength can be registered at a time, as the mask is scanned through the range of Doppler shifts expected for the star. This shortcoming can be overcome by using an imaging detector directly at the focal plane of the spectrograph to record simultaneously all the wavelengths in the spectrum, in just the same way that photography was used to make a spectrogram, except that a modern digital detector can now be used. The determination of the Doppler shift can then be carried out digitally in software by cross-correlating a template spectrum against the observed spectrum.

Perhaps the most dramatic advantage of this approach is that silicon diode arrays, such as large-format CHARGE-COUPLED DEVICES (CCDs), can be used as the detectors, and these can have detective quantum efficiencies that are so good that they detect nearly all the incident light over a wide range of wavelengths from the ultraviolet to the near infrared. Also, with the advent of large array detectors with good sensitivity in the near infrared, this approach can now be extended to considerably longer wavelengths.

A second advantage of digital cross-correlations is that the template spectrum can be chosen after the fact from a large library of templates and thus can be optimized to match the temperature, rotational velocity, metallicity and surface gravity of the target star. If better templates become available, or better software is developed, then the analysis can be carried out all over again from scratch. With a physical mask spectrometer, you are stuck with the pattern of slots that was built into the mask.

The digital speedometers developed at the HARVARD–SMITHSONIAN CENTER FOR ASTROPHYSICS (CfA) are early examples of instruments designed to use digital correlation techniques. They used photon-counting intensified Reticons for the detectors, and normally recorded about 50 Å centered near 5187 Å in a single order of an echelle spectrograph. Operationally the photon-counting Reticons had the advantage that they provided a real-time display of the incoming count rates and of the spectrum as it accumulated. This was useful for optimizing the telescope guiding and for deciding when to end an exposure. However, because of the limited spectral coverage and a peak detective quantum efficiency of not much more than 10%, these detectors fell far short of what is now obtainable with CCDs.

To calibrate the wavelength scale, every observation of a stellar spectrum with the CfA digital speedometers is bracketed by an exposure of a thorium–argon hollow-cathode lamp. This naturally establishes the scale for converting a wavelength shift to a Doppler shift, but it

Copyright © Nature Publishing Group 2001

leaves open the possibility of a systematic error in setting the zero point of the velocity system. Exposures of the dawn and dusk sky are obtained every night, and these are used to monitor the velocity zero point (the actual radial velocity of the Sun can be calculated very accurately for any given observatory and time, from the known orbit and rotation of the Earth). As a double-check on the velocity zero point, more than a thousand observations of several dozen minor planets have been made over the years (absolute radial velocities can be calculated very accurately from the known astrometric orbits of the minor planets). The velocity zero point based on minor planet observations agrees with the dawn and dusk sky calibration within about 100 m s^{-1}.

Initially the CfA digital speedometer spectra were analyzed using observed spectra as the templates. Subsequently a large library of more than 60 000 synthetic spectra was calculated by Jon Morse using Kurucz model atmospheres. Not only did this make it possible to choose an optimum template during the reductions, but it also opened up the possibility of determining temperatures, rotational velocities up to about $v \sin i = 140$ km s^{-1}, metallicities and even surface gravities from the same spectra. Another important advantage of having a closely spaced grid of synthetic template spectra came in the analysis of composite spectra, such as the spectra of double-lined spectroscopic binaries, using a two-dimensional correlation technique, TODCOR. The choice of templates for the primary and secondary stars could be optimized simultaneously for the TODCOR analysis.

Three nearly identical CfA digital speedometers were put into operation, on the 1.5 m Wyeth Reflector at the Oak Ridge Observatory in the town of Harvard, Massachusetts, and on the 1.5 m Tillinghast Reflector and MMT, both located at the F L Whipple Observatory atop Mt Hopkins, Arizona. With the MMT it was possible to reach stars as faint as visual magnitude 16. Altogether nearly 200 000 radial velocities have been measured with the CfA digital speedometers, with velocity precisions mostly in the range 0.5–1.0 km s^{-1}.

A major application of the CfA digital speedometers was a study of the structure and early history of the Galaxy using a sample of nearly 1500 nearby stars selected for high PROPER MOTION. An example of how these observations were used to study the relationship between kinematics and chemistry is shown in figure 2, which plots the Galactic V velocity (the component in the direction of Galactic rotation, relative to the local standard of rest) versus metallicity, [m/H] (the logarithm of the metal-to-hydrogen ratio compared with the Sun). The broad distribution of stars centered near $V = -210$ km s^{-1} and [m/H] $= -1.5$ is the halo population, the first generation of stars that formed even as the Galaxy was still collapsing out of a vast intergalactic cloud composed of metal-poor gas and dust. These stars are distributed roughly in a giant sphere centered on the Galaxy, and on average they do not participate in the rotation of the Galaxy. As the Sun passes them by in its circular orbit around the center of the Galaxy, the halo stars appear to be streaming past us into the solar system's wake. The more concentrated distribution of stars near $V = 0$ and [m/H] $= 0$ is the disk population, stars that lie in a highly flattened disk and orbit the center of the Galaxy along with the Sun. These stars formed after the Galaxy had collapsed into its present disk configuration and after the interstellar medium had been enriched by initial generations of massive stars that finished their lives quickly and spewed metals from their interiors, where they were created by nuclear reactions, back into the raw material for the next generation of stars.

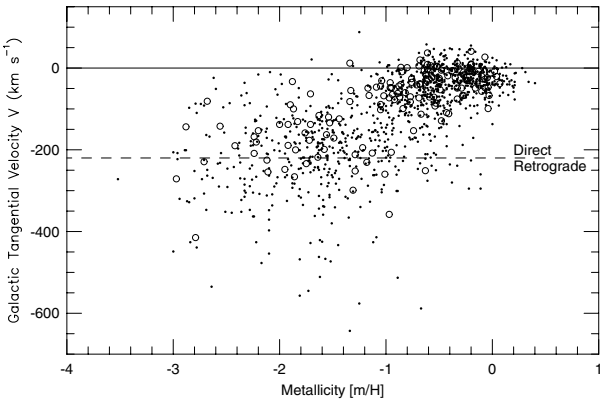

Figure 2. Galactic V velocity versus metallicity for the stars in a large sample selected for high proper motion. The single-lined binaries are plotted as open circles, the stars without detected velocity variations are plotted as small filled circles.

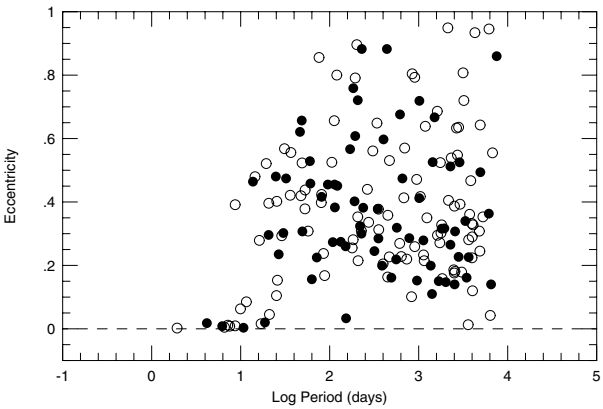

Figure 3. Eccentricity versus log(period) for the spectroscopic binaries in the proper-motion sample. The halo stars are plotted as filled circles, the disk stars as open circles.

Long-term monitoring of the radial velocities of the stars in the proper-motion sample over a span of more than 15 yr revealed that the frequency and orbital characteristics of spectroscopic binaries are pretty much the same for solar-type dwarfs in the halo as in the disk populations of the Galaxy. Figure 3 shows the distribution of eccentricity versus period for all the binaries with orbital solutions in the proper-motion sample. The halo stars are plotted as

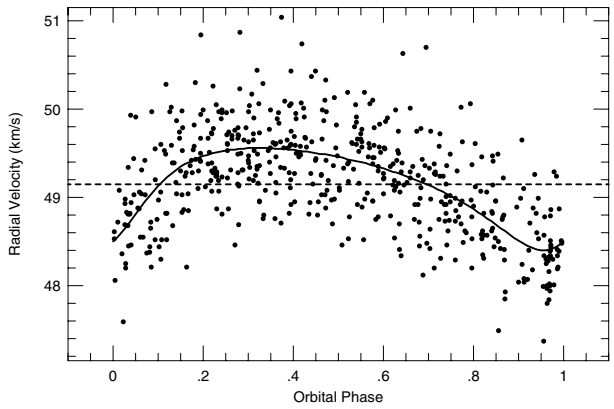

Figure 4. The orbital solution for HD 114762. The theoretical velocity curve is plotted as a solid line, the individual velocity measurements from the CfA digital speedometers are plotted as filled circles.

filled circles and the disk stars as open circles. The two populations show similar distributions, with the exception that the transition from circular to eccentric orbits occurs at a longer period for the halo binaries because they are older and tidal circularization has managed to reach out to binaries with wider separations and longer periods.

Together with the CORAVELs, the CfA digital speedometers have been used to monitor large samples of solar-type stars, from which optimum targets have been selected for extrasolar planet searches and searches for extraterrestrial intelligence (SETI), namely targets without evidence for a companion star that would interfere with the formation and/or survival of planets in the habitable zone.

A prophetic discovery, made with observations jointly from the CfA digital speedometers and the CORAVELS, was the detection in 1988 of an unseen low-mass companion orbiting the solar-type star HD 114762. This target had been especially well observed by both teams because it was one of the INTERNATIONAL ASTRONOMICAL UNION (IAU) radial-velocity standard stars. The mass of the companion could be as small as 10 Jupiter masses (M_J) if the orbit happens to be oriented edge-on to the line of sight (the orbital inclination cannot be determined from radial-velocity observations alone). The orbital characterisitic of this companion that dissuaded most astronomers from thinking it could be a giant planet was the relatively short period, $P = 84$ days. This implied that the companion was orbiting too close to the parent star to have formed the way that giant planets were thought to form, by core accretion in the icy regions of the stellar system, out beyond the snow line. Figure 4 shows the velocity curve for HD 114762's orbital solution, together with the velocities observed with the CfA digital speedometers. The observed velocities show a scatter that is similar to the amplitude of the orbital motion, but the solution is secure and gives reliable parameters because many cycles have been covered with a large number of observations.

Very precise radial velocities

A proper exploration of the realm of extrasolar planets using stellar radial velocities required the development of a new generation of instruments: ultrastable echelle spectrographs coupled to large-format CCDs as the detectors. Two examples of such instruments are the High Resolution Echelle Spectrograph (HIRES) built by Steven S Vogt for the Keck I telescope on Mauna Kea in Hawaii and ELODIE built by Michel Mayor's team for the 1.93 m reflector at the Observatoire de Haute Provence in France. With these instruments it is possible to record enough photons in a single CCD spectrogram of a slowly rotating solar-type dwarf so that the photon-noise limit to the determination of the Doppler shift is only a few m s^{-1}. At this level of precision, where the shift of the system of absorption lines must be determined to less than one-thousandth of the width of a typical line, it is the systematic drifts and image distortions in the spectrograph that set the most difficult limitations.

Gas absorption cells

Two different approaches have been developed for monitoring the spectrograph drifts so that systematic errors in the velocities can be corrected to better than 10 m s^{-1}. The first technique was pioneered by a Canadian team, who used a hydrogen-fluoride gas absorption cell to impress many sharp absorption lines of known wavelength on each stellar spectrum. An improvement of this technique was developed by R Paul Butler and Geoffrey W Marcy. For the absorbing gas they chose to use iodine, which has a rich spectrum of lines in the region 5000–6000 Å.

One approach to the reduction of these spectra is to use a very-high-resolution Fourier transform spectrometer (FTS) scan of the iodine lamp to model the temporal and spatial variations of the instrumental profile of the spectrograph. A high-quality spectrum of each star without the iodine absorption lines is also needed, to serve as a template, and velocities relative to the template are then determined for each stellar spectrum taken with the iodine gas absorption cell. With careful attention to the characteristics of the CCD readout electronics and detailed modeling of the instrumental profile, it has been possible to achieve a precision of a few m s^{-1} with HIRES. A version of the two-dimensional cross- correlation technique TODCOR has also been used to analyze stellar spectra taken with the iodine gas absorption cell and HIRES and has achieved a precision of 10 m s^{-1}.

Optical fiber feeds

A second approach for achieving very high precision is to use optical fibers to scramble the stellar light as it is fed onto the spectrograph slit and to monitor the drifts in the spectrograph during a stellar exposure using a simultaneous exposure of a thorium–argon comparison lamp. This approach has the advantage that it can provide wider spectral coverage than the limited window over which iodine absorption lines are available, at the cost of

minor light loses in the optical fibers. This approach has been used both with ELODIE and with CORALIE on the 1.2 m Swiss telescope at ESO on La Silla. These instruments can both produce velocities with a precision of better than 10 m s^{-1}.

The speed of the Earth in its annual orbit around the Sun is nearly 30 km s^{-1}, and the daily rotation amounts to about 0.5 km s^{-1} at the Earth's equator. When reporting a radial velocity, it has been customary to remove these motions and to state the velocity relative to the Sun. Now that it is feasible to measure velocities with precisions of a few m s^{-1}, additional motions must also be taken into account, including the monthly orbit of the Earth and Moon and the orbits of the other planets in the solar system. In particular, the gravitational pull of Jupiter causes a reflex motion in the Sun of about 12 m s^{-1} with a period of about 12 yr. Thus, for very precise work it is necessary to refer radial velocities to the center of mass, or BARYCENTER, of the solar system.

Extrasolar planets

Most of the excitement in stellar radial-velocity research during the 1990s was the discovery of dozens of extrasolar planets orbiting nearby solar-type stars (see EXTRASOLAR PLANETARY COMPANIONS AND BROWN DWARFS). Perhaps the biggest surprise was the announcement in 1995 of a Jupiter-sized companion orbiting 51 Pegasi with a period of only 4 days. This placed the companion in a very tight orbit, 20 times smaller than the Earth's orbit around the Sun, and led to the development of new theoretical ideas for how to get giant planets to migrate inward from where they originally formed out beyond the snow line. The problem of how to stop the migration and park the planet in an orbit like that of 51 Pegasi remained unsolved.

A particularly significant discovery was the detection in 1999 of transits for the planet orbiting the solar-type star HD 209458. This marked the opening of a new era in extrasolar planet research, when the physical characteristics of extrasolar planets could be studied in detail. By measuring the amount of dimming the parent star undergoes as the planet transits in front of the star, it is possible to deduce how much of the stellar surface is being shadowed, which allows the radius of the planet to be determined, assuming the radius of the star can be estimated accurately. Moreover, from the shape of the light curve it is possible to deduce the exact inclination of the planet's orbit, thus eliminating any ambiguity in the mass of the planet. In turn this makes it possible to deduce the bulk density of the planet, simply by dividing the mass by the volume.

In the case of the planet orbiting HD 209458, the mass is $0.69 M_J$, the radius is $1.40 R_J$ and the density works out to be 0.31 g cm^{-3}, about one-third the density of water. This implies that the planet must be made mostly of gas, more or less like Jupiter and Saturn, but puffed up by the intense heating due to its close proximity to its parent star. However, despite this heating, the gravity of the planet is strong enough to keep its atmosphere from boiling away. The escape velocity from the planet's surface works out to about 40 km s^{-1}, while the typical thermal velocity for an atom in the planet's atmosphere is only a few km s^{-1}. The prospects for learning more about this planet are fascinating. For example, astronomers expect to be able to study the atmosphere of the planet by observing the absorption lines that are introduced into the spectrum of the parent star during transits, when the planet passes between us and the star and some of the starlight passes through the planet's atmosphere. Another possibility is to look for the light reflected from the surface of close-in giant planets and to measure radial velocities from the Doppler shift of the reflected stellar absorption lines.

Another important development was the discovery in 1999 of two more planets orbiting υ Andromedae, in addition to the close-in giant planet reported in 1996, making this the first planetary *system* to be discovered around a solar-type star. The outer two planets are more massive than Jupiter, and their orbits are more eccentric and smaller than that of Jupiter, so the υ Andromedae system does not look anything at all like our own solar system. Nevertheless, this is path-breaking progress towards understanding the characteristics of systems of extrasolar planets and whether or not our own system is unusual (see also EXOPLANETS).

Future developments for radial-velocity research

So far, we have not detected any true Jupiters, planets the size of Jupiter orbiting with periods of 10 or 20 yr. This does not mean that such systems do not exist. It does not mean that the configuration of our solar system is unique, with the terrestrial planets huddled in close to the parent star and the giant planets patrolling the outskirts, warding off incoming intruders such as asteroids or comets that might be instruments of mass extinction. Such a conclusion is premature, because we have so far barely achieved the Doppler precision that is needed to detect a true Jupiter, and with few exceptions the observations do not yet cover long enough time spans. Both these shortcomings are being addressed. New and better instruments and techniques are being developed. Gradually enough additional data with sufficient time coverage will be accumulated to detect true Jupiters.

It is not yet clear what the ultimate limit to the precision of stellar radial velocities will be. The limit may already have been reached for stars rotating more rapidly than a few km s^{-1} in $v \sin i$, where the velocity residuals are often larger than 10 m s^{-1}, perhaps because of stellar spots that distort the stellar line profiles as the star rotates. For giant stars there is good evidence that some astrophysical phenomena, such as oscillations in the stellar atmospheres, are the source of significant velocity jitter, often exceeding 1 km s^{-1} for the most luminous evolved stars. For well-behaved solar-type dwarfs that are hardly rotating and have no unusual surface activity, the ultimate limit to the velocity precision may turn out to be smaller than 1 m s^{-1}. Instruments that should be able to reach that level of precision are now under development.

The future of radial-velocity research will be intimately connected with the success of space astrometric missions, such as the Full-Sky Astrometric Mapping Explorer (FAME) and the Space Astrometric Mission (SIM) under development by the National Aeronautics and Space Administration (NASA). In the case of the European Space Agency's (ESA's) Global Astrometric Interferometer for Astrophysics (GAIA) there are even plans to include the capability to measure radial velocities of millions of stars, although the velocity precision cannot be much better than a few km s^{-1} because of photon starvation.

Data from the space astrometric missions will usher in a new era in the study of the structure and kinematics of the Galaxy and of stellar subsystems such as star-forming regions and clusters. Radial velocities will be an important part of this research, because they can be combined with proper motions and distances to derive space motions for literally millions of stars.

Another important area of study for the space astrometric missions will be the characterization of extrasolar planets. For most of the planets discovered by radial-velocity observations it should be possible to derive the orbital inclinations using ASTROMETRY, thus removing the ambiguity about the actual masses of the planets. Astrometry can also look for evidence of outer planets with orbital velocities too small to be detected using radial velocities. When applied to systems with known radial-velocity planets in short-period orbits, astrometry should be able to explore what kind of systems those planets come in.

Despite all the excitement about the discovery of extrasolar planets and the outstanding prospects for learning more about the characteristics of these planets and their systems in the coming years, one should not forget that we have a lot more to learn about the frequency and orbital characteristics of stellar companions in a variety of populations, building on the good progress in this field over recent years. Indeed, a full understanding of how and where planets form and evolve will also require a fuller understanding of the formation and evolution of stellar companions. Only then can we hope to understand how stars decide whether they will have planets or stars for companions.

Radiant

The point on the celestial sphere from which the meteors of a particular meteor shower all appear to diverge. Meteoroids in a particular meteor stream impinging on the Earth's atmosphere do so on essentially parallel paths. That they appear to an observer to radiate from a single point is an effect of perspective. Some showers have more than one radiant, representing different strands of meteoroids within the meteor stream. Radiants move eastward at a rate of 4 min of RA per day as a result of the Earth's orbital motion.

Radiation

The emission and propagation through space of electromagnetic energy (photons) or subatomic particles. Electromagnetic radiation, of which visible light is an example, can be regarded as a wave-like disturbance that travels through space at the speed of light, 300 000 km s^{-1}; it may also be regarded as a stream of particles, 'packets' of energy called photons. Examples of particle radiation include alpha and beta 'radiation' resulting from radioactivity, the solar wind, and cosmic rays. High-energy subatomic particles or electromagnetic radiation (gamma rays and x-rays) cause ionization and are harmful to living tissue. Most of the ionizing radiation absorbed by living creatures at the surface of the Earth comes from natural radioactivity and cosmic rays.

Electromagnetic radiation may be emitted or absorbed in a variety of ways. In general, any electrically charged particle will emit or absorb radiation when it is accelerated or oscillated. For example, if an electron moving freely through a gas, makes a close encounter with an ion, and is not captured by that ion, its kinetic energy will be changed by a finite amount, the change in energy corresponding to the emission or absorption of a photon (a 'packet' of electromagnetic energy). Radiation emitted in this way is called free–free radiation (the electron moves freely before and after the encounter). When a large number of electrons and ions are involved in these kinds of encounters (the assemblage of ions and electrons is called a plasma), their individual free–free emissions add together to produce a continuous spectrum, or continuum, of radiation. Because the temperature of the plasma determines the energies of the electrons, radiation produced in this way is often called thermal emission.

If a freely moving electron is captured by an ion, the kinetic energy that it loses is radiated away as a photon. Electromagnetic energy released in this way is called free–bound radiation (the electron, which was moving freely before the encounter, ends up bound to the ion). Again, where a large number of electrons are involved, with a spread of kinetic energies, free–bound emission takes place over a wide range of wavelengths, so producing a continuous spectrum. An electron that is bound to an atom exists in one of a restricted number of possible energy levels. If an electron drops from a higher to a lower energy level, it emits a photon of energy equal to the difference between the two levels; this corresponds to the emission of light of one particular wavelength. The various possible transitions (changes in level) correspond to emissions (or absorptions) at a discrete set of wavelengths and give rise to various series of emission or absorption lines. Electron transitions of this kind are called bound–bound transitions (the electron remains bound to the atom before and after the transition) and the resulting radiation is sometimes referred to as bound–bound radiation.

Radiative Transfer

Astronomy is an observational science and astronomers rely mostly on the electromagnetic radiation emitted by cosmic sources. Indeed over 95% of the information comes from observed radiation, with the remaining 5% coming from COSMIC RAYS, METEORITES, NEUTRINOS and possibly GRAVITATIONAL WAVES. Before reaching an observer, the radiation has interacted with matter in the source and in the intervening space between the source and observer. Understanding the interaction with and transport of radiation through matter is crucial for astronomers to interpret the observations. Radiative transfer deals with the propagation and interaction of radiation with matter.

When radiation passes through a region of space containing gas particles and dust grains, energy is generally removed from the beam either by absorption or by scattering. In addition, the material in a medium may emit radiation, with the source of energy coming from the internal energy of excitation or indirectly from the kinetic energy of motion. In scattering, the photon energy is only slightly altered (energy transferred to the internal energy of the scatterer) and is not being converted into the kinetic or thermal energy. In general scattering does not couple the radiation field to the thermodynamic properties of the medium. Examples of scattering are: Thomson or Compton scattering by electrons, Raman or Rayleigh scattering by molecules and coherent scattering by dust grains. On the other hand, in absorption the photon energy is being converted into kinetic energy or thermal energy. Radiation is coupled to the thermodynamic properties of the medium. Examples of absorption are photoionization of gas particles, bremsstrahlung of free electrons and absorption of radiation by dust grains (see also PHYSICS OF MOLECULES, SOLAR SPECTROSCOPY: ATOMIC PROCESSES).

The theory of radiation transport has many applications. Some important applications in astrophysics include: (a) formation of spectral lines and continuum radiation in STELLAR ATMOSPHERES, (b) excitation mechanisms of interstellar molecular lines and cosmic masers, (c) interpretation of dust spectral features in the energy spectrum of circumstellar envelopes and molecular clouds, (d) modeling PLANETARY ATMOSPHERES, and (e) ionization and thermal structures of HII REGIONS. Some applications in physics and engineering include: (a) neutron transport in nuclear reactors, (b) radiation hydrodynamics in nuclear explosions, and (c) GREENHOUSE EFFECTS in the Earth's atmosphere.

Basic concepts and definitions

To understand the theory of radiation transport, we first introduce a few basic concepts and definitions.

Description of radiation field

Microscopically a radiation field is simply an ensemble of photons. A photon may be described as a point particle of zero mass which moves with constant speed c in free space. It has spin 1 and obeys Bose–Einstein statistics. At any time t, we may represent a photon as a point in phase space, characterized by six phase-space variables: (a) three spatial coordinates (components of position vector $\boldsymbol{r}$) which specifies the location in some reference frame, (b) two angular variables (direction cosines of direction unit vector $\widehat{\Omega}$) which denotes the direction of propagation, and (c) a frequency ν such that the photon has energy $h\nu$ and momentum $h\nu/c$, where h is the Planck constant. Hence a radiation field is a function of $\boldsymbol{r}$, t, $\widehat{\Omega}$ and ν. We often specify $\widehat{\Omega}$ by a polar angle θ and an azimuthal angle ϕ. The components of $\widehat{\Omega}$ in Cartesian coordinates are known as *direction cosines*: $\widehat{\Omega} = \Omega_x\widehat{\boldsymbol{x}} + \Omega_y\widehat{\boldsymbol{y}} + \Omega_z\widehat{\boldsymbol{z}}$, where $\Omega_x = \sin\theta\cos\phi$, $\Omega_y = \sin\theta\sin\phi$, $\Omega_z = \cos\theta$, and $|\widehat{\Omega}| = \sqrt{\Omega_x^2 + \Omega_y^2 + \Omega_z^2} = 1$. Furthermore, $\widehat{\Omega}$ is related to the solid angle element $\mathrm{d}\Omega$ defined by

$$\mathrm{d}\Omega \equiv \frac{\mathrm{d}A}{r^2} = \frac{(r\sin\theta\,\mathrm{d}\phi)(r\,\mathrm{d}\theta)}{r^2} = \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi. \qquad (1)$$

When integrated over all directions, the total solid angle, measured in steradians (sr), is 4π.

Photon distribution function

To describe the radiation field as a statistical ensemble of photons, we define a photon distribution function $\Psi(\boldsymbol{r}, t; \widehat{\Omega}, \nu)$ such that

$$\mathrm{d}n = \Psi(\boldsymbol{r}, t; \widehat{\Omega}, \nu)\,\mathrm{d}V\,\mathrm{d}\Omega\,\mathrm{d}\nu \qquad (2)$$

is the number of photons at time t with frequency ν in a frequency interval $\mathrm{d}\nu$ located within a differential volume $\mathrm{d}V$ near a point $\boldsymbol{r}$ and traveling with speed c in a direction $\widehat{\Omega}$ in a solid angle element $\mathrm{d}\Omega$. In other words, Ψ is the number of photons at time t per unit phase-space volume (not spatial volume) centered at position $(\boldsymbol{r}, \widehat{\Omega}, \nu)$ in phase space. In general $\boldsymbol{r}$ and $\widehat{\Omega}$ are not specified by the same coordinate system. A radiation field is said to be homogeneous, stationary, isotropic or gray according to whether Ψ is independent of $\boldsymbol{r}$, t, $\widehat{\Omega}$ or ν. Blackbody radiation is an example of a homogeneous, stationary and isotropic radiation field.

In the KINETIC THEORY OF GASES, the particle distribution function f is usually defined such that $f(\boldsymbol{r}, t; \boldsymbol{p})\,\mathrm{d}\boldsymbol{p}$ is the number of particles per unit spatial volume at $(\boldsymbol{r}, t)$ with momenta in the range $(\boldsymbol{p}, \boldsymbol{p} + \mathrm{d}\boldsymbol{p})$. By noting that $\boldsymbol{p} = (h\nu/c)\widehat{\Omega}$ for photons and that the number of particles per unit spatial volume is the same irrespective of what distribution function we use, one can show that $\Psi = (h^3\nu^2/c^3)f$.

Specific intensity

Consider a beam of photons with frequency ν at a position $\boldsymbol{r}$ traveling in direction $\widehat{\Omega}$ (see figure 1). During a time interval $\mathrm{d}t$, the number of photons $\mathrm{d}n$ crossing an element of surface area $\mathrm{d}A$ which is oriented at an angle θ with $\widehat{\Omega}$ is simply $\mathrm{d}n = \Psi\,\mathrm{d}V\,\mathrm{d}\Omega\,\mathrm{d}\nu$, where $\mathrm{d}V$ is the differential volume swept through by those photons in crossing $\mathrm{d}A$ during $\mathrm{d}t$. Hence,

$$\mathrm{d}V = (c\,\mathrm{d}t)(\widehat{\Omega}\cdot\mathrm{d}\boldsymbol{A}) = (c\,\mathrm{d}t)(\cos\theta\,\mathrm{d}A) \qquad (3)$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

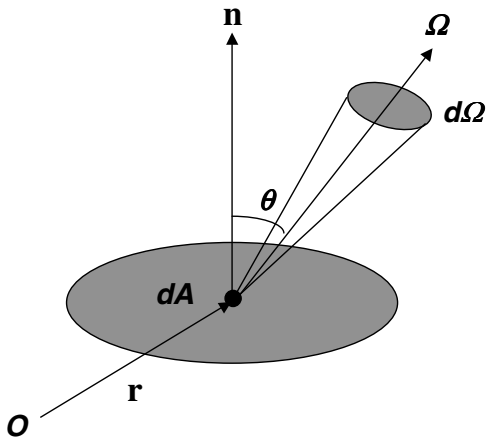

Figure 1.

$$\mathrm{d}n = \Psi(c\,\mathrm{d}t)(\cos\theta\,\mathrm{d}A)\,\mathrm{d}\Omega\,\mathrm{d}\nu. \tag{4}$$

The amount of energy transported across $\mathrm{d}A$ is then

$$\mathrm{d}E = (h\nu)\,\mathrm{d}n = (ch\nu)\Psi\cos\theta\,\mathrm{d}A\,\mathrm{d}\Omega\,\mathrm{d}\nu\,\mathrm{d}t. \tag{5}$$

The specific intensity $I(\boldsymbol{r}, t; \widehat{\Omega}, \nu)$ of radiation at position $\boldsymbol{r}$, traveling in direction $\widehat{\Omega}$, with frequency ν, at time t is defined as the amount of energy, per unit frequency interval, passing through a unit area oriented normal to the beam, into a unit solid angle, in a unit time, i.e.

$$I(\boldsymbol{r}, t; \widehat{\Omega}, \nu) \equiv \lim_{\mathrm{d}A,\,\mathrm{d}\Omega,\,\mathrm{d}\nu,\,\mathrm{d}t\to 0}\left(\frac{\mathrm{d}E}{\cos\theta\,\mathrm{d}A\,\mathrm{d}\Omega\,\mathrm{d}\nu\,\mathrm{d}t}\right). \tag{6}$$

The specific intensity is a scalar quantity with dimensions erg cm^{-2} sr^{-1} Hz^{-1} s^{-1}, and is spatially invariant in free space, i.e. independent of the distance between the source and the observer if there are no sources or sinks of radiation along the line of sight. Observationally, the quantity I can be measured approximately if a source is spatially resolved. Provided POLARIZATION effects can be ignored, the specific intensity completely describes the radiation field. From the above, we see that I and Ψ are related by $I(\boldsymbol{r}, t; \widehat{\Omega}, \nu) = ch\nu\Psi(\boldsymbol{r}, t; \widehat{\Omega}, \nu)$.

Characterization of radiation by either $I(\boldsymbol{r}, t; \widehat{\Omega}, \nu)$ or $\Psi(\boldsymbol{r}, t; \widehat{\Omega}, \nu)$ ignores the wave nature of radiation. Such a description is valid only if the uncertainty principle is satisfied. This condition implies that $\mathrm{d}A\,\mathrm{d}\Omega \geq \lambda^2$ and $\mathrm{d}\nu\,\mathrm{d}t \geq 1$.

Energy density and mean intensity

The energy density $E_R(\boldsymbol{r}, t; \nu)$ of radiation at frequency ν and at time t is defined as the amount of energy at position $\boldsymbol{r}$ per unit frequency interval $\mathrm{d}\nu$ per unit volume $\mathrm{d}V$

$$E_R(\boldsymbol{r}, \nu, t) = \oint \frac{\mathrm{d}E}{\mathrm{d}\nu\,\mathrm{d}V} = h\nu \oint \Psi(\boldsymbol{r}, t; \widehat{\Omega}, \nu)\,\mathrm{d}\Omega. \tag{7}$$

This is physically consistent since Ψ is the number of photons, per unit volume, of energy $h\nu$, propagating in direction $\widehat{\Omega}$ into intervals $\mathrm{d}\nu\,\mathrm{d}\widehat{\Omega}$, so that the energy density is just this number, multiplied by the energy per photon and summed over all solid angles. E_R is a scalar quantity and has dimensions erg cm^{-3} Hz^{-1}.

The mean intensity $J(\boldsymbol{r}, t; \nu)$ is defined as the average of the specific intensity over all solid angles, i.e.

$$J(\boldsymbol{r}, t; \nu) = \frac{1}{4\pi}\oint I(\boldsymbol{r}, t; \widehat{\Omega}, \nu)\,\mathrm{d}\Omega. \tag{8}$$

The mean intensity is the *zeroth angular moment* of the specific intensity. It is also a scalar quantity and has the same dimensions as specific intensity, erg cm^{-2} Hz^{-1} s^{-1} sr^{-1}. From the above, we see that

$$E_R(\boldsymbol{r}, t; \nu) = \frac{4\pi}{c}J(\boldsymbol{r}, t; \nu) \tag{9}$$

so that the mean intensity is basically a measure of the energy density.

Radiative flux

The radiative flux $\boldsymbol{F}(\boldsymbol{r}, t; \nu)$ at position $\boldsymbol{r}$, frequency ν, and time t is a vector defined as the net rate of energy flowing across a fixed surface of unit area in all directions per unit frequency interval (flow $\rightarrow$ direction)

$$\boldsymbol{F}(\boldsymbol{r}, t; \nu) = h\nu \oint \Psi(\boldsymbol{r}, t; \widehat{\Omega}, \nu)c\widehat{\Omega}\,\mathrm{d}\Omega \tag{10}$$

where $(c\widehat{\Omega})$ is just the velocity vector indicating the direction of photon propagation. For an arbitrarily oriented surface $\mathrm{d}\boldsymbol{A} = \widehat{\boldsymbol{n}}\,\mathrm{d}A$, $\boldsymbol{F}\cdot\mathrm{d}\boldsymbol{A}$ gives the net rate of energy flow across the surface $\mathrm{d}\boldsymbol{A}$ per unit frequency interval. The component of $\boldsymbol{F}$ in the direction $\widehat{\boldsymbol{n}}$ is just

$$\begin{aligned} F(\widehat{\boldsymbol{n}}) = \widehat{\boldsymbol{n}}\cdot\boldsymbol{F} &= \oint \frac{1}{\mathrm{d}A\,\mathrm{d}\nu}\left(\frac{\mathrm{d}E}{\mathrm{d}t}\right) \\ &= ch\nu \oint \Psi(\boldsymbol{r}, t; \widehat{\Omega}, \nu)\cos\theta\,\mathrm{d}\Omega \end{aligned} \tag{11}$$

where θ is the angle between $\widehat{\Omega}$ and the normal to $\mathrm{d}A$ ($\cos\theta = \widehat{\boldsymbol{n}}\cdot\widehat{\Omega}$). The net flux $F(\widehat{\Omega}')$ in the given direction $\widehat{\Omega}'$ can be written as (see figure 2)

$$F(\widehat{\Omega}') = F^+ - F^- \tag{12}$$

where $\left\{\begin{matrix} F^+ \text{ (outward net flux)} \\ F^- \text{ (inward net flux)} \end{matrix}\right\}$ represents the part of $F(\widehat{\Omega}')$ due to the radiation from the direction $\widehat{\Omega}$ such that $\widehat{\Omega}'\cdot\widehat{\Omega}\left\{\begin{matrix} > 0 \\ < 0 \end{matrix}\right\}$. Note that the amount of radiant energy per unit volume at a given point is characterized by energy density E_R whereas the direction and velocity of its flow at the point are given by the radiative flux $\boldsymbol{F}$. The radiative flux has dimensions erg cm^{-2} Hz^{-1} s^{-1}. It is the *first angular moment* of the radiation field. For an isotropic radiation field $\boldsymbol{F} = 0$. Observationally, if a source is spatially unresolved, we can measure only the flux, and the energy received falls off as the inverse square of the distance between the source and the observer.

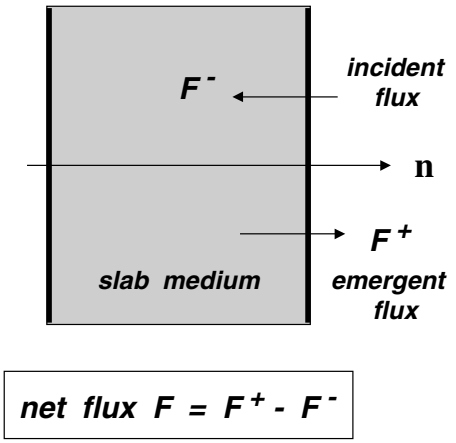

Figure 2.

Radiation pressure tensor

In the kinetic theory of gases, pressure at a given point is defined as the net rate of momentum transfer normal to an arbitrarily oriented surface of unit area at that point. The same definition applies to radiation field which is essentially a photon gas. In general, the radiation pressure tensor is defined as

$$\mathsf{P}(\boldsymbol{r}, t; \nu) = h\nu \oint \Psi(\boldsymbol{r}, t; \widehat{\Omega}, \nu)\widehat{\Omega}\widehat{\Omega}\, \mathrm{d}\Omega. \qquad (13)$$

Physically we may interpret the $i - j$ component of the radiation pressure tensor as the rate of momentum flow in the j-direction from radiation of frequency ν through a surface of unit area oriented perpendicular to the i-direction

$$P_{ij}(\boldsymbol{r}, t; \nu) = \oint (c\Omega_i)(h\nu\Omega_j/c)\Psi(\boldsymbol{r}, t; \widehat{\Omega}, \nu)\, \mathrm{d}\Omega \qquad (14)$$

where $(c\Omega_i)$ is the projected velocity in the i-direction and $(h\nu\Omega_j/c)$ is the momentum in the j-direction. $\mathsf{P}(\boldsymbol{r}, t; \nu)$ is a tensor of second rank and has nine components. It is the *second angular moment* of the radiation field. It has the same dimensions as energy density, erg cm^{-3} Hz^{-1}. It is symmetric, i.e. $P_{ij} = P_{ji}$, and obeys the trace relationship $\sum_i P_{ii} = P_{xx} + P_{yy} + P_{zz} = E_R$. For an isotropic radiation field, P is diagonal and isotropic

$$P_{ij} = \left\{ \begin{array}{ll} 0 & i \neq j \text{ (all off-diagonal terms are zero)} \\ \frac{1}{3}E_R & i = j \text{ (all diagonal terms are equal)} \end{array} \right\}. \qquad (15)$$

Note that for an isotropic radiation field $\mathsf{P} \neq 0$ while $\boldsymbol{F} = 0$.

Simplifications in 1D geometries

In most astrophysical problems, the following one-dimensional (1D) geometries are assumed:

(a) Planar or slab geometry: if one employs Cartesian (x, y, z) coordinates to specify $\boldsymbol{r}$ and introduces polar and azimuthal angles (θ, ϕ) to denote $\widehat{\Omega}$, 1D planar or slab geometry implies azimuthal independence and infinite extent in x and y, i.e. $\boldsymbol{r}$ is independent of x and y while $\widehat{\Omega}$ is independent of ϕ, so that $I(\boldsymbol{r}, t; \widehat{\Omega}, \nu)$ becomes $I(z, t; \mu, \nu)$, where $\mu = \cos\theta = \widehat{\Omega} \cdot \widehat{z}$.

(b) Spherical geometry: in spherical coordinates, the position vector $\boldsymbol{r}$ is specified by (r, Θ, Φ) while the direction $\widehat{\Omega}$ is specified in terms of the polar and azimuthal angles (θ, ϕ), now measured with respect to a unit vector $\widehat{r}$ in the radial direction. 1D spherical geometry implies that $\boldsymbol{r}$ depends only on r and is independent of Θ and Φ, while $\widehat{\Omega}$ is independent of ϕ so that $I(\boldsymbol{r}, t; \widehat{\Omega}, \nu)$ becomes $I(r, t; \mu, \nu)$, where $\mu = \cos\theta = \widehat{\Omega} \cdot \widehat{r}$.

In both geometries, $\widehat{\Omega} \rightarrow \mu$ so that $\widehat{\Omega}\widehat{\Omega} \rightarrow \mu^2$ and

$$\oint \ldots \mathrm{d}\Omega = \int_0^{2\pi} \ldots \mathrm{d}\phi \int_0^{\pi} \sin\theta\, \mathrm{d}\theta = 2\pi \int_{-1}^{+1} \ldots \mathrm{d}\mu. \qquad (16)$$

With these simplifications, the angular moments of the specific intensity can be written as

$$M^n(r, t; \nu) = \frac{1}{2} \int_{-1}^{+1} I(r, t; \mu, \nu)\mu^n\, \mathrm{d}\mu \qquad (17)$$

so that we have mean intensity $J = M^0$, *Eddington flux* $H = M^1$, K-integral $K = M^2$.

For 1D geometries, the angular distribution of a radiation field may be characterized by the scalar ratio $f \equiv K/J$, known as the *Eddington factor* or *anisotropy factor*.

$f \equiv K/J$	Radiation field anisotropy
$0 < f < 1/3$	Sideward peaking
$f = 1/3$	Isotropic or linearly anisotropic
$1/3 < f < 1$	Forward peaking

The assumption of $f = 1/3$ is known as the *Eddington approximation* which is valid for stellar interiors. In the outer layers of stellar atmospheres and for centrally heated sources, the radiation tends to stream radially and $f \rightarrow 1$. On the other hand, for externally illuminated sources (interstellar clouds embedded in the ambient interstellar radiation field) in which radiation tends to peak sideways and non-radially, $f < 1/3$.

Observational implications

The energy received from an unresolved astronomical source by a distant observer depends on the geometry of the source. The energy received, per unit area normal to the line of sight, from a differential area $\mathrm{d}A$ on the surface of the source with its normal $\hat{\boldsymbol{n}}$ making an angle θ with the observer's line of sight is

$$\mathrm{d}F = I\, \mathrm{d}\Omega = I(\hat{\boldsymbol{n}} \cdot \mathrm{d}\boldsymbol{A})D^{-2} = I\, \mathrm{d}A \cos\theta D^{-2} \qquad (18)$$

where $\mathrm{d}\Omega$ is the solid angle subtended by the surface element, D is the distance of the source from the observer

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

and I is the specific intensity emergent at the surface of the source.

Consider two sources of the same surface brightness I_0: one is a sphere of radius R and the other is a disk of radius R and half-thickness Z. In both cases $D \gg R$ or Z so that all rays from the source to the observer may be considered to be parallel. Below we show that if $R = Z$, $F_{\rm disk} \geq F_{\rm sphere}$ for all viewing angles.

For a spherically symmetric source of radius R, the surface element is just a differential annulus on the disk (projected image of sphere), i.e. $\hat{\boldsymbol{n}}\cdot\mathrm{d}\boldsymbol{A} = 2\pi r\,\mathrm{d}r = 2\pi(R\sin\theta)(R\cos\theta\,\mathrm{d}\theta)$ so that the flux received by a distant observer ($D \gg R$) from the visible face of the sphere is

$$F_{\rm sphere} = \int I(\hat{\boldsymbol{n}}\cdot\mathrm{d}\boldsymbol{A})D^{-2} = \left(\frac{R}{D}\right)^2 I\cos\theta\sin\theta\,\mathrm{d}\theta. \quad (19)$$

The upper limit of integration for θ is $\pi/2 = 90^\circ$ because we assume that $R \ll D$ so that all rays from the source to the observer may be considered to be parallel. For a sphere of uniform brightness I_0, this reduces to $F_{\rm sphere} = (\pi R^2/D^2)I_0$ which is independent of θ. Note that $\Delta\Omega \equiv (\pi R^2/D^2)$ is just the solid angle subtended by the source at the observer, so that $F_{\rm sphere} = I_0\Delta\Omega$.

For a disk of radius R, half-thickness Z, and with its symmetry axis making an angle θ with the line of sight, we can view the element area $\mathrm{d}A$ as having two components: $(\hat{\boldsymbol{n}}\cdot\mathrm{d}\boldsymbol{A})_{\rm face} = \cos\theta(r\,\mathrm{d}r\,\mathrm{d}\phi)$ for the planar surface of the disk and $(\hat{\boldsymbol{n}}\cdot\mathrm{d}\boldsymbol{A})_{\rm edge} = \sin\theta(\cos\phi R\,\mathrm{d}\phi\,\mathrm{d}z)$ for the curved surface of the disk edge. Hence the total flux received by a distant observer ($D \gg Z$ or R) is

$$F_{\rm disk} = \left(\cos\theta\int_{\phi=0}^{2\pi}\int_{r=0}^{R} I_{\rm face} r\,\mathrm{d}r\,\mathrm{d}\phi + R\sin\theta\int_{z=-Z}^{+Z}\int_{\phi=-\pi/2}^{\pi/2} I_{\rm edge}\cos\phi\,\mathrm{d}\phi\,\mathrm{d}z\right)D^{-2}. \quad (20)$$

For a disk of uniform surface brightness I_0, this reduces to $F_{\rm disk} = I_0\Delta\Omega$, where again $\Delta\Omega \equiv (\pi R^2\cos\theta + 4RZ\sin\theta)/D^2$ is the solid angle subtended by the total projected area of the disk. Compared to a sphere with the same I_0 and R, and if $R = Z$, the ratio of observed fluxes for the two geometries is just given by the ratio of their projected areas

$$\frac{F_{\rm disk}}{F_{\rm sphere}} = \frac{\pi R^2\cos\theta + 4R^2\sin\theta}{\pi R^2} \Rightarrow 1 \leq \frac{F_{\rm disk}}{F_{\rm sphere}} \leq \frac{4}{\pi} \quad (21)$$

which indicates that $F_{\rm disk} \geq F_{\rm sphere}$ for all viewing angles.

Equation of radiation transport

To derive the equation of radiation transport, we introduce a few terms to quantify the physical processes of absorption, scattering and emission.

Basic definitions

When radiation passes through material, energy is generally removed from the beam either by pure absorption or by scattering. The sum of scattering and absorption is called extinction. In addition, the material in a medium may emit radiation.

Extinction coefficient The *volume extinction coefficient* χ is defined such that an element of material of cross section $\mathrm{d}A$ and length $\mathrm{d}s$, oriented normal to a beam of radiation having specific intensity $I(\boldsymbol{r}, t; \widehat{\Omega}, \nu)$ propagating along $\widehat{\Omega}$ into solid angle $\mathrm{d}\Omega$ within a frequency interval $\mathrm{d}\nu$, removes from the beam in a time $\mathrm{d}t$ an amount of energy

$$\mathrm{d}E_- = \chi(\boldsymbol{r}, t; \widehat{\Omega}, \nu)I(\boldsymbol{r}, t; \widehat{\Omega}, \nu)\,\mathrm{d}A\,\mathrm{d}s\,\mathrm{d}\Omega\,\mathrm{d}\nu\,\mathrm{d}t. \quad (22)$$

χ has the dimension of cm^{-1} and is given by the product of an extinction cross section $\sigma(\mathrm{cm}^2)$ and the number density of interacting particles $n(\mathrm{cm}^{-3})$ summed over all states that can interact with photons of frequency ν, i.e. $\chi = n\sigma$. Some authors use the term mass extinction coefficient κ which is related to χ by $\chi = \kappa\rho$, where ρ is the mass density. It can be shown that $1/\chi$ is the photon mean free path, defined as the average distance traveled by a photon before it is absorbed or scattered.

The extinction coefficient χ is made up of two contributions, pure absorption and scattering, with the corresponding coefficients χ^a and χ^s

$$\chi(\boldsymbol{r}, t; \widehat{\Omega}, \nu) = \chi^a(\boldsymbol{r}, t; \widehat{\Omega}, \nu) + \chi^s(\boldsymbol{r}, t; \widehat{\Omega}, \nu). \quad (23)$$

Emission coefficient The *volume emission coefficient* or simply *emissivity* η is defined such that the amount of energy released from a material element of cross section $\mathrm{d}A$ and length $\mathrm{d}s$, into a solid angle $\mathrm{d}\Omega$ around a direction $\widehat{\Omega}$, within a frequency interval $\mathrm{d}\nu$ in a time $\mathrm{d}t$ is

$$\mathrm{d}E_+ = \eta(\boldsymbol{r}, t; \widehat{\Omega}, \nu)\,\mathrm{d}A\,\mathrm{d}s\,\mathrm{d}\Omega\,\mathrm{d}\nu\,\mathrm{d}t. \quad (24)$$

η has units of erg cm^{-3} s^{-1} sr^{-1} Hz^{-1}, the same as specific intensity I. The emissivity may be isotropic in the rest frame of the material, but is anisotropic in the laboratory frame when the material moves.

The emission coefficient η can be represented as a combination of two different coefficients

$$\eta(\boldsymbol{r}, t; \widehat{\Omega}, \nu) = \eta^t(\boldsymbol{r}, t; \widehat{\Omega}, \nu) + \eta^s(\boldsymbol{r}, t; \widehat{\Omega}, \nu) \quad (25)$$

where η^t is the true or thermal emission coefficient and η^s is the scattering emission coefficient.

For a system in thermodynamic equilibrium, χ and η are related by *Kirchhoff's law* $\eta^*(\nu) = \chi^*(\nu)B(\nu, T)$, where $B(\nu, T)$ is the Planck function.

Source function The *source function* $S(\boldsymbol{r}, t; \widehat{\Omega}, \nu)$ is defined as the ratio of η and χ

$$S(\boldsymbol{r}, t; \widehat{\Omega}, \nu) \equiv \eta(\boldsymbol{r}, t; \widehat{\Omega}, \nu)/\chi(\boldsymbol{r}, t; \widehat{\Omega}, \nu) \quad (26)$$

so that from Kirchhoff's law $S(\boldsymbol{r}, t; \nu) = B(\nu, T)$ in thermodynamic equilibrium.

Optical depth The optical depth τ is defined as the volume extinction coefficient integrated over a path length

$$\tau \equiv \int \chi \, \mathrm{d}s. \tag{27}$$

Note that τ is a dimensionless quantity. A medium is said to be *optically thin* if $\tau \ll 1$ and *optically thick* if $\tau \gg 1$. In dimensionless units, a path length of one photon mean free path corresponds to $\tau = 1$.

Scattering and redistribution functions During scattering, there are changes in both direction and frequency of the radiation. These changes are described in terms of a *redistribution function* $R(\widehat{\Omega}', \nu'; \widehat{\Omega}, \nu)$ which is the probability of a photon in the frequency interval $(\nu', \nu' + \mathrm{d}\nu')$ in the direction $\widehat{\Omega}'$ within a solid angle $\mathrm{d}\Omega'$ being scattered in the direction $\widehat{\Omega}$ within solid angle $\mathrm{d}\Omega$ in the frequency interval $(\nu, \nu + \mathrm{d}\nu)$. More simply, it is the joint probability that a photon with direction and frequency $(\widehat{\Omega}', \nu')$ is absorbed and a photon with $(\widehat{\Omega}, \nu)$ is emitted. It satisfies the normalization condition

$$\left(\frac{1}{4\pi}\right)^2 \oint_{\Omega'} \mathrm{d}\Omega' \oint_{\Omega} \mathrm{d}\Omega \int_{\nu'} \mathrm{d}\nu' \int_{\nu} \mathrm{d}\nu R(\widehat{\Omega}', \nu'; \widehat{\Omega}, \nu) = 1. \tag{28}$$

If $\sigma_{\mathrm{sca}}(\boldsymbol{r}, t; \widehat{\Omega}, \nu)$ is the scattering cross section, and n is the number denisty of scatters, then the scattering emission coefficient η^s is given by

$$\eta^s(\boldsymbol{r}, t; \widehat{\Omega}, \nu) = n\sigma_{\mathrm{sca}}(\boldsymbol{r}, t; \widehat{\Omega}, \nu) \oint_{\Omega'} \frac{\mathrm{d}\Omega'}{4\pi} \int_{\nu'} \mathrm{d}\nu' \times [I(\boldsymbol{r}, t; \widehat{\Omega}', \nu') R(\widehat{\Omega}', \nu'; \widehat{\Omega}, \nu)]. \tag{29}$$

Similarly, the scattering coefficient χ^s is given by

$$\chi^s(\boldsymbol{r}, t; \widehat{\Omega}, \nu) = n\sigma_{\mathrm{sca}}(\boldsymbol{r}, t; \widehat{\Omega}, \nu)\varphi(\nu) \tag{30}$$

where we have defined a scattering profile $\varphi(\nu)$ as

$$\varphi(\nu) \equiv \oint_{\Omega'} \frac{\mathrm{d}\Omega'}{4\pi} \oint_{\Omega} \frac{\mathrm{d}\Omega}{4\pi} \int_{\nu'} \mathrm{d}\nu' R(\widehat{\Omega}', \nu'; \widehat{\Omega}, \nu). \tag{31}$$

For coherent scattering, $\nu = \nu'$, the redistribution function can be expressed as

$$R(\widehat{\Omega}', \nu'; \widehat{\Omega}, \nu) = p(\widehat{\Omega}', \widehat{\Omega})\varphi(\nu')\delta(\nu - \nu') \tag{32}$$

where $p(\widehat{\Omega}', \widehat{\Omega})$ is known as the *phase function* which gives the probability of scattering in the direction $\widehat{\Omega}$ of radiation arriving from the direction $\widehat{\Omega}'$ on a volume element at point $\boldsymbol{r}$. It is normalized as

$$\frac{1}{4\pi} \oint p(\widehat{\Omega}, \widehat{\Omega}') \, \mathrm{d}\widehat{\Omega}' = 1. \tag{33}$$

For coherent scattering (e.g. scattering by dust grains), the scattering emission coefficient becomes

$$\eta^s(\boldsymbol{r}, t; \widehat{\Omega}, \nu) = n\sigma_{\mathrm{sca}}(\boldsymbol{r}, t; \widehat{\Omega}, \nu) \oint_{\Omega'} \frac{\mathrm{d}\Omega'}{4\pi} \times [I(\boldsymbol{r}, t; \widehat{\Omega}', \nu) p(\widehat{\Omega}', \widehat{\Omega})]. \tag{34}$$

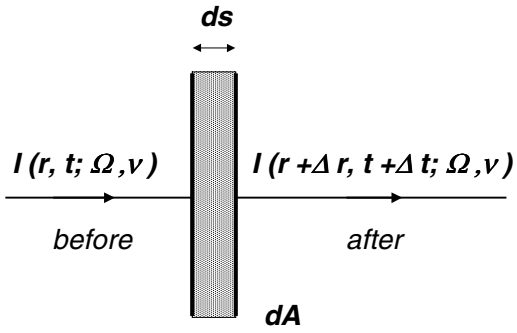

Figure 3.

Derivation of the transport equation
Consider an element of material of length $\mathrm{d}s$ and cross section $\mathrm{d}A$, fixed in the laboratory frame. We calculate the change, in a time $\mathrm{d}t$, in the energy of the radiation field contained in a frequency interval $\mathrm{d}\nu$, traveling into solid angle $\mathrm{d}\Omega$ along a direction $\widehat{\Omega}$ normal to $\mathrm{d}A$, as it passes through the material. The difference between the amount of energy that emerges at position $\boldsymbol{r} + \Delta\boldsymbol{r}$ at time $t + \mathrm{d}t$ and the amount incident at position $\boldsymbol{r}$ at time t must equal the difference between the amount of energy created by emission from the material and the amount removed by extinction (see figure 3). The equation of radiation transport is just a statement of the energy conservation along a ray path $\mathrm{d}s$

$$\underbrace{\Delta E}_{\text{energy change}} = \underbrace{\mathrm{d}E_+}_{\text{energy emitted}} - \underbrace{\mathrm{d}E_-}_{\text{energy removed}}. \tag{35}$$

From the definitions of I, η, and χ, this means

$$[I(\boldsymbol{r} + \Delta\boldsymbol{r}, t + \Delta t; \widehat{\Omega}, \nu) - I(\boldsymbol{r}, t; \widehat{\Omega}, \nu)] \, \mathrm{d}A \, \mathrm{d}\Omega \, \mathrm{d}\nu \, \mathrm{d}t = [\eta(\boldsymbol{r}, t; \widehat{\Omega}, \nu) - \chi(\boldsymbol{r}, t; \widehat{\Omega}, \nu) I(\boldsymbol{r}, t; \widehat{\Omega}, \nu)] \, \mathrm{d}A \, \mathrm{d}s \, \mathrm{d}\Omega \, \mathrm{d}\nu \, \mathrm{d}t \tag{36}$$

where we have $\Delta t = \mathrm{d}s/c$. Applying Taylor's expansion in $(\boldsymbol{r}, t)$ to $I(\boldsymbol{r} + \Delta\boldsymbol{r}, t + \Delta t; \widehat{\Omega}, \nu)$

$$I(\boldsymbol{r} + \Delta\boldsymbol{r}, t + \Delta t; \widehat{\Omega}, \nu) \approx I(\boldsymbol{r}, t; \widehat{\Omega}, \nu) + \left(\frac{1}{c}\frac{\partial}{\partial t} + \frac{\partial}{\partial s}\right) I(\boldsymbol{r}, t; \widehat{\Omega}, \nu) \, \mathrm{d}s + \text{higher-order terms}.$$

Neglecting the higher-order terms and substituting into the energy conservation statement, we obtain the time-dependent equation of radiation transport

$$\left(\frac{1}{c}\frac{\partial}{\partial t} + \frac{\partial}{\partial s}\right) I(\boldsymbol{r}, t; \widehat{\Omega}, \nu) = \eta(\boldsymbol{r}, t; \widehat{\Omega}, \nu) - \chi(\boldsymbol{r}, t; \widehat{\Omega}, \nu) I(\boldsymbol{r}, t; \widehat{\Omega}, \nu). \tag{37}$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Suppressing the functional dependence of the quantities involved, we may write

$$\underbrace{\frac{1}{c}\frac{\partial I}{\partial t}}_{\text{temporal change}} + \underbrace{\frac{\partial I}{\partial s}}_{\text{spatial change}} = \eta - \chi I. \tag{38}$$

This derivation is based entirely on a classical, macroscopic and phenomenological approach. It neglects the wave nature of radiation such as polarization, dispersion, coherence, interference and other quantum effects. For situations in which

$$\frac{\partial I}{\partial s} \gg \frac{1}{c}\frac{\partial I}{\partial t} \approx 0 \tag{39}$$

we have the time-independent equation of radiation transport

$$\underbrace{\frac{\partial I}{\partial s}}_{\text{geometry}} = \underbrace{\eta - \chi I}_{\text{physics}}. \tag{40}$$

The term on the left depends on the *geometry* of the medium while the term on the right represents the *physics* of how radiation interacts with matter. Since s is a coordinate-independent path length, the above equation is valid in arbitrary coordinate systems, provided we use an appropriate expression to evaluate $\partial/\partial s$.

Expressions for $\partial/\partial s$ in different geometries

The directional derivative $\partial/\partial s$ basically describes how $\widehat{\Omega}$ changes with $\boldsymbol{r}$. In general $\boldsymbol{r}$ and $\widehat{\Omega}$ are not specified by the same coordinate system. If both $\widehat{\Omega}$ and $\boldsymbol{r}$ are specified in Cartesian coordinates ($\boldsymbol{r} = x\widehat{\boldsymbol{x}} + y\widehat{\boldsymbol{y}} + z\widehat{\boldsymbol{z}}$, $\widehat{\Omega} = \Omega_x\widehat{\boldsymbol{x}} + \Omega_y\widehat{\boldsymbol{y}} + \Omega_z\widehat{\boldsymbol{z}}$), then $\partial/\partial s$ can be expressed in vector notation as

$$\begin{aligned}\frac{\partial}{\partial s} &= \left(\frac{\partial x}{\partial s}\right)\left(\frac{\partial}{\partial x}\right) + \left(\frac{\partial y}{\partial s}\right)\left(\frac{\partial}{\partial y}\right) + \left(\frac{\partial z}{\partial s}\right)\left(\frac{\partial}{\partial z}\right) \\ &= \Omega_x\frac{\partial}{\partial x} + \Omega_y\frac{\partial}{\partial y} + \Omega_z\frac{\partial}{\partial z} = \widehat{\Omega}\cdot\nabla.\end{aligned} \tag{41}$$

In curvilinear coordinates, the coordinate basis vectors rotate with respect to the direction determined by $\widehat{\Omega}$ and we must evaluate $\partial/\partial s$ as

$$\partial/\partial s = \widehat{\Omega}\cdot\nabla + (\mathrm{d}\widehat{\Omega}/\mathrm{d}s)\cdot\nabla_\Omega \tag{42}$$

where ∇_Ω denotes differentiation with respect to the direction cosines of $\widehat{\Omega}$. Specifically, for arbitrary curvilinear coordinates (x_1, x_2, x_3) with unit vectors $(\boldsymbol{i}, \boldsymbol{j}, \boldsymbol{k})$, the directional derivative is

$$\begin{aligned}\frac{\partial}{\partial s} = {} & \frac{1}{h_1}\sin\theta\cos\phi\frac{\partial}{\partial x_1} + \frac{1}{h_2}\sin\theta\sin\phi\frac{\partial}{\partial x_2} + \frac{1}{h_3}\cos\theta\frac{\partial}{\partial x_3} \\ & - \frac{1}{\sin\theta}\left\{\widehat{\Omega}\left[\frac{1}{\sin\theta}\nabla(\widehat{\Omega}\boldsymbol{i}) - \frac{\cos\theta\cos\phi}{\sin^2\theta}\nabla(\widehat{\Omega}\boldsymbol{k})\right]\right\}\frac{\partial}{\partial\phi} \\ & - \frac{1}{\sin\theta}\{\widehat{\Omega}[\nabla(\widehat{\Omega}\mathbf{k})]\}\frac{\partial}{\partial\theta}\end{aligned} \tag{43}$$

where

$$h_i = \left[\left(\frac{\partial x}{\partial x_i}\right)^2 + \left(\frac{\partial y}{\partial x_i}\right)^2 + \left(\frac{\partial z}{\partial x_i}\right)^2\right]^{1/2}, \quad i = 1, 2, 3 \tag{44}$$

are the Lamé coefficients. Below we summarize the expressions for $\partial/\partial s$ in various 3D geometries

Geometry	$\boldsymbol{r}, \widehat{\Omega}$	Directional derivative ($\partial/\partial s = \widehat{\Omega}\cdot\nabla$)
Slab	$(x, y, z), (\theta, \phi)$	$\sin\theta\cos\phi\frac{\partial}{\partial x} + \sin\theta\sin\phi\frac{\partial}{\partial y} + \cos\theta\frac{\partial}{\partial z}$
Sphere	$(r, \Theta, \Phi), (\theta, \phi)$	$\cos\theta\frac{\partial}{\partial r} + \frac{\sin\theta\cos\phi}{r}\frac{\partial}{\partial\Theta} - \frac{\sin\theta\sin\phi}{r\sin\Theta}\frac{\partial}{\partial\Phi} - \frac{\sin\theta}{r}\frac{\partial}{\partial\theta} - \frac{\sin\theta\sin\phi}{r\tan\Theta}\frac{\partial}{\partial\phi}$
Cylinder	$(r, z, \Phi), (\theta, \phi)$	$\sin\theta\cos\phi\frac{\partial}{\partial r} + \frac{\sin\theta\sin\phi}{r}\frac{\partial}{\partial\Phi} + \cos\theta\frac{\partial}{\partial z} - \frac{\sin\theta\sin\phi}{r}\frac{\partial}{\partial\phi}$

For 1D geometries, the above expressions simplify to ($\mu \equiv \cos\theta$)

1D geometry	$(\boldsymbol{r};\widehat{\Omega})$	Directional derivative $(\partial/\partial s)$
Slab	$(z;\theta)$	$\cos\theta\frac{\partial}{\partial z} = \mu\frac{\mathrm{d}}{\mathrm{d}z}$
Sphere	$(r;\theta)$	$\cos\theta\frac{\partial}{\partial r} - \frac{\sin\theta}{r}\frac{\partial}{\partial\theta} = \mu\frac{\partial}{\partial r} + \frac{1-\mu^2}{r}\frac{\partial}{\partial\mu}$
Cylinder	$(r;\theta,\phi)$	$\sin\theta\left[\cos\phi\frac{\partial}{\partial r} - \frac{\sin\phi}{r}\frac{\partial}{\partial\phi}\right]$

For 2D disk geometry with axial symmetry, we have

$$\frac{\partial}{\partial s} = \cos\theta\frac{\partial}{\partial z} + \sin\theta\left(\cos\phi\frac{\partial}{\partial r} - \frac{\sin\phi}{r}\frac{\partial}{\partial\phi}\right). \tag{45}$$

Moments of the transport equation

For simplicity we suppress the functional dependence of the quantities involved, except for the frequency dependence which we denote by subscript ν. Starting with

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the time-dependent transport equation and rewriting $\partial/\partial s$ as $\nabla\cdot\widehat{\Omega}$, we integrate over all directions and frequencies to get

$$\int_0^\infty \mathrm{d}\nu \oint \mathrm{d}\Omega\left(\frac{1}{c}\frac{\partial I_\nu}{\partial t}+(\nabla\cdot\widehat{\Omega})I_\nu\right) = \int_0^\infty \mathrm{d}\nu \oint \mathrm{d}\Omega(\eta_\nu - I_\nu\chi_\nu). \tag{46}$$

Re-arranging the terms yields

$$\frac{\partial E_R}{\partial t} = \int_0^\infty \mathrm{d}\nu \oint \mathrm{d}\Omega(\eta_\nu - I_\nu\chi_\nu) - \nabla\cdot\boldsymbol{F}. \tag{47}$$

This is the *zeroth moment equation* and is a statement of energy conservation for the radiation field. Integrating the equation over a fixed volume element and applying the divergence theorem, we see that the rate of change of radiative energy in the volume equals the emission from the material, minus the absorption by the material, and minus the net flow of radiant energy (flux) through the volume element's boundary surface.

In steady state when the energy density does not depend on time, and if there is no internal energy source so that the radiative energy absorbed in any volume element is balanced locally by the energy emitted, we have the condition of *radiative equilibrium*

$$\int_0^\infty \mathrm{d}\nu \oint \mathrm{d}\Omega(\eta_\nu - I_\nu\chi_\nu) = 0 \tag{48}$$

which leads to the vanishing of flux divergence, $\nabla\cdot\boldsymbol{F} = 0$. Thus radiative equilibrium implies that the integrated net flux is constant with depth in 1D planar geometry while the luminosity is constant with radius in 1D spherical geometry.

The *first moment equation* is obtained by multiplying the transport equation by $\widehat{\Omega}$ and then integrating over all directions and frequencies

$$\int_0^\infty \mathrm{d}\nu \oint \mathrm{d}\Omega\left(\frac{1}{c}\frac{\partial I_\nu}{\partial t}\widehat{\Omega} + (\nabla\cdot\widehat{\Omega})I_\nu\widehat{\Omega}\right) = \int_0^\infty \mathrm{d}\nu \oint \mathrm{d}\Omega \times [(\eta_\nu - I_\nu\chi_\nu)\widehat{\Omega}] \tag{49}$$

which simplifies to

$$\frac{1}{c^2}\frac{\partial \boldsymbol{F}}{\partial t} = \frac{1}{c}\int_0^\infty \mathrm{d}\nu \oint \mathrm{d}\Omega[(\eta_\nu - I_\nu\chi_\nu)\widehat{\Omega}] - \nabla\cdot\mathsf{P}. \tag{50}$$

This may be viewed as the momentum equation of the radiation field. Now the momentum of a photon with energy $h\nu$ is $(h\nu/c)\widehat{\Omega}$ so that the net rate of radiative momentum transport across a surface $\mathrm{d}\boldsymbol{A}$ is $c^{-1}\mathbf{F}\cdot\mathrm{d}\boldsymbol{A}$. Since the transport by particles occurs at a speed of c, the radiative momentum density vector is just $c^{-2}\boldsymbol{F}$. Integrating the equation over a fixed volume element and applying the divergence theorem, we see that the rate of change of radiative momentum density equals the gain from material emission, minus the loss due to material absorption and the transport across the boundary surface of the volume element.

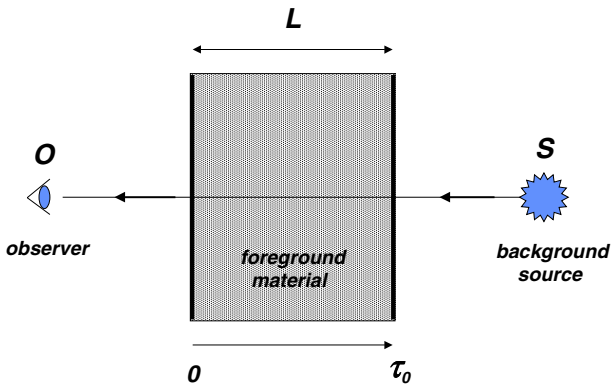

Figure 4.

Formal solution of the transport equation

The solution to the transport equation under the assumption that either χ and η (or equivalently τ and S) of the medium are known is called the *formal solution*. In this case, the transport equation becomes a linear first-order differential equation.

Consider an observer looking through an intervening medium that absorbs and emits radiation. There is a background source behind the medium (see figure 4). In terms of the optical depth τ and source function S, the time-independent transport equation may be written as

$$\frac{\mathrm{d}I}{\mathrm{d}s} = -\chi I + \eta \Rightarrow \frac{\mathrm{d}I}{\mathrm{d}\tau} = I - S \tag{51}$$

where, by convention, we measure τ inward from the observer into the medium

$$\mathrm{d}\tau \equiv -\chi\,\mathrm{d}s \Rightarrow \tau(s) = \int_0^s \chi(s')\,\mathrm{d}s'. \tag{52}$$

Using the integrating factor $\exp(-\tau)$, we obtain the formal solution

$$I^+(o) = I(s)\,\mathrm{e}^{-\tau} + \int_0^\tau S(\tau')\,\mathrm{e}^{-\tau'}\,\mathrm{d}\tau'. \tag{53}$$

The superscript '+' means emergent intensity. Hence the observed intensity is the sum of two contributions: contribution from attenuated background source and contribution from the emitting/absorbing medium of the foreground layer. For a medium with constant properties (both S and τ are uniform), the above result simplifies to

$$I^+(o) = I(s)\,\mathrm{e}^{-\tau} + S(1 - \mathrm{e}^{-\tau}). \tag{54}$$

In terms of χ and η, the formal solution is

$$I^+(o) = I(s)\exp\left(-\int_0^s \chi(s')\,\mathrm{d}s'\right) + \int_0^s \eta(s')\exp\left(-\int_0^{s'} \chi(s'')\,\mathrm{d}s''\right)\mathrm{d}s'. \tag{55}$$

Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Consider the following situations:

(a) No background source; only uniform foreground material. The formal solution becomes

$$I^+(o) = S(1 - \mathrm{e}^{-\tau}). \tag{56}$$

If the layer is optically thin, i.e. $\tau \ll 1$, we have

$$I^+(o) \approx S\tau = \left(\frac{\eta}{\chi}\right)(\chi L) = \eta L. \tag{57}$$

This means we can see through the layer and the observed intensity is just the sum of all the emission from different points along the total path length L. On the other hand, if the medium is optically thick, i.e. $\tau \gg 1$, we have

$$I^+(o) \approx S = \eta\left(\frac{1}{\chi}\right). \tag{58}$$

This means we can see up to a distance of $\tau = 1$ in the layer if we regard $\left(\frac{1}{\chi}\right)$ as the distance to $\tau = 1$ or just one *photon mean-free-path*.

(b) Background source only; no emission by foreground material. In this case, the formal solution is

$$I^+(o) = I(s)\,\mathrm{e}^{-\tau} \tag{59}$$

which is just simple attenuation of background intensity by the foreground material.

(c) Background source + uniform foreground material. The formal solution is

$$I^{+'}(o) = I^+(s)\,\mathrm{e}^{-\tau} + S(1 - \mathrm{e}^{-\tau}) \tag{60}$$

Consider the observational technique of '*position switching*' which consists of combining two observations:

on source: $I^+(o) = I(s)\,\mathrm{e}^{-\tau} + S(1 - \mathrm{e}^{-\tau})$
off source: $I^{+'}(o) = I(s)$

so that

$$\Delta I^+(o) = I^+(o) - I^{+'}(o) = [S - I(s)]\,(1 - \mathrm{e}^{-\tau}). \tag{61}$$

This implies that one would see (i) an emission line if $\Delta I^+(o) > 0$ or $S > I(s)$, (ii) an absorption line if $\Delta I^+(o) < 0$ or $S > I(s)$, and (iii) no line or signal if $\Delta I^+(o) = 0$ or $S = I(s)$.

We may view the equation of radiation transport as a description of a relaxation process in which the radiation field asymptotically approaches the source function in the limit of large optical depth, i.e.

$$I^+(o) = I^+(s)\,\mathrm{e}^{-\tau} + S(1 - \mathrm{e}^{-\tau}) = S + \mathrm{e}^{-\tau}[I^+(s) - S] \tag{62}$$

which implies that $\lim_{\tau\to\infty} I^+(o) \to S$.

Input physics

To solve the problem of radiation transport for a medium containing dust grains and gas particles, we need to express the extinction and emission coefficients in terms of microphysical parameters. Below we first consider the interaction of radiation with a gaseous medium.

Gas component

When a gaseous particle (atom, ion or molecule) absorbs radiation, it will undergo a transition from a lower energy level i to a higher energy level j. Subsequently two different recombination transitions may take place: *spontaneous emission* for which the emitted photons are isotropic and *induced or stimulated emission* in which the emitted and incident photons have the same direction. Since the emitted and incident photons for an induced transition have the same direction, the induced emission is often treated as negative absorption. If both levels i and j are bound states, we have bound–bound transitions. If j is a free state (or continuum level), we have bound–free transitions (e.g. ionization). Free–free transitions occur when both i and j are free states. The total volume extinction coefficient (of a gaseous species at a given degree of ionization) due to bound–bound, bound–free and free–free transitions can be written as

$$\begin{aligned}\chi(\nu) = &\sum_{j=2}^{N}\sum_{i=1}^{j-1}\sigma_{ij}(\nu)\left(n_i - \frac{g_i}{g_j}n_j\right)\\ &+ \sum_{i=1}^{N}\sigma_{ik}(\nu)\left[n_i - n_e n_k \phi_i(T)\exp\left(-\frac{h\nu}{kT}\right)\right]\\ &+ n_e n_k \sigma_{kk}(\nu)\left[1 - \exp\left(-\frac{h\nu}{kT}\right)\right]\end{aligned} \tag{63}$$

where the subscript k refers to a continuum or ionized state, n_e is the number density of electrons and $\phi_i(T)$ is the Saha–Boltzmann factor given by

$$\phi_i(T) = \left(\frac{h^2}{2\pi mkT}\right)^{3/2}\frac{U_i}{2U_k}\exp\left(\frac{h}{kT}(\nu_k - \nu_i)\right). \tag{64}$$

The gs and Us are the statistical weights of the energy levels and partition functions of the ionization states. The σs are the relevant cross sections for radiative excitations (either photoabsorption or photoionization). For example, for bound–bound transitions

$$\sigma_{ij}(\nu) = \frac{c^2}{8\pi}\frac{g_j}{g_i}\frac{A_{ji}}{\nu_{ji}^2}\phi(\nu) \tag{65}$$

where A_{ji} is Einstein's coefficient for spontaneous emission and $\phi(\nu)$ is the line profile function. The interaction cross sections for bound–free and free–free are normally determined from laboratory measurements. For example, an empirical formula for bound–free transitions is

$$\sigma_{ik}(\nu) = \sigma_0\left[\beta\left(\frac{\nu_0}{\nu}\right)^{\gamma} + (1 - \beta)\left(\frac{\nu_0}{\nu}\right)^{\gamma+1}\right] \tag{66}$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

where $\sigma_0, \beta, \gamma, \nu_0$ are fitting parameters. Likewise, the corresponding emission coefficient is

$$\eta(\nu) = \frac{2h\nu^3}{c^2}\left\{\sum_{j=2}^{N}\sum_{i=1}^{j-1}\sigma_{ij}(\nu)\frac{g_i}{g_j}n_j + n_e\sum_{i=1}^{N}\sigma_{ik}(\nu)n_k\phi_i(T)\exp\left(-\frac{h\nu}{kT}\right) + n_e n_k\sigma_{kk}(\nu)\exp\left(-\frac{h\nu}{kT}\right)\right\}. \quad (67)$$

Both $\chi(\nu)$ and $\eta(\nu)$ depend on the level populations, which in turn are determined by both collisional and radiative processes, the latter dependent upon the intensity of the radiation field. On the other hand, the radiation intensity depends on $\chi(\nu)$ and $\eta(\nu)$ of the medium. Hence a self-consistent solution of the radiation transport problem involves solving simultaneously the equation of radiation transport and equations which govern the level populations. These depend on the thermodynamic state of the medium as discussed below.

Local thermodynamic equilibrium A system of gas particles (e.g. atoms, ions, molecules) and photons are said to be in *thermodynamic equilibrium* (TE) when all of the following conditions are met:

(a) The velocities of each species of particles have a *Maxwellian velocity distribution* $f_M(v)$, characterized by the same temperature T for all species

$$f_M(v) = 4\pi\frac{m^3}{(2\pi mkT)^{\frac{3}{2}}}v^2\exp\left(-\frac{mv^2}{2kT}\right) \quad (68)$$

or in terms of kinetic energy $E = \frac{1}{2}mv^2$

$$f_M(E) = \frac{2\pi}{(\pi kT)^{\frac{3}{2}}}\sqrt{E}\exp\left(-\frac{E}{kT}\right). \quad (69)$$

(b) The distribution of atoms or molecules over the energy levels obeys the *Boltzmann law or distribution*, i.e. for levels i and j, the populations n_i^* and n_j^* are given by

$$\frac{n_j^*}{n_i^*} = \frac{g_j}{g_i}\exp\left(-\frac{h\nu_{ji}}{kT}\right) \quad (70)$$

where $h\nu_{ji} = E_j - E_i$ and g_i, g_j are the statistical weights.

(c) The distribution of electrons, ionized and neutral atoms is given by the *Saha equation*

$$n_e\frac{n_+^*}{n_0^*} = \frac{U_+}{U_0}\frac{2(2\pi mkT)^{\frac{3}{2}}}{h^3}\exp\left(-\frac{h\nu_0}{kT}\right) \quad (71)$$

where $h\nu_0 = E_0$ is the ionization potential, U_+ and U_0 are the partition functions of the ionized and neutral atoms.

(d) The radiation field is isotropic, homogeneous and stationary. The frequency dependence of the intensity is a universal function of the system's temperature T. It is given by the *Planck function* and does not depend upon the properties of the matter

$$I(\nu) = B(\nu) = \frac{2h\nu^3}{c^2}\left[\exp\left(\frac{h\nu}{kT}\right) - 1\right]^{-1}. \quad (72)$$

(e) The *principle of detailed balancing* applies, which states that in thermodynamic equilibrium (TE) every detailed microscopic process is statistically balanced by its precise inverse (reciprocal) process.

(f) *Kirchhoff's law* applies, which relates the emission and extinction coefficients to the Planck function

$$\eta(\nu) = \chi(\nu)\,B(\nu, T), \text{ or } S(\nu) \equiv \frac{\eta(\nu)}{\chi(\nu)} = B(\nu, T). \quad (73)$$

In other words, if a system of gas particles and photons is in TE, its properties can be characterized by a single parameter, the temperature T. In most astronomical situations, the conditions for TE are rarely met. However, it is often found that the above conditions may be satisfied locally in a small region. If we can characterize the properties of each region by a different T, then it may be possible to describe the properties of the whole system by a temperature distribution. If these conditions are satisfied at each point in a gas, and the temperature T is permitted to change from point to point, the gas is said to be in *local thermodynamic equilibrium (LTE)*. One often finds that when collisional processes dominate radiative processes in the ionization and excitation of atoms, the state of the gas is close to LTE, such as in stellar interiors.

When more than one of the conditions for TE are violated in a system, either locally or globally, the system is said to be in *non-local thermodynamic equilibrium (NLTE)*. Even in systems which are described as NLTE, sometimes one or more species of particles has a Maxwellian velocity distribution and it is possible to introduce the concept of kinetic temperature. In most astrophysical problems, deviation from the Maxwellian velocity distribution is small, although the assumption of TE or LTE cannot be made.

Under LTE, the level populations are governed by the Boltzmann distribution for bound levels and by the Saha equation for ionized states. Hence under LTE conditions both the extinction and emission coefficients can be determined if the gas temperature is known. On the other hand, for NLTE one must determine the level populations which in turn are governed by both collisional and radiative processes, the latter dependent upon the intensity of the radiation field.

Equations of statistical equilibrium Let us now consider the equations by which we determine the level populations of atoms. These are governed by the rates of all processes,

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

collisional and radiative, by which an atom leaves a certain state i to some other state j and return rates of processes from all states j back to state i. The collisional and radiative processes that determine the level populations for bound–bound and bound–free transitions are:

Bound–bound	Bound–free
Radiative	
Photoabsorption (R_{ij})	Photoionization (R_{ik})
Spontaneous + stimulated emission (R_{ji})	Spontaneous + stimulated recombination (R_{ki})
Collisional	
Collisional excitation (C_{ij})	Collisional ionization (C_{ik})
Collisional de-excitation (C_{ji})	Three-body recombination (C_{ki})

Let the total rate be:

$$\begin{array}{ll} \text{upward rate:} & P_{ij} = C_{ij} + R_{ij} \\ \text{downward rate:} & P_{ji} = C_{ji} + R_{ji}. \end{array} \tag{74}$$

The *equations of statistical equilibrium*, also known as *rate equations*, for an atom with N levels are given by

$$\frac{\mathrm{d}n_i}{\mathrm{d}t} = \sum_{j\neq i}^{N} n_j P_{ji} - n_i \sum_{j\neq i}^{N} P_{ij} = 0, \qquad \text{for level } i. \tag{75}$$

The first term represents the gain in population due to contributions from all other levels while the second term is the loss of population to all other levels. Note that while we can write down one such equation for each of the N levels, only $(N-1)$ of these are truly independent. These $(N-1)$ equations must be solved subject to the constraint of particle conservation

$$\sum_{i=1}^{N} n_i = n_T \tag{76}$$

leading to N equations in N unknowns.

For a moving medium with local fluid velocity $\boldsymbol{v}$ and time-dependent situations, the equations governing level populations take the form

$$\frac{\partial n_i}{\partial t} = -\nabla\cdot(n_i\boldsymbol{v}) + \sum_{j\neq i}^{N} n_j P_{ji} - n_i \sum_{j\neq i}^{N} P_{ij} \tag{77}$$

which simply states that the rate of change of n_i is determined by the net rate of flow of particles into the volume and the net rate of transitions into level i from all other levels j by collisional and radiative processes. Summing over all states, the rate terms cancel one another, and we obtain a continuity equation

$$\frac{\partial n_T}{\partial t} = -\nabla\cdot(n_T\boldsymbol{v}) \tag{78}$$

where we made use of the constraint of particle conservation. The equations of statistical equilibrium are linear equations if the collisional and radiative rates are known.

Expressions for radiative and collisional rates Hence, to describe a system under NLTE conditions we must determine in detail the collisional and radiative processes by solving the rate equations. In particular, for each transition (or pair of energy levels), we need to determine the cross sections: collisional excitation, collisional de-excitation, radiative excitation and radiative de-excitation. We can express the radiative rates for both bound–bound and bound–free transitions in a common form

$$\text{upward rate:} \quad R_{ij} = 4\pi \int \frac{\sigma_{ij}(\nu)J(\nu)}{h\nu}\,\mathrm{d}\nu \tag{79}$$

$$\text{downward rate:} \quad R_{ji} = 4\pi \int \frac{\sigma_{ij}(\nu)J(\nu)}{h\nu} G_{ij}(\nu) \times \left(\frac{2h\nu^3}{c^2} + J(\nu)\right)\mathrm{d}\nu \tag{80}$$

$$G_{ij}(\nu) = \begin{cases} g_i/g_j & \text{(b-b)} \\ n_e\phi_i(T)\exp\left(-\frac{h\nu}{kT}\right) & \text{(b-f)} \end{cases} \tag{81}$$

where the subscript k stands for continuum or ionized state. $\phi_i(T)$ is the Saha–Boltzmann factor and $\sigma_{ij}(\nu)$ is the appropriate cross section for radiative excitations (either photoabsorption or photoionization). $J(\nu)$ is the mean intensity at frequency ν.

Consider the excitation scheme in which an electron with kinetic energy E excites an atom and so loses energy E. In the corresponding de-excitation, the electron follows the reverse path. The total collisional rates are given by

$$\text{excitation:} \quad C_{ij} = n_e \int_{E_0}^{\infty} \sigma_{ij}(E)\sqrt{\frac{2E}{m}}\, f(E)\,\mathrm{d}E \tag{82}$$

$$\text{de-excitation:} \quad C_{ji} = n_e \int_{0}^{\infty} \sigma_{ji}(E-E_0)\sqrt{\frac{2(E-E_0)}{m}} \times f(E-E_0)\,\mathrm{d}(E-E_0) \tag{83}$$

where $f(E)$ is the energy distribution of the colliding particles. It can be shown that the collisional cross sections are related by

$$\frac{\sigma_{ij}(E)}{\sigma_{ji}(E-E_0)} = \frac{g_j}{g_i}\frac{E-E_0}{E}. \tag{84}$$

This relation is valid in general, independent of the energy (or velocity) distribution of the electrons because the ratio σ_{ij}/σ_{ji} depends only on atomic parameters (e.g. g_i, g_j and E_0) and is independent of quantities like n_i, n_j, and $f(E)$ that depend on the thermodynamic state of the system. For a Maxwellian velocity distribution, the ratio of collisional rates is

$$\frac{C_{ij}}{C_{ji}} = \frac{g_j}{g_i}\exp\left(-\frac{E_0}{kT}\right). \tag{85}$$

For non-Maxwellian velocity distribution, one must use the relation σ_{ij}/σ_{ji} to derive a different expression for the ratio C_{ij}/C_{ji}.

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Consider the process of collisional ionization in which an electron of energy E produces an ion together with a pair of electrons of energies E' and $E - E_0 - E'$, where E_0 is the ionization potential of an atom in state i. The cross sections in collisional ionization (σ_{ik}) and three-body recombination (σ_{ki}) are related by

$$\frac{\sigma_{ik}(E, E')}{\sigma_{ki}(E', E - E_0 - E')} = \frac{16\pi}{h^3}\frac{U_k}{U_i}\frac{mE'(E - E_0 - E')}{E} \quad (86)$$

where U_i and U_k are partition functions of the atoms of states i and k. The collisional ionization rate is given by

$$C_{ik} = n_e \int_{E_0}^{\infty} \mathrm{d}E \int_0^{E-E_0} \sigma_{ik}(E, E')\sqrt{\frac{2E}{m}} f(E)\,\mathrm{d}E' \quad (87)$$

where $f(E)$ is the velocity distribution of electrons. A similar expression can be written for C_{ki}, the three-body recombination rate. For Maxwellian velocity distribution, we have

$$\frac{C_{ik}}{C_{ki}} = \frac{U_k}{U_i}\frac{2(2\pi mkT)^{3/2}}{h^3}\exp\left(-\frac{E_0}{kT}\right). \quad (88)$$

Gas cooling by line radiation Atoms or molecules are excited either by collisions or by radiation. The excitation energy is supplied either from the kinetic energy of the exciting particle, in the case of collisional excitation, or from the absorption of a photon, as in the case of radiative excitation. Similarly, excited molecules may lose their energy either by collisional de-excitation or by spontaneous and stimulated emission. In stimulated emission, a photon stimulates the emission of a similar photon from an excited molecule which is then de-excited. Thus the conversion of radiative to kinetic energy occurs through collisional de-excitation of an excited molecule following the absorption of a photon. On the other hand, kinetic energy is converted into radiative energy in collisional excitation followed by stimulated or spontaneous emission.

To derive an expression for the rate of gas cooling, we consider a two-component system consisting of gas atoms (or molecules) and photons. Since collisional and radiative processes are the only physical processes occurring in the system, the net rate of energy loss by the gas component must be equal to the net rate of radiative energy gain by the photon component, from the principle of conservation of energy, i.e. the energy gain or loss through collisional processes must be equal to that by radiative processes. We may generalize the above results to atoms with N bound levels. In this case, the net cooling rate becomes

$$\Lambda = \sum_{j=2}^{N}\sum_{i=1}^{j-1}(n_i C_{ij} - n_j C_{ji})E_{ji} = \sum_{j=2}^{N}\sum_{i=1}^{j-1}(n_j R_{ji} - n_i R_{ij})E_{ji}. \quad (89)$$

The net cooling rate due to line emission can also be expressed in terms of the emission and extinction coefficients as

$$\Lambda = \int_0^{\infty} \mathrm{d}\nu \oint \mathrm{d}\Omega[\eta(\nu) - \chi(\nu)I(\nu)]. \quad (90)$$

When a system of gas and photons is in TE, the principle of detailed balancing applies, i.e.

$$\left.\begin{array}{l} n_i C_{ij} = n_j C_{ji} \\ n_j R_{ji} = n_i R_{ij} \end{array}\right\} \Rightarrow \Lambda = 0 \quad (91)$$

so that there is no net cooling. While TE clearly implies $\Lambda = 0$, the reverse is not necessarily true. Indeed the condition that $\Lambda = 0$ is equivalent to that of radiative equilibrium, which states that the radiative energy absorbed in any volume element is balanced locally by the energy emitted. It does not require the balancing of individual microscopic processes.

Theoretically the temperature distribution in the gas component is determined by the thermal balance between various heating and cooling processes. The gas cools by the emission of line photons. In general, the gas cooling rate is determined by the difference between the kinetic energy loss through collisional excitations and the kinetic energy gain through collisional de-excitations. For isothermal and homogeneous media, the cooling rate decreases toward the interior region where radiation trapping is most significant. Because cooling results from a binary process (collisions), we expect the cooling rate to depend quadratically on the gas density under many astrophysical environments. In extreme cases of very high densities and optical depth, the cooling rate is roughly independent of density, because most of the cooling lines are saturated and thermalized. The cooling rate increases with temperature because more cooling species are excited collisionally to higher levels. Because photons from higher transitions not only carry more energy but also are created more frequently, the net cooling rate is increased. In general, the line transitions contributing most to the total cooling rate are those in which the energy for excitation is comparable to the thermal energy of the gas.

Dust component

When radiation passes through a region of space containing dust grains, the photons can be either absorbed, with conversion of radiation into heat, or scattered, with a change in the photon's direction of travel. The sum of these two processes is called extinction, since a collimated beam of light can be extinguished by either process. The probabilities of absorbing and scattering photons are given respectively by the absorption and scattering cross sections, the sum of which is called the extinction cross section. The ratio of the scattering cross section to the total extinction cross section is called the ALBEDO which measures the relative importance of scattering as opposed to true absorption. For dust grains in astrophysical environments, both the extinction cross section and the albedo decrease as the wavelength increases, with scattering dominating absorption in the UV and visible and vice versa in the infrared. The albedo approaches unity in the UV and visible, while in the infrared there is very little scattering and the albedo essentially goes to zero.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

In general, the scattering and absorption cross sections for dust grains depend on the grain composition, shape, size and wavelength of radiation. The interaction of radiation with a particle of homogeneous solid material and refractive index m is completely described by Maxwell's equations of electromagnetism. If we can solve these equations for the appropriate boundary conditions, we can determine the cross sections. For spherical particles which are homogeneous and optically isotropic, these cross sections can be calculated from the Mie theory of scattering based on optical constants of the grain material. The cross sections are often expressed as the product of a dimensionless efficiency factor Q and the geometric cross section πa^2, where a is the grain radius

$$\text{absorption efficiency factor } Q_{\rm abs}(\lambda) \equiv \frac{\sigma_{\rm abs}(\lambda)}{\pi a^2} \qquad (92)$$

$$\text{scattering efficiency factor } Q_{\rm sca}(\lambda) \equiv \frac{\sigma_{\rm sca}(\lambda)}{\pi a^2}. \qquad (93)$$

In general we find:

(a) $Q_{\rm abs}(\lambda)$ and $Q_{\rm sca}(\lambda)$ depend on the wavelength λ only via the dimensionless quantity $x \equiv 2\pi a/\lambda$, i.e. $Q_\alpha = Q_\alpha(x)$. Furthermore, $Q_\alpha(x)$ may be greater than unity for some values of x.
(b) As $x \to \infty$ ($\lambda \gg a$), we have the geometrical limit so that $Q_{\rm sca} \to 1$ and $Q_{\rm abs} \to 1$.
(c) As $x \to 0$ ($\lambda \ll a$), we have Rayleigh scattering for which $Q_{\rm sca} \propto x^4 \propto \lambda^{-4}$ and $Q_{\rm abs} \propto x \propto \lambda^{-1}$.

Although the interaction cross sections for spherical grains may be calculated from the Mie scattering theory, cosmic dust grains have irregular shapes as they are most likely formed by stochastic growth processes. The cross sections for grains of arbitrary shapes may be calculated using a technique called *discrete dipole approximation* (DDA) in which an irregularly shaped grain is approximated by a collection of dipoles. The DDA is valid only when the dipole lattice spacing (Δ) is less than the wavelength of the incident radiation. For a grain approximated by N dipoles, $\Delta = (4\pi/3N)^{1/3} a_{\rm eff}$, where $a_{\rm eff}$ is the radius of a sphere containing the same number of dipoles. For $a_{\rm eff} = 0.1\ \mu$m and $N = 512$, the DDA introduces typical errors of 5% in spectral regions where the approximation is valid.

Before using the DDA to calculate the interaction cross sections, one must first generate a grain shape by computer simulation. A useful parameter to characterize the topology of irregularly shaped grains is the fractal dimension (D), defined by the relation $N(r) \propto r^D$, where $N(r)$ is the number of monomers within a sphere of radius r. For a spherical grain, $D = 3$, while for a rod shaped grain, $D = 1$. In general $1 < D < 3$ and the smaller the fractal dimension, the more filamentary the structure. The thermal and radiative properties of a dust grain depend on the ratio of volume to surface area, which is determined by D. For a given mass, grains with the same D show no significant difference in their absorption cross sections, temperature and energy spectrum, independent of the overall grain shape. Hence in modeling phenomena involving irregularly shaped grains, we need to introduce just one parameter, the fractal dimension D, to characterize the shape. It should be emphasized that porosity [$\equiv$1$-$(volume of solid)/(total volume)] and fractal dimension are not uniquely related. Porosity measures the effect of volume filling factor in a grain and is ill-defined for a dust grain with an open and filamentary structure. Grains with the same porosity may have very different fractal dimensions, and vice versa.

The absorption and scattering coefficients as a function of frequency ν are respectively given by

$$\chi^a(\nu) = n_d \sigma_{\rm abs}(\nu) = n_d Q_{\rm abs}(\nu) \pi a^2 \qquad (94)$$

$$\chi^s(\nu) = n_d \sigma_{\rm sca}(\nu) = n_d Q_{\rm sca}(\nu) \pi a^2. \qquad (95)$$

In general dust grains emit radiation over a continuum of wavelengths, similar to a blackbody but mediated by the overall $\sigma_{\rm abs}$ profile. For continuum radiation, the assumption of LTE is valid so that the thermal emission coefficient can be derived from Kirchhoff's law

$$\begin{aligned}\eta^t(\nu) &= [\chi^a(\nu) + \chi^s(\nu)] B_\nu(T_d) \\ &= n_d [Q_{\rm abs}(\nu) + Q_{\rm sca}(\nu)] \pi a^2 B_\nu(T_d)\end{aligned} \qquad (96)$$

where $B_\nu(T_d)$ is the Planck function at dust temperature T_d. Since coherent scattering is valid for dust grains, the scattering emission coefficient is given by

$$\eta^s(\nu) = \chi^s(\nu) \left(\oint_{\Omega'} \frac{{\rm d}\Omega'}{4\pi} I(\widehat{\Omega}', \nu) p(\widehat{\Omega}', \widehat{\Omega}) \right) \qquad (97)$$

where $p(\widehat{\Omega}', \widehat{\Omega})$ is the scattering phase function.

Phase function and asymmetry parameter The scattering process involving dust grains is coherent since it involves only a change of direction of radiation but not of its wavelength. Coherent scattering by dust particles is described in terms of a phase function $p(\widehat{\Omega}, \widehat{\Omega}')$ which gives the probability of scattering in the direction $\widehat{\Omega}$ of radiation arriving from the direction $\widehat{\Omega}'$ on a volume element at point $\boldsymbol{r}$. The scattering is isotropic or linearly anisotropic when $p(\theta) = 1$ or $p(\theta) = 1 + x \cos\theta$, where $x = \pm 1$ and $\cos\theta = \widehat{\Omega} \cdot \widehat{\Omega}'$. The phase function may either be given in the form of a numerical table from measurements or computations, or represented by a mathematical expression. A useful form is an expansion in Legendre polynomials written as

$$p(\theta) = \sum_{l=0}^{L} \beta_l P_l(\cos\theta);$$

$$\beta_l = \frac{2l+1}{2} \int_{-1}^{+1} p(\theta) P_l(\cos\theta)\, {\rm d}(\cos\theta) \qquad (98)$$

with $\beta_0 = 1$ from the normalization condition and $\beta_1 = 3g$ where g is the *asymmetry parameter* defined as

$$g = \frac{1}{2} \int_{-1}^{+1} p(\theta) \cos\theta\, {\rm d}(\cos\theta) = \frac{\beta_1}{3}. \qquad (99)$$

Two commonly used analytic approximations for the phase function are the Henyey–Greenstein phase function

$$p(\theta) = \frac{1 - g^2}{(1 + g^2 - 2g\cos\theta)^{3/2}} \tag{100}$$

and the two-parameter phase function for highly anisotropic scattering

$$p(\theta) = \frac{4\alpha g(1 - g^2)^{2\alpha}}{[(1 + g)^{2\alpha} - (1 - g)^{2\alpha}](1 + g^2 - 2g\cos\theta)^{\alpha+1}} \tag{101}$$

which reduces to the Henyey–Greenstein form for $\alpha = \frac{1}{2}$. The phase function for Rayleigh scattering is given by

$$p(\theta) = \frac{3}{4}(1 + \cos^2\theta). \tag{102}$$

Once the extinction and emission coefficients quantifying the interaction of radiation with gas and dust particles are expressed in terms of microphysical parameters, the equation of radiation transport can be solved in principle. For physically realistic situations, analytical solutions are seldom available so one must resort to numerical methods. Even for time-independent situations involving 1D geometries, the problem of radiation transport is three-dimensional because of the intrinsic dependence of the radiation field on direction and wavelength.

Due to space limitation, the following topics are not covered in this article: methods of solution (numerical and semi-analytic) of the equation of radiation transport; transfer of polarized radiation; radiation hydrodynamics that deal with transfer phenomena involving velocity (relativistic and non-relativistic) flows and/or time dependence.

Radiatively Driven Stellar Winds from Hot Stars

A stellar wind is the continuous, supersonic outflow of matter from a star. Among the most massive stars—which tend also to be the hottest and most luminous—the winds can be very strong, with important consequences both for the star's own evolution as well as for the surrounding interstellar medium. Such hot-star winds are understood to be driven by the pressure of the star's emitted radiation.

Our Sun has a SOLAR WIND, but it is so tenuous and transparent that it would be difficult to detect directly from a more distant star. However, many stars have winds that are dense enough to be opaque at certain wavelengths of the star's radiation, and this makes it possible to study them remotely through careful interpretation of the observed stellar spectra. The winds from massive, hot stars—with surface temperatures above about 10 000 K—form a well-defined class, distinct from the winds from cooler stars, and characterized by the central role of the star's own radiation in driving the mass outflow. The high temperature of such stars means that they have a very high surface brightness. Because light carries momentum as well as energy, this high surface brightness imparts a force to the atoms that scatter the light. At the level of the star's atmosphere where this force exceeds the inward force of the stellar gravity, material is accelerated upward and becomes the stellar wind.

An important aspect of this radiative driving process is that it stems mostly from *line* scattering, wherein an electron is shuffled between two discrete, bound energy levels of an atom. In a static medium such scattering is confined to radiation with a photon energy near the energy difference between the levels, corresponding to a range of wavelengths near a distinct, line-center value. However, in an accelerating stellar wind flow, the Doppler effect shifts the resonance to increasingly longer wavelengths, allowing the line scattering to sweep gradually through a much broader portion of the stellar spectrum. This gives the dynamics of such winds an intricate feedback character, in which the radiative driving force that accelerates the stellar wind depends itself on that acceleration.

Overview and comparison with the solar wind
